**The Tonic Alterative Action of Copper and Arsenic in Primary and Secondary Spanemic States.**—Dr. GEORGE F. BUTLER of Chicago said that arsenic had a very decided action on tissue change, and markedly affected the glandular, nervous, respiratory, and cutaneous systems. Copper was reputed to be a violent poison, yet, except so far as its toxic effects as a foreign body in the eye were concerned, this repute was decidedly undeserved. Copper was recommended as an alterative tonic useful in epilepsy, chorea, and other spasmodic conditions, especially those connected with debility, by the older authors, and later therapeutists sustained this old repute of copper. Several authorities were quoted to the effect that the drug, in small doses, stimulated both the heart and the capillary circulation, and was a general nerve tonic. As to the preparation to be employed, all agreed that while copper sulphate was of value, it had at times unexpected dangerous untoward effects when the point of saturation was reached. These effects, through the influence of the drug on the vascular system, often took the direction of cardiac neuralgias and pseudoanginas. The double salts of copper in small doses exerted a cardiac action similar to that of digitalin, strophanthus, helleborein, etc. Hare preferred copper arsenite. He had found that under its use digestion and nutrition improved. It was superior to Fowler's solution in chorea and similar neuroses. In toxemic conditions, like secondary malarious manifestations, with the resultant pallor, copper and arsenic were of decided value. Cases in which the periodic tendency had disappeared improved decidedly under copper and arsenic, whereas quinine and iron were worse than useless. The influence of arsenic was very marked on chronic rheumatism and so-called rheumatic gout, neuralgias of various sorts, in tic, and hemicrania, as well as in angina pectoris, chorea, epilepsy, and asthma. In certain of the gouty bronchites, at the onset of phthisis, in imperfectly cleared-up pneumonic lung consolidation, arsenic acted sometimes with remarkable efficiency. The influence of both drugs on the liver, whose double functions were so necessary to the tissue changes of the system, showed that both played a part in assisting assimilation, and at the same time destroying waste products.

**The Claims of the Adolescent.**—Dr. FRANK P. NORBURY of Jacksonville, Ill., said that the claims of the adolescent for recognition by the medical profession were genuine, not hypothetical, and involved three important considerations: (1) Physiological—a study of growth, development, sex differentiation. (2) Psychological—normal and morbid, involving honest endeavor of the physician to see the real needs of the individual. (3) Pedagogical—training and treatment to go together. All of these considerations showed that a demand existed for qualified men to consider earnestly the problems of mind and body of this period.

The following papers were likewise read: "Heads and Tails," by Dr. T. B. Greenley, of Meadow Lawn, Ky.; "Simple Eye Conditions That Should be Familiar to Every Physician," by Dr. Mark P. Stevenson, of Akron, O.; "Some Interesting Problems in Urinary Diagnosis," by Dr. Arthur R. Elliott of Chicago; "Concerning Hepatic Uremia and Its Treatment," by Dr. Alfred C. Croftan of Chicago; "Enterotoxismus (Auto-Intoxication) from Meat," by Dr. Fenton B. Turck of Chicago; "The Leucocytes in Pertussis," by Dr. F. S. Churchill of Chicago; "Remarks on Poliomyelitis," by Dr. Hugh T. Patrick of Chicago; "Demonstration of Sleep-Inducing Method," by Dr. J. B. Learned of Northampton, Mass.; "Some Rare Sequelæ of Syphilis," by Dr. Henry J. Scherck of St. Louis, Mo.

**Officers.**—The following officers were elected for the ensuing year: *President*, Dr. J. Henry Carstens, Detroit, Mich.; *First Vice-President*, Dr. Joseph Rilus Eastman, Indianapolis, Ind.; *Second Vice-President*, Dr. H. H. Grant, Louisville, Ky.; *Secretary*, Dr. Henry Enos Tuley, Louisville, Ky., reelected; *Treasurer*, Dr. S. C. Stanton, Chicago, reelected. Hot Springs, Ark., was selected as the place for holding the next annual meeting.

---

## NEW YORK STATE MEDICAL ASSOCIATION.

*Twenty-second Annual Meeting, Held in New York City, October 16, 17, 18, and 19, 1905.*

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. J. RIDDLE GOFFE, IN THE CHAIR.

(*Concluded from page 715.*)

**The Radical Removal of Cancer of the Stomach.**—Dr. WILLIAM J. MAYO of Rochester, Minn., said that there certainly was no truthfully recorded example of a cancer of the stomach cured by medical means, yet these cases were treated by medical men, were sent into the medical wards and subjected to treatment which must result in 100 per cent. mortality. Cancer of the stomach was the most frequent form in which this disease was found in the human body, at least 30 per cent. of the total. Since 1900, great improvement in technique had lowered the mortality to less than ten per cent., and exploratory incision in suspicious cases gave the diagnosis. Dr. Mayo gave a report of eighty-one gastric resections with a mortality of 14.5 per cent., including early operations. Thirty-four patients were operated upon in the last thirty months, with a mortality of 8 per cent. In twenty-five consecutive operations there was but one death, a mortality of 4 per cent. As to relief, he said that eleven cases had been operated upon too recently to be of statistical value. There were five who failed to live six months. Thirty-eight lived six months to a year, and twenty-four were alive now. Twenty-one lived from one to two years, and thirteen were alive now. Ten lived from two to three years, and eight were alive. Four lived from three to four years, and three were alive; as only sixteen were operated upon more than three years ago, this gave 25 per cent. living three years. One was alive and well after four years and ten months. In regard to the clinical symptoms of most value in early diagnosis, he said traces of blood and reduction of hydrochloric acid were of some importance. The history of past ulcer was not against later diagnosis of cancer, as ulcer often degenerated into cancer.

Dr. JOHN B. DEAVER of Philadelphia suggested that the internist should witness all stomach operations, and with the surgeon familiarize himself with the living pathology. The diagnosis of gastric carcinoma might be approached in three ways: by means of its symptoms, by a physical examination, and by laboratory methods. The most valuable laboratory methods were the examination of the stomach contents and the blood. He believed that the absence of hydrochloric acid or the presence of lactic acid was an extremely fallacious sign of cancer of the stomach. He did not think blood examinations were of any but confirmative value. The absence of normal hyperleucocytosis was considered by some almost a pathognomonic symptom, but he did not think it justifiable for a surgeon to base treatment on no stronger evidence than that. He relied more on the character of the vomitus and the progressive emaciation. Unless the disease was well advanced the presence of a tumor had come to be no longer sure evidence of the existence of carcinoma. To his mind an exploratory laparotomy

was less objectionable in this class of cases than in any other. Nevertheless he was opposed to the doctrine of some surgeons "when in doubt as to diagnosis, do an exploratory laparotomy." He believed that every case of gastric indigestion not promptly cured by diet and suitable drugs would be found to be due to lesions of the gall-bladder, of the pancreas, or of the stomach itself. He agreed with Dr. Mayo that only when gastric carcinoma was operated upon in the precancerous stage could we expect a radical cure. He said that he would limit partial gastrectomy to very few cases if not encountered early. Total gastrectomy he considered beyond the pale of legitimate surgery. Gastroenterostomy was, in his opinion, the operation of choice for patients with advanced gastric carcinoma; neither did he limit it to cases where pyloric obstruction was present.

Dr. Willy Meyer of New York said that the subject of gastric carcinoma was one of burning interest because if not diagnosticated and treated at the proper time the patient was bound to go to the grave. He asked what we could do regarding the early diagnosis. We had heard of the chemical examination and of the subjective signs, the clinical examination of these patients, etc., but they told us but little. If one waited until the tumor could be palpated, one made the same mistake that was formerly made in waiting for tumor formation in cases of appendicitis; it was too late. Tumor formation in gastric carcinoma meant generally that the condition was too far advanced to bring help by operation. Therefore, the suggestion offered by Dr. Deaver was advisable. His own cases showed eighty gastroenterostomies, and but five gastrectomies. Among the five latter, there were four recoveries and but one death, this occurring in a young man suffering from specific disease, and only two days before the operation he had a severe hemorrhage. Of the four recoveries, over two years had elapsed in two. The carcinomas that were found in the posterior wall of the stomach were the deceptive ones. They presented no symptoms. If in doubt, palpation should be tried during anesthesia.

Dr. Mayo said that the good medical men of the future would go to the operating room so as to see just what the conditions were during life. The operation as advised by him he did not believe to be more difficult than an hysterectomy.

**Carcinoma of the Intestinal Tract.**—Dr. James P. Tuttle read this paper. (See page 728.)

Dr. Arpad G. Gerster of New York said that while he indorsed nearly all that Dr. Tuttle had stated, there were some remarks to which he took exception. The fact that the malignancy of the carcinoma decreased as the growth approached the anal aperture, was for a long time known, while carcinoma of the stomach and small intestines was more malignant and more inclined to cause metastasis than if it involved the sigmoid or rectum. Self-medication was more common in this country than anywhere else. Dr. Gerster did not believe that we were justified in opening the stomach just because the patient complained of subjective symptoms alone. As involvement of the gastrointestinal tract extended lower down, the diagnosis became more and more easy. He indorsed what was said regarding instrumental examination of the rectum, and said that many obscure conditions of the intestines would be found by this means. Operative treatment of carcinoma involving the lowest part of the intestinal tract gave excellent results. He told of a patient he had in 1880 upon whom he had operated for cancer, removing eleven inches of the rectum. Relapse occurred four or five months after operation, and was again operated upon and had remained well until today. He cited a number of cases in which radical operation for rectal carcinoma and of the sigmoid flexure had been done, and which resulted in a long continued immunity from the disease, and in a perfect cure in some. Every endeavor should be made to arrive at an early diagnosis and then resort to radical measures, not only removing the cylinder of diseased tube, but the lymphatic glands as well.

Dr. Tuttle differed with Dr. Gerster in the statement that carcinoma became less and less malignant as it descended the intestinal tract. That was true up to the lower end of the bowel, near the anal margin, where one met with the most malignant type one had to deal with. There were 90 per cent. of recurrences when carcinoma was operated upon at this point. Carcinoma of the small intestines he said was rather rare, while sarcoma was more common.

**A New Aid in the Treatment of Malignant Tumors.**—Dr. C. Am Ende of New York called attention to a paper that he had already presented upon superior results obtained in the treatment of a series of malignant tumors by combining with the Roentgen rays, internal administration of thyroid extract, which could be administered in larger doses without producing thyroidism. While the tumors of the patients previously presented had been more or less superficial, that in the case now reported was deep seated. The patient, aged 62, at the end of February, after previous establishment of an artificial anus for complete obstruction, was found to have an inoperable tumor involving the sigmoid flexure and upper rectum. The treatment consisted of Roentgen rays and radium, 7,000, in capsule three times a week; half an ounce daily of the thyroid fluid extract, injected into the transverse colon, and for the last two months fluorescin in one-half grain doses. The mucoid discharges had long since disappeared; the rectal pains had ceased, the tumor protruding into the rectal canal had disappeared almost entirely, as also had a neoplasm in the iliac fossa. The patient's general health was better than for some years past; this might be due to continuous outdoor work and more exercise. The feces had been passing the natural way for some time, but the closure was delayed in order to continue the administration of the fluid extract by injecting it into the colon.

**Cancer of the Uterus.**—Dr. C. P. Noble of Philadelphia said that the most striking facts concerning cancer of the uterus were: (1) that it was a common disease; (2) in a large number of cases the disease had passed the curative stages before the patient was brought to the surgeon, and (3) that in cancer of the cervix the methods of treatment usually employed had failed to cure more than ten per cent. of the patients subjected to radical operation From his experience and a study of statistics, he had been led to believe that not more than 20 per cent. of cancers of the uterus, when seen by the American surgeon, were operable. The family physician and lay public should be educated as to the importance of the early diagnosis of this disease. The greatest hope now lay in the early diagnosis and treatment of the disease by radical operation. There was a general agreement that the results of hysterectomy for adenocarcinoma of the corpus uteri were very favorable, from 60 to 75 per cent. of permanent cures having been obtained by methods hitherto in use. He said that in his own work, excluding patients who died as a result of operation, there had been 17 per cent. who had remained well at the end of five years or longer. This was based on only twenty-three cases. Dr. Byrne of Brooklyn reported 367 cases operated upon with the galvano cautery, without operative mortality. One hundred and fifty of these were carcinoma of the cervix; 219 both body and cervix, and in eight cases the disease was confined to the corpus uteri One hundred and fifty-one cases were lost sight of during the first year. Nineteen remained free from the disease from ten to eighteen years, and twenty-two for five years or more; thus, upon the five year basis, 19 per cent. were cured. The Germans claimed better results. It was hoped by some operators that a much more extensive removal of the papametria, together with the pelvic glands, would give the same improvement in results in operations for cancer of the uterus as had been effected in operations for cancer of the breast. While the five year estimate of the radical operation had not elapsed, sufficient recurrences had already taken place to discourage many from adopting the operation, especially as the primary mortality was about double that of the typical hysterectomy. A recent study of

literature showed that in 364 cases of cancer of the uterus, including cases both of the body and of the cervix, in which the pelvic glands were studied, in 27.7 per cent. glandular involvement had occurred. In his own experience with the radical operation, its higher primary mortality and the impossibility in his judgment of actually removing the pelvic lymphatics, led him to abandon the operation some years ago. It had been well recognized clinically that invasion of the parametria was present in a large percentage of cases. From a study of statistics it was evident that unless the parametria as well as the cervix was removed in over one-half the cases, operation would be useless. For some years he had adopted the Byrne principle and had operated for cancer of the uterus by abdominal section, applying heat by means of the Downes' electrothermic clamps. The method had given gratifying results with one exception, the burning of the ureter or bladder, which had occurred five times, resulting in necrosis and fistula. To avoid this he intended to dissect out the ureters and free them from the broad ligaments before removing the parametria by means of the Downes' clamps. This method offered a number of positive advantages, the most marked being: (1) The absence of troublesome venous oozing, particularly as the operation approached the vaginal plexus. (2) The leaving of a dry field. (3) The freedom from pain subsequent to the operation. (4) The theoretical advantage in the prevention of implantation. In conclusion, he said that it seemed to him that until some revolutionary discovery was made through which, by means of serum therapy or otherwise, cancer might be eradicated, the greatest prospect in improvement lay in teaching the profession and the public the necessity for the early recognition of cancer of the uterus, and its immediate subjection to operation, and the application of the principle of Byrne to whatever operation might be adopted for the removal of the uterus, together with the parametria.

Dr. C. C. Frederick of Buffalo said that as a result of his experience with carcinoma of the uterus, he had come to the conclusion that patients were not seen early enough, nor were they sent early enough to the surgeon. Often they were kept too long under observation and local applications. The crying need to-day in carcinoma of the uterus was the same as in carcinoma elsewhere, and the people should be educated to seek advice of the family physician early, when there was hemorrhage or an abnormal discharge; the family physician, likewise, should be taught to recognize the condition in its early stages. With regard to the various methods advocated, for a long time in his early experience he did the abdominal operation. The pelvic glands he did not remove because such a course, in his opinion, was not destined to give results commensurate to the dangers involved. The recurrences, when the uteri had been entirely removed, were in the scars or in the vaginal tissues, immediately adjacent to the scar. Therefore, to remove the pelvic glands, outside all other questions involved, was advisable, because the lymphatics in the immediate neighborhood of the cicatrix were the ones in which recurrences occurred. He had lately inclined to the vaginal method of operating, using the cautery and clamp, and he believed that the principle of burning carried out in a modified way was likely to give the best results. The vaginal method had many advantages over the abdominal. The cautery and clamp method had the great advantage, in that reinfection was prevented. He was opposed to the radical operation performed in cancer of the cervix when done indiscriminately.

Dr. H. N. Vineberg of New York said that in dealing with the large number of people at the dispensaries, he was struck at the comparative immunity from cancer of the uterus, and that among 1,500 or 1,600 patients examined, one would not find more than one or two cases here. He tried to explain this comparative immunity, and it occurred to him that, as a rule, these women nursed their children, and had involution fully carried out. That might account for the increase of such cases amongst the better classes where nursing was becoming more and more out of fashion. Every obstetrician should see that involution was fully carried out, and in order that this should be done, the patients should be kept under observation for several weeks. He said that the Germans cauterized the disease one or two days before the radical operation was performed.

Dr. Charles P. Noble of Philadelphia spoke of the relation between laceration of the cervix and cancer, and his experience led him to believe that there was a certain amount of relation between the two conditions. Up to the present, he had seen but two cases of cancer of the cervix in virgins. One of these cases was a remarkable one. At operation, a large gland was found over the common iliac vein, and it was thought the patient would die, but she lived five years. He advised that every woman who was approaching the age of fifty should have her cervix repaired or amputated, and that was all that could be done in the way of prophylaxis.

**Carcinoma of the Larynx.**—Dr. John N. Mackenzie of Baltimore, M. D., read this paper. He said that there was no chapter in the whole book of laryngology that needed more careful revision than the chapter on cancer of the larynx. He called attention to two phases of the cancer question, which, in view of the unsettled state of the subject, seemed of most pressing and immediate importance. In the present state of our knowledge, there were three methods of diagnosis, the naked eye method, thyrectomy, and the microscope. The second was often included with the first. Taken all in all, he considered the first method by far the most practicable and satisfactory of the three. For some time past he had become more and more impressed with the possibilities of naked eye inspection. Bloodgood, in a careful analysis of over 13,000 cases of tumor at the Johns Hopkins Hospital, came to the conclusion that it was possible, in the majority of cases, to recognize the character of the growth by the naked eye appearance alone. From this study it was also shown that it was not only possible, as a rule, to differentiate the benign tumors from the malignant at the exploratory incision, but to recognize in the malignant the different groups of varying malignancy, and in the benign growth which had a tendency to become malignant. It was difficult, if not impossible, to satisfactorily depict the appearance of tumors by means of language. He was sure that much of the material for surgical pathology could only be correctly described when it was fresh: it could not be painted because in a few seconds a freshly cut surface was greatly changed. Color photography might be employed with great benefit in describing the appearance of fresh specimens. He said that he could not insist too strongly on the application of the naked eye method of diagnosis in the case of malignant tumors of the larynx. Every resource and refinement of clinical diagnosis, including the exclusion of syphilis by the iodide and tuberculosis by tuberculin, should be resorted to before an appeal to the microscope was made. Every tumor of the larynx, no matter how benign it might appear, should be examined with the greatest possible care, and especially in the case of growths of a suspicious character. Some of the most fatal diseases make their appearance in the larynx in the guise of benignity. In speaking of the partial extirpation of laryngeal cancer for microscopic examination, he said that his objections to the indiscriminate removal of tissue for examination were: (1) that it subjected the patient to autoinfection; (2) that it stimulated the local growth of the cancer; (3) that the method was often inconclusive, misleading, and sometimes practically impossible. If ulceration had already taken place, a portion of the growth could be taken, if skillfully removed. He thought that the general sentiment of laryngologists was that attempts at incomplete removal of malignant growths of the larynx had little or no stimulating effect upon the disease. In view of the established and glaring fact that cancer elsewhere in the body was stirred into greater activity by incautious manipulation of the local lesion, it seemed well nigh incredible that any difference of opinion should

exist in the case of cancer of the larynx. In the light of his own experience, he did not hesitate to say that cancer of the larynx behaved in exactly the same way under incautious manipulations. As to the question of direct inoculation of the laryngeal tissues by constant contact of opposing broken or unbroken surfaces, he could only say that, while not denying the possibility of its existence, where the foul discharge from a cancerous mass might come in contact with an eroded surface, he had never met with an authenticated case of the kind in literature, nor had he seen this accident in practice. He said that the difficulties in the way of microscopic diagnosis of cancer of the larynx were multitudinous. He wished to state decidedly that he did not repudiate the microscope, but thought it should be a last resort in doubtful cases. No one would advise a radical operation without a certainty of diagnosis. If microscopic examination was necessary, then let the patient and surgeon be prepared for immediate operation. The indications for operation depended upon the size, the situation and extent, and upon the character of the growth. A specially malignant type of growth, no matter what its size or appearance, no matter whether it was situated inside the larynx or outside, would demand the most drastic surgical procedure, while in the case of a less malignant and dangerous tumor, a less radical operation might be called for. Laryngologists had hitherto committed the common error of grouping together all malignant and quasimalignant laryngeal growths. The finer anatomical differentiation of malignant laryngeal tumors was a fertile field for future research. He did not believe that any other than the most radical operation should be undertken in cases in which the disease was medially situated. An incomplete operation would be especially hazardous in cases where the disease apeared as an infiltration. He very emphatically condemned operations through the natural passages and subhyoid pharyngotomy. Two lines of study presented itself, viz., (1) the relative malignancy of tumors of the larynx, and (2) the determination of the glandular involvement in the case of various kinds of tumors, as well as various situations of tumors. Investigations along these lines must determine the means of future operative procedure. Whatever operation be done it should always be borne in mind that we were dealing with cancer. No matter how minute the original lesion, the area of possible poisoning was boundless, and if the slightest doubt existed as to the character and circumscription of the growth, the complete operation should be performed. He said the chief objections that had been urged against the radical operation were that: (1) it was a ghastly method of procedure, which produced terrible mutilation of the patient; (2) it was full of unavoidable dangers; and (3) there was a hopeless destruction of function. He thought there were dangers in all capital operations, but in careful hands they were largely, if not wholly, preventable. Whatever operation was done, we should always bear in mind that we were dealing with *cancer,* and that no matter how minute the original point of infection might be, the area of possible poisoning was practically boundless, and that, in the slightest doubt as to the character and circumscription of the growth, complete operation should be done.

Dr. D. Brysjn Delavan of New York, in discussing this paper, said that the results of the surgical treatment of cancer of the larynx had sometimes been exceedingly brilliant, but more often they had shown a degree of failure at once disheartening and surprising. He dealt, in his discussion, only with those operations intended to effect the radical removal of the disease, thyrotomy and partial and complete laryngectomy. He did not think that there were any serious differences of opinion as to the main principles which should govern the surgical treatment of cancer of the larynx. He thought a differential diagnosis should be made by every possible means, including examination for tuberculosis and a short course of potassium iodide. Diagnosis through the aid of the microscope was most desirable, if the histological conditions were such that a correct diagnosis could be made by this means. Repeated attempts to remove the growth, whether for purposes of diagnosis or for treatment, were to be strongly condemned. The most important question apparently now at issue, was as to the choice between partial removal of the larynx and complete laryngectomy. In every department of surgery it was being urged that cancer should be early diagnosed, and early operated upon, in order to obtain the best results. He contended that cancer in its early stages were confined to the interior of the larynx, and certain superficial cancers in their early stages were curable. One argument in favor of limited operation in suitable cases, was the overwhelming weight of statistics. Recent general statistics assume that about 15 or 16 per cent. of patients operated upon remained well over a period of three years. In thyrotomy, with the removal of the diseased soft parts, the permanent cures in general were estimated at about 44 per cent. He said save the patient, if one could, by means of the less serious operation; if not, save him even at the expense of radical and complete removal of all offending tissues, but, at any cost save him. If the treatment of every given case was studied in the light of what had already been proven, and announced by those of best experience, and if it were managed in strict accord with well established rules, fewer patients would be sacrificed to shock, to sepsis, and to pneumonia. In his experience many beginners had neglected to study the easily obtainable classics on this subject. Laryngeal operations of this class were difficult at the best; they were not at all of the same class with ordinary surgical procedures. They never had been and probably never would be within the reach of the average operator. The history of laryngectomy showed that operators had improved with experience. Surgical measures seemed to be our only reliance in cases of cancer. Such operations might be done, but only by men of experience, and under such rules and conditions as were most likely to save the life of the patient, and to bring to him a maximum of comfort and usefulness.

Drs. Emil Mayer and Robert C. Myles of New York also discussed the paper.

---

## MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

*Fifty-fifth Annual Meeting, Held at Scranton, September 26, 27, and 28, 1905.*

(Special Report to the Medical Record.)

(*Concluded from page 718.*)

THIRD DAY—THURSDAY, SEPTEMBER 28.

**Observations on Cancer of the Head and Neck, with an Analysis of 110 Operative Cases.**—Dr. George W. Crile, Cincinnati, presented a detailed report of one hundred and twenty-eight operations in one hundred and ten cases. He believed that the same method of procedure should be instituted in these cases as was followed in cases of cancer in other parts of the body, and the regional lymphatics should be completely dissected, sufficient tissue being removed to insure the destruction of all the infected glands. He also exhibited a number of photographs and diagrams illustrating the course of infection and the mode of operation.

Dr. Robert H. M. Dawbarn, New York, recommended complete extirpation of the growth, even removing a portion of the deep jugular vein, if involved. In order to avoid tying vessels as much as possible, and the consequent danger of embolism, he suggested the cording first of the lower extremities for ten minutes and then the upper extremities; for the purpose of keeping infection from the lungs the foot of the bed should be raised. The patient should not be allowed to sit up until he could drink a glass of water without coughing. In some instances it was necessary to divide the operation, on account of the extreme weakness of the patient.

**A New Intestinal Bobbin.**—Dr. JOHN G. CLARKE, Philadelphia, reported his experiments with this device on dogs and illustrated its practical application. He claimed as one of the most important points in favor of its use, shortening of the time required for the operation.

Dr. WILLIAM L. RODMAN, Philadelphia, believed that whenever possible mechanical devices should be done away with; he, however, thought the bobbin presented was superior to the Murphy button, as it was less likely to cause intestinal obstruction. It would be of value in an end-to-end anastomosis of the intestines.

Dr. ROBERT H. M. DAWBARN, New York, believed the device to be superior to the Murphy button, and expressed his intention to try it in posterior gastroenterostomies, which he believed to be about the only cases in which mechanical devices were justifiably employed. In experiments upon dogs, he said, we must consider the greater resisting power of the intestinal walls, and remarked that the hog's intestines more closely resembled the human viscera.

Dr. REED BURNS, Scranton, said that nothing was better than the suture, except in cases of end-to-end anastomosis, in which he had found the Murphy button entirely satisfactory.

Dr. J. C. O'DAY, Oil City, said that if one could place the ends of the intestines in perfect apposition one had accomplished the desired result, no matter what means might have been used to attain that end, and while not favoring too free use of mechanical devices, he believed there were cases in which nothing but the Murphy button would give satisfactory results.

Dr. EDWARD MARTIN, Philadelphia, attributed the preferences for the different mechanical devices, in a large measure, to the experience of the individual operators, and believed that the suture would continue to be the most generally used.

Dr. CLARKE, in closing, stated that the presentation was but an incomplete report, and that he hoped to present further results, including those of experiments on hogs, in the not distant future. In all cases sutures should be employed in conjunction with the intestinal bobbin.

**Wandering Gallstones.**—Dr. WILLIAM L. ESTES, South Bethlehem, read this paper, in which he stated that cases of indubitable perforation of this organ are comparatively rare, and referred to the work of Mayo Robson, Mayo, Maclaren, and others, showing the relative frequency of these cases and other diseases of the gall-bladder. He stated that if the ulceration was slow, and the patient survived the first septicemic condition, the stones would burrow in the direction of the least resistance and might be found in almost any part of the posterior portion of the right abdomen. The symptomatology was fully discussed, and among the prominent factors mentioned were severe pain, tumor, disturbance of gastric and intestinal function, jaundice present only in the early stages, or absent entirely, with general symptoms of septicemia.

**Surgery of the Gall-Bladder and Ducts.**—Dr. J. MONTGOMERY BALDY, Philadelphia, in this paper referred to the limited knowledge of the pathology and diagnosis of disease in these regions. He believed that in many instances too radical treatment had been instituted, reporting as illustrative to this point a case in which the gall-bladder and part of the cystic duct were removed, after which the patient's condition cleared up and remained so for slightly less than a year, when she again returned to the hospital with the same symptoms as before; another operation was performed and intestinal adhesions were broken up; five months later she again returned, suffering from jaundice and the other symptoms, and after rest in bed for a couple of weeks without operation, the symptoms disappeared. In conclusion, he stated that he believed the gall-bladder was too frequently removed upon slight symptoms, and that he felt in the future drainage without removal would be more frequently resorted to.

Dr. WALTER S. STEWART, Wilkes-Barre, urged early diagnosis, the removal of gallstones from the bladder, and the establishment of drainage. He reported a case, in which, in doing an operation for ventral hernia, he incidentally examined the gall-bladder and common duct, and found stones in both of them; these were removed and the wound was closed without drainage, on account of the other operation, and the patient made a good recovery.

Dr. CHARLES P. NOBLE, Philadelphia, reported two cases of wandering gallstones, one of which gave a long-standing history of gallstone colic, rendering the diagnosis easy; in the other, upon operation, the stone was found between the stomach and gall-bladder.

Dr. Estes, in closing, stated that in many instances the abscesses in these cases were attributed to some other than the true condition, as was the case with the first case reported by him, while in the other the diagnosis was comparatively easy on account of accidental discovery of bile.

**Decompressive Operation in Inoperable Brain Tumors.**—Dr. HARVEY W. CUSHING, Baltimore, referred in detail to the various methods employed for the removal of brain tumors, and felt that the bone should not be removed entirely, as, if it was, in a short time there would be a protrusion through the opening frequently resulting in paralysis of a more or less extended type. The chief end to be attained was to relieve the pressure and still leave some sort of a covering to keep the brain within the cranium; the most favorable site for the operation was the intramuscular temporal region.

Dr. ROBERT H. M. DAWBARN, New York, believed that it was best not to remove the bone entirely, but to prevent the edges growing together, by placing a piece of non-irritating tissue between them. When he found it necessary to remove the bone, he had covered the opening with a specially prepared celluloid, which would not be absorbed, is a nonirritant, and formed a protection against trauma, as well as cold.

**Direct Fixation of Fractures.**—Dr. JOHN B. ROBERTS, Philadelphia, while believing that in ordinary instances outward appliances were sufficient, referred particularly to the extraordinary cases, and discussed in detail the various methods employed in the fixation of fractures, including wire, catgut, bone ferrules, metallic plates, etc. For transcutaneous fixation, he had at first used ordinary wire nails, but afterwards devised a surgical nail with a sharp point; for the open fractures, or closed fractures which had been explored, he thought better results would follow the use of staples or plates.

Dr. GEORGE W. GUTHRIE, Wilkes-Barre, stated that his experience with direct fixation had been chiefly in cases of delayed union, and he preferred an end-to-end fixation and the insertion of a silver wire, which could be allowed to remain.

Dr. CHARLES E. THOMPSON, Scranton, reported several cases of direct fixation, and referred particularly to one, in which a fracture of the femur was united by means of a wire nail, and the man became able to walk around, and it was supposed union had taken place, but upon his death, eighteen months later, from another cause, autopsy revealed the fracture ununited, the ends being held together only by the nail.

Dr. DEFOREST WILLARD, Philadelphia, believed that direct fixation should be employed in all cases where it was necessary in order to bring the fragments of the bone into direct apposition, and believed that the method should be decided by the individual case.

Dr. JOHN S. NILES, Carbondale, referred to the fact that in the mining regions, many of the men were not seen until several hours after they had been injured, when they were in a very unsanitary condition; the surroundings were equally unsanitary, and in only rare instances could operation be performed under aseptic conditions.

Dr. ROBERT H. M. DAWBARN, New York, stated that in the cases referred to by the last speaker, he would wait for twenty-four to forty-eight hours before effecting a union, in the mentime disinfecting the wound by means of bichloride of mercury, etc.

Dr. Roberts, in closing, concurred with the last speaker in regards to the advisability of disinfecting the wound. He also suggested that direct fixation immediately following the injury might in some instances prevent bony union by causing bone necrosis.

---

GENERAL SESSION.

THIRD DAY—THURSDAY, SEPTEMBER 28.

**How May the Scientific Meetings of County Societies Be Made More Profitable?**—Dr. THEODORE DILLER of Pittsburg in a paper by this title, presented the following suggestions: Efforts should be made to get all the members of the county societies to take part in the program, and that the program should exhibit as much variety as possible as to men, methods, and methods of presentation. The symposium should not be repeated too often. The possibility of meeting at hospitals where physicians have patients who could be seen, was thought worthy of consideration. Since all of the members were physicians and not all surgeons, the suggestion was made that medical subjects be discussed two or three times as often as surgical. A paper or address by a visiting physician was considered particularly desirable, and this should be discussed by the local men. Occasionally, the visiting physician should be appointed to discuss the papers of the local men. For the best preparation of papers it was suggested that nothing was so helpful as a critical study of the literary form of the best known medical writers. A single, well-reported clinical case was said to be the easiest task for the young man, and the most acceptable.

Dr. CHARLES A. E. CODMAN of Philadelphia stated that the Philadelphia County Medical Society, which the reader of the paper had mentioned as meeting twice a month, did in reality meet seven times a month, having established branch societies in different sections of the city.

**The Question of Lower Gastric Secretion.**—Dr. CHARLES G. STOCKTON of Buffalo referred, as a reason for reopening this question, to the apparently growing belief that the digestive power of the stomach is unimportant to the well being of the organism. In reviewing a large number of cases, some of which have been studied for more than fifteen years, Dr. Stockton concluded that the rule might be laid down that in the absence of, or, with a very low standard of gastric secretion, individuals were almost invariably found with impaired health, and this often when the intestinal digestion was relatively good. It seemed to him that the question of stomachic digestion was of the greatest importance, and should be considered in the selection of an operation for the reestablishment of an adequate gastric drainage. Governed by his own personal experience, he concluded that a more normal gastric digestion was likely to ensue after a pyloroplasty than after a gastroenterostomy. The objections raised against pyloroplasty had not been apparent in patients coming under his observation, and he predicted that some form of pyloroplasty would replace gastroenterostomy in cases where it was practicable.

**The Surgical Treatment of Cardiospasm.**—Dr. EDWARD MARTIN of Philadelphia read this paper, reporting a case of cardiospasm in which he had opened the stomach and introduced three fingers through the cardiac orifice to stretch it. There was complete recovery of the patient with a gain of forty pounds in six months.

**The Treatment of Benign Stenosis of the Pylorus and Duodenum, Resulting from Spasm and Scar Tissue, and from Abdominal Adhesions.**—Dr. ALBERT BERNHEIM of Philadelphia gave histories of the cases presented and detailed the treatment. He concluded that not all cases of dilatation of the stomach need necessarily be subjected to the knife of the surgeon. The treatment employed was that of Dr. A. Hartz—hypodermic injections of allylsulphocarbamide, a chemical product prepared from oil of mustard with absolute alcohol and ammonia water. Improvement was rapid with a gain of 17 pounds in two months. The improvement had lasted over fifteen months in the case recorded.

**Symptomatology and Diagnosis of Cancer of the Stomach.**—Dr. JOHN J. GILBRIDE of Philadelphia presented this paper. He stated his belief that the analysis of the stomach contents was not sufficiently recognized in this connection, and that if the method were employed, diagnosis would be possible at a much earlier stage with consequent benefit to the patient. Reference was made to a case in which paralysis of the gastric contents revealed neither free hydrochloric or lactic acid. Tumor of the stomach in his opinion did not necessarily occupy the epigastric region, for it was not uncommon to find one in other parts of the abdomen, and he recalled one case in the clinic of Professor Sailer in the Philadelphia Polyclinic, in which the carcinoma of the pylorus was felt in the right iliac fossa.

**Gastroenterostomy; Its Indications and Its Technique.**—Dr. WILLIAM L. RODMAN of Philadelphia enumerated the indications for, and described the technique of the operation, which he said meant literally an opening or communication between the stomach and some portion of the bowel below. His remarks had special reference to gastrojejunostomy, which he said was practically the only form of gastroenterostomy generally used at the present time. To-day the operation was made by placing the communication between the stomach and the intestine on the anterior or posterior surface. The first operation was the anterior methods, consisting in bringing up the jejunum, and anastomosing it with the lower end of the stomach. While it was far easier than the posterior operation, certain objections had caused it to fall practically into disuse at the present time. One objection to the anterior method was that the loop must be eighteen or twenty inches long, and on that account the end of the loop filled up with the contents of the stomach, and gave rise to regurgitant vomiting. Another objection was the fact that the loop passing up in front of the transverse colon might easily make compression upon the colon, and cause intestinal obstruction. Adhesions between the loop and transverse colon formed another source of danger. Even a greater objection was the fact that, the anastomosis being made so low in the upper alimentary canal, the upper portion of the intestine was put out of commission, and the patient did not, therefore, receive the same benefit from food taken into the stomach. The anterior operation, he stated, was done to-day as a last resort, when speedy operations seemed requisite, and in cancerous operations it was still possibly the operation of choice.

Dr. JAMES TYSON reported two cases which had come under his observation, and which he thought strikingly illustrated the purposes, the accidents, and the results of the operation. One case was that of a woman aged fifty, who had had a frightful hemorrhage supposedly due to gastric ulcer. She survived the effects of the hemorrhage and was in comparatively good health for three years, when she again had severe hemorrhages. Gastroenterostomy was performed, and for forty-eight hours the patient did well, and then died. In another case, the vicious circle of vomiting set in following operation, and it seemed as if the woman must perish. A second operation was performed, and the woman was said to be in good health at the present. Dr. Tyson expressed his belief that cases of gastric ulcer with dangerous hemorrhage formed one of the most justifiable indications for operation.

Dr. JOHN B. ROBERTS said there was no doubt that gastric surgery had now become a more prominent branch of surgery than was the case a few years ago, and no doubt also, that the earlier the cases were brought to the surgeon, the more cures there would be. The difficulty which he had encountered was in making the diagnosis between the functional cases and those of organic disturbance; and in this connection, he said he had opened the stomach, thinking, after experts had made the usual examinations, that he would find some serious condition, and had found practically nothing. With Dr. Stockton he believed that the operation of pyloroplasty was more satisfactory than

gastroenterostomy, by either the anterior or the posterior method, and that it would be more frequently adopted within the next few years. A difficult question to decide was which cases to operate upon during the early symptoms and which not. He believed that if patients could be made to live hygienically, given happy homes, and ample means, there would be few cases of functional disease; that it was bad living, drunken husbands, and unfortunate surroundings which brought the cases to the neurologist, to the surgeon, and to the general practitioner. If that class of cases could be got rid of, and operation done only upon the organic cases, it was the belief that surgery would have more triumphs and the graves fewer occupants.

**Officers.**—The following officers were elected: *President*, Dr. W. H. Hartzell, Allentown; *Vice-President*, Dr. Morgan J. Williams, Scranton; *Secretary*, Dr. C. L. Stevens, Athens. The meeting adjourned to meet at Bedford Springs in 1906.

## Books Received.

*While the* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

NOUVEAU TRAITÉ DE MÉDECINE ET DE THÉRAPEUTIQUE. Sous la Direction de MM. P. BROUARDEL et A. GILBERT. VI. MALADIES EXOTIQUES. By various authors. 8vo, 439 pages, illustrated. J. B. Baillière et Fils, Paris.

THE PRINCIPLES OF BACTERIOLOGY. By A. C. ABBOTT, M.D. Seventh edition. 8vo, 689 pages, illustrated, muslin. Lea Brothers & Company, Philadelphia.

STATE OF NEW YORK STATE COMMISSION IN LUNACY. Sixteenth Annual Report, October 1, 1903, to September 30, 1904. 8vo, 1,050 pages, muslin.

MANUAL OF CHEMISTRY. A GUIDE TO LECTURES AND LABORATORY WORK FOR BEGINNERS IN CHEMISTRY. A Text-Book Specially Adapted for Students of Medicine, Pharmacy and Dentistry. By W. SIMON, Ph.D., M.D. Eighth edition. 8vo, 643 pages, illustrated, muslin. Lea Brothers & Company, Philadelphia.

## Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 28, 1905:

| | Cases | Deaths |
|---|---|---|
| Measles | 113 | 2 |
| Diphtheria and Croup | 262 | 17 |
| Scarlet Fever | 61 | 4 |
| Smallpox | .... | .... |
| Chickenpox | 85 | .... |
| Tuberculosis | 342 | 157 |
| Typhoid Fever | 94 | 19 |
| Cerebrospinal Meningitis | 2 | 5 |
| Typhus Fever | .... | .... |
| Yellow Fever | .... | .... |
| Cholera | .... | .... |
| Totals | 959 | 204 |

**Conservation of the Ovaries and the Uterus in Operative Procedures Upon the Uterine Adnexæ.**—Th. Tuffier in describing his technique, says that he attempts as far as possible to attack the tube from the uterus toward the fimbriæ. He insists upon the necessity of perfect hemostasis. It has been shown that the blood vessels that supply the tube are largely independent of those of the ovary, and they are also independent of each other. They form a comb, the teeth of which are lost in the tube. The writer warns against hemorrhage from the uterine angle and from the tuboovarian ligament. The second tube is to be treated like the first. There are still the uterine angles and the intrauterine course of both tubes. These he destroys with the thermocautery. The angles are closed with deep catgut sutures, overlapped with Lembert sutures. In this way the uterine mucosa is well isolated and cannot infect the neighboring tissues. Nearly always the writer fixes one end of the tuboovarian ligament to the round ligament. This leaves a median uterus with two lateral ovaries resembling the two tonsillar fossæ. The abdomen is closed in two layers with catgut, while the skin is united with hooks. The writer has operated in twenty-eight cases, with a mortality of 3½ per cent.—one death. As to sclerocystic ovaries, the writer believes that they are more often dependent upon disturbances of ovarian vascularization than upon infection, and he removes them in only exceptional instances. Many painful uteri after the removal of the adnexæ, owe their symptoms to the persistence of an infected stump left in the cornu of the uterus. This stump is easily removed. As to the fate of the ovum, when it falls into the peritoneal cavity—it leaves a small aseptic cyst, or it is absorbed. The writer concludes his paper by stating that he considers the conservation of the organs at the same time that one secures the disappearance of the symptoms of which they are the seat, one of the characteristics of modern surgery.—*Surgery, Gynecology, and Obstetrics.*

**The Use of Rye Bread in Diabetes.**—M. C. Lidwill has for some time been prescribing black rye bread (pumpernickel) in the case of diabetic patients. It is used as a substitute for wheat bread. The results of its use are entire disappearance or diminution of the sugar from the urine, gain in weight, and contentment on the part of the patient. The writer was led to the use of rye bread by the craving and empty feeling of which patients complain who are on the so-called diabetic diets. He sums up the advantages of rye bread as follows: It is satisfying; it stops the empty feeling; patients eat but little of it in proportion to wheat bread, about one and a half loaves sufficing for each week. This bread contains but little digestible starch; it is a laxative, combating constipation. The sugar in the urine during its use decreases to a considerable extent. Patients do not tire of it. It is a cheap food. The writer adds that rye bread is employed with the greatest benefit in the milder forms of glycosuria met with in the middle-aged or old.—*Intercolonial Medical Journal of Australasia.*

### NOTES ON NON-OPERATIVE GYNECOLOGY.*

By SARAH J. McNUTT, M.D.,

NEW YORK AND ALBANY.

LATE GYNECOLOGICAL SURGEON TO THE NEW YORK INFIRMARY FOR WOMEN AND CHILDREN; LATE LECTURER ON DISEASES OF CHILDREN AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; FOUNDER AND ATTENDING PHYSICIAN TO THE BABIES' WARDS OF THE POST-GRADUATE HOSPITAL; LATE ATTENDING PHYSICIAN TO THE BABIES' HOSPITAL; LATE MEMBER OF THE AMERICAN NEUROLOGICAL SOCIETY; MEMBER OF THE NEW YORK ACADEMY OF MEDICINE, NEW YORK PATHOLOGICAL SOCIETY, NEW YORK COUNTY MEDICAL SOCIETY.

ALTHOUGH the subject of this paper is non-operative gynecological work, I trust that I shall not be suspected therein of desiring to minimize the operative side of such practice. During the twenty-five years of my professional life I have seen much of surgery in diseases of women, and I have always held and taught that where an operative procedure is indicated and there is neglect to give the patient the benefit of such procedure, the gynecologist in charge is recreant to duty.

In the early days of my practice the operative craze was in the air. To operate with a promise of accomplishing so much at a rapid rate was very attractive, and unless there were decided counter-indications, the patient was urged to accept the radical rather than the conservative method of treatment. The patient was assured that she would avoid a long, tedious experience, and the surgeon was pleased at the prospect of quick work. The routine and unending patience required to restore a gynecological patient to health and comfort had small credit in those days. Many cases gave brilliant results. Many others, although operated upon after the most approved methods and under strict aseptic and antiseptic precautions, were disappointing. Individual idiosyncrasies, unexpected local involvement, and systemic conditions modified the expected result.

The pendulum began to swing back, and each individual case became a law unto itself

To-day, the most frequent division of gynecological cases that comes to us is those that must be operated upon to save life, and those that may be, to save time and a long disability.

In placing before our patients the question of operative interference, with its probable advantages and possible disadvantages, the working woman will, as a rule, elect the operation, for time means much to her. But as women rise in the social scale they are less ready to embrace operative interference, except as a last resort, but are willing to spend time and means indefinitely if there is prospect of ultimate recovery.

No experienced specialist will for a moment question the propriety of early operative interference, where possible, in most pelvic or abdominal tumors, solid or cystic. I have usually excepted small fibroids, so situated as not to give pressure, and of non-hemorrhagic nature, with a warning to the patient of their possible rapid development and a caution to be prepared for immediate operation should unfavorable symptoms arise. However, there is a class of fibroid cases where the symptoms appear serious, but where they will soon yield to non-operative measures, and defer indefinitely the question of operation, The following case illustrates this class:

Now traveling in Egypt is a patient who considers herself perfectly well. Five years ago, at the age of 48, she came to me with a history of profuse and painful menstruation, lasting six, eight, and ten days. She had marked gastric and intestinal disturbances, and more or less constant pelvic distress, which became more pronounced at each menstruation. Leucorrhea was present during the intermenstrual period. She was much depressed. There was a history of gradual enlargement of the abdomen. On examination it was found that while the cavity of the uterus measured only three inches, there were multiple fibroids reaching half way to the umbilicus. One was pedunculated, the size of a tangarine orange, and had dropped down into the posterior cul-de-sac. It had become impacted there by development and was extremely sensitive. In the knee-chest position, I was able with some effort to dislodge it, and with a properly adjusted tampon to keep it out of the pelvis. An operation was advised, but while the patient and her husband were considering the matter, she was made so comfortable with palliative treatment that they elected to try that method for a time. Ergot and later compound viburnum tablets were taken to aid in diminishing congestion. Six months later all symptoms had disappeared. The tumor had so much diminished in size that it reached but slightly above the pubes. The patient could take long walks with comfort, menstruation was scanty and painless, and she refused to consider an operation. Two years later, the menopause was established. The patient still reports every few months. Now there is only an irregular tumor, freely movable behind the pubis, and entirely without sensitiveness. She was allowed, without question, to go abroad. Both the patient and her husband are fully aware that degenerative changes may come at any time, and are ready to return should any pelvic symptoms arise.

Further conditions, involving the question of operation, are: Accidents of childbirth and malignant disease. With improved methods of midwifery, the former are now seldom seen calling for secondary operation. But malignant disease is a constant possibility. No one familiar with its contributing causes would leave cicatricial tissue to become an irritant, or interfere with pelvic circulation. It is inexcusable to treat a beginning malignant condition for an eroded cervix, when by the use of cocaine, in one's office, it is so easy to remove, without the patient's knowledge, a small piece for miscroscopical examination. Of course, pus collections should not be al-

*Read by invitation before the Albany County Medical Association, October 10, 1905.

lowed to remain in the pelvis any more than in any other part of the body.

With this definition of the limits of my subject, I will mention some of the more frequent general conditions that call for treatment in non-operative gynecological patients, and methods used to correct them; and some of the most frequent local troubles found in these patients, and the means utilized to relieve them.

There will be no attempt to treat this subject exhaustively.

In dealing with these cases successfully, one must realize that while they present themselves for gynecological treatment, many of their symptoms are not purely and exclusively gynecological, although often they are reflexes from functional disturbances springing from the original pelvic disorder. While the local conditions must be treated, the local measures adopted will be made more effective if, in each case, combined with them, is a careful consideration of the general condition, and those measures utilized that will most quickly restore any functional disorder that may be present.

The most frequent general symptoms of these patients are the derangements of secretion and excretion, anemia, and symptoms of the nervous system. The most frequent local conditions are: (1) Displacements of the uterus, with or without displacements of the adnexa; (2) catarrhs, acute, subacute, and chronic, confined to the uterus, and (3) the same, with extension to the tubes and secondary involvement of the ovaries.

I have unbounded faith in local treatment, but in many cases one can use local treatment indefinitely and utterly fail to cure the patient if with it do not go general medication and hygiene. This includes diet, clothing (few women dress properly), carefully regulated out-of-door life, with some interest to divert the mind from introspection.

The most frequent nervous symptoms that gynecological patients wish to be relieved of are their nervous instability ("nervousness"), headache, backache and other neuralgias, and insomnia. The nervous symptoms generally arise from imperfect capillary circulation in some part of the nervous centers, more often the spinal cord, and are often associated with deficient excretion from the skin, kidneys, or bowels, or defective cardiac action. In considering the nervous symptoms, the condition and improvement of secretion and excretion first demand attention.

To assist excretion by the skin, I always insist upon a daily bath, preferably on rising, and taken as hot as can be borne for three minutes, scrubbing well with a brush or coarse cloth and soap, and followed by a cold shower, or cold water poured over the body from a pitcher. With delicate patients the latter is preferable, since salt can be added to saturation, which will raise the specific gravity of the cold water, and less shock will be felt. One unconvinced of the amount of waste thrown off by such a procedure, need only examine a specimen of urine taken before and another after such a bath, and note the amount of urinary solids in both. I always give my patients, with the directions for the bath, a little idea of the anatomy of the skin, its condition when the glands are not acting well, and also of the vasomotor physiology involved, thus insuring their hearty cooperation. Engelman, of Kreuznach, has written that "for gynecological patients general bathing under scientific supervision is a remedy of great value. Associated with friction it acts on the same priciple as a counterirritant, attracting a considerable volume of the circulation to the surface, thereby relieving splanchnic congestions, and by stimulating the nervous system becomes an active promoter of absorption. It is valuable as a remedy for chronic exudates, adhesions, neoplasms, and in the treatment of amenorrhea due to obesity."

The amount of urinary solids voided daily by a gynecological patient should be early determined. Not infrequently I have found the excretion of solids 30 to 40 per cent., or even more, less than normal. These patients present varying degrees of nervous irritability, and in some extreme cases are near uremic convulsions. I consider that it is far more important in such cases that the renal insufficiency be determined than that the displaced uterus, or prolapsed or diseased ovary or tube, be diagnosed. We must not forget that the kidneys, ovaries, and tubes spring from the same source embryologically. It is a clinical observation that a close sympathy exists between renal insufficiency and pelvic disorders. Patients with renal insufficiency will complain of irritable nerves, more or less headache, backache, and insomnia. Large draughts of water often restore the kidney action without medication. I have such patients take at least eight glasses a day, either hot or cold, on an empty stomach. Where insomnia is a marked symptom, I have found two or three glasses of water, two or three hours after dinner, in the evening, to be a better hypnotic than drugs. I always direct that, upon lying down, the patient shall rest upon the right side for a time to allow the water to pass readily out of the stomach into the bowel. If one selects a pure and tasteless spring water it is not difficult to have any amount desired taken with the most satisfactory results. Malted milk is valuable as a hypnotic in this connection, a cupful taken hot on retiring, and again in the night if wakeful. Of course, a weekly laboratory examination of the urine is a matter of routine.

It has been aptly said that "constipation, that protean monster, can derange more lives with neurotic symptoms than any other one pathological condition that can be named." It is, as a rule, present, to a greater or less degree, in all gynecological cases. Mild cases will be corrected by simple laxations and régime. The loaded colon exists much oftener than is suspected in those who have daily movements, as well as those who have not. The daily movement may pass down through the accumulation of feces, impacted in the loculi. Two symptoms without an abdominal examination are suggestive of a possible colonic impaction, the presence of chloasmic spots and the voiding habitually of very dark feces. When laxatives are relied upon, I have found it advantageous to give with them calomel or blue pills, more or less frequently. The best means to rely on to empty a loaded colon has, in my experience, been colonic flushings. They should be used daily, as long as dark feces are voided, once or twice a week when the discharges become yellow. These flushings have been called "liver washers," because, if properly given, a large part of the water is absorbed from the intestine, taken up by the portal circulation, and passed through the liver. A more or less congested liver is always present in these cases.

The patient in the knee-chest position receives from two to six pints of water as hot as can be borne, either soapsuds, or a physiological salt solution. As the colon becomes distended, the scybalous masses usually separate from the wall of the loculi, and fall into the lumen of the bowel, but if this does not readily occur gentle kneading of the bowel after it is filled with water will help to dislodge them.

The specialist who sees many cases of diseases of

women realizes the very great importance of having a careful abdominal examination precede the pelvic one. Many cases show varying degrees of fecal retention, but the following case is fortunately an unusual one in its exaggerated degree of colonic involvement:

Mrs. L. Md., age 68, an extremely nervous and hysterical woman, a patient of Dr. Julia G. McNutt's recently presented herself, after an absence of some months. She reported that she had been more or less confined to her bed for four months, and that she had been trying for several weeks to get strength enough to come to the city from one of the suburbs, in order to see if she could not be relieved of the constant discomfort in her right side. She came into the office walking with difficulty, supported by her son, a broad-shouldered athlete over six feet in height. Her local physician had assured her that there was a gradual development of a tumor in the right side, and from the position, it was probably connected with the appendix. Immediate operation was advised. She wished to see Dr. Julia McNutt before deciding. She could distinctly define the mass herself. It was extremely sensitive. It was noticed on shaking hands with her that her skin was cold and clammy, the sclera yellow, complexion pale and muddy, chloasmic spots on the face. There had been no elevation of temperature. With this history the condition of the colon was interrogated before a pelvic examination was made. As suspected, the large, defined mass was found to be entirely within the bowel, doughy to the touch, and very sensitive on account of the long retention. The ascending, transverse, and descending colon was crowded with feces, and on vaginal examination the whole pelvis was found to be filled with a protruding rectum containing hard scybalous masses. It was difficult at first to make the patient understand the real condition. She had had a daily movement by rochelle salts and found it hard to realize how the salines could keep a canal through the center while allowing the mass to remain. In her thankfulness at escaping from the dreaded operation, she was willing to follow the directions, which were, colonic flushings daily, laxatives, bitter tonics, and strychnine. In a week she returned, smiling and unsupported, and happy to have lost her tumor. Examination confirmed its entire disappearance.

I believe autoinfection from renal, intestinal, or cutaneous insufficiency, to be of supreme importance in these cases. It is well recognized by neurologists as an etiological factor in their specialty, and as a very important point in considering the nervous symptoms of gynecological cases it is not to be lightly passed by.

No one symptom is reported to us so frequently as occipital headache. It will be found frequently in conjunction with a weak heart, the most common cause of which is the poison absorbed from intestinal decomposition. It has been said very tritely that "the weakness of a weak heart is of the greatest possible consequence." This occipital headache yields readily to one or two doses of digitalis. Coal tar derivatives are decidedly counterindicated. It used to be supposed that it was because of the direct cardiac stimulation that digitalis behaved so well. But Sajous points out that it is quite indirectly a heart stimulant. He says: "Digitalis is probably the most perfect cardiac stimulant of our pharmacopeia, but only because better than any other drug it enhances the activity of the pituitary body, which, in return, so stimulates the suprarenal glands as to bring them to their highest functional possibilities. The physiological action of the suprarenal glands is to transform or destroy the toxic substances which are produced in the organism under the influence of muscular activity and of the nervous system." Its action, then, is is to start up this circle of activities that neutralize the toxins that depress the heart.

Most of these patients are anemic, partly from autoinfection. Although iron is so much needed, it is, as a rule, badly borne. Those substances that increase nutrition, usually give the most valuable results, peptonoids, phosphates, malt extracts, and cod liver oil when tolerated. It is important to have blood examinations made at regular intervals as indicated. The full benefit of a blood examination can be obtained only by the examination of all the constituents of the blood. During the last year this fact has been most clearly demonstrated in the case of three sisters, who, although with the same heredity and environment, presented very different temperamental states. Their hemoglobin varied but slightly, being respectively 78, 72 and 60 per cent. This test could have been of little service as a guide to the general treatment, if there had not been other marked characteristics in the blood of each, which pointed to decided differences in their general conditions, and suggested entirely different lines of treatment in the individual cases. The results entirely justified the adoption of measures along the lines indicated by the several blood analyses. The following is a report of the blood examinations in these cases made by Dr. R. L. Watkins, together with notes of diagrams and treatment:

Miss O. D., single, 36. Myofibroma. Hysterectomy. Hematocele. Blood corpuscles diminished from hemorrhages. Microcytes. Neurasthenic.

| | Hemoglobin. | Red cells. | White cells. | Microcytes. |
|---|---|---|---|---|
| July 20, 1904 | 78 per cent. | 2,950,000 | 5,900 | Many. |
| Oct. 25, 1904 | 85 " " | 3,450,000 | 6,500 | Diminished |
| Feb. 23, 1905 | 93 " " | 3,500,000 | 4,500 | Less. |
| June 8, 1905 | 98 " " | 3,900,000 | 5,900 | Very few. |

Treatment.—High, dry inland air; Laxatives; Bitter and heart tonics; Peptonoids; Electricity.

Miss A. D., single, 28. Endometritis. Salpingitis. Autoinfection. Neurasthenic.

| | Hemoglobin. | Red cells. | White cells. | Microcytes. |
|---|---|---|---|---|
| Jan. 28, 1905 | 72 per cent. | 3,140,000 | 5,850 | Many. |
| Feb. 23, 1905 | 80 " " | 4,140,000 | | " |
| June 8, 1905 | 80 " " | 3,540,000 | 6,550 | Absent. |

Treatment—Hygienic measures; Laxatives; Digestives; Mineral acids; Nerve tonics; Electricity.

Miss W. D., single, 24. Pelvic peritonitis. Anemia. Exostoses of middle turbinated bones.

| | Hemoglobin. | Red cells. | White cells. | Microcytes. |
|---|---|---|---|---|
| Feb. 23, 1905 | 60 per cent. | 3,750,000 | 6,000 | Very few. |
| June 8, 1905 | 72 " " | 3,900,000 | 7,100 | " |

Treatment.—Operation on nose; Laxative; Iron; Fat emulsion; Electricity.

All had pelvic disturbances, and all were anemic. The first had a large myofibroma of the uterus, with very profuse hemorrhages. Following operation her blood showed red and white cells in good condition, but their number really diminished to about one-half the normal quantity. A great many microcytes were present, probably the result of the repeated hemorrhages (Jaksch). The second had dysmenorrhea of long standing, with endometritis and salpingitis, autoinfection, and was neurasthemic. The pelvic reflexes had been the cause of marked disturbances of excretion and secretion, which in turn induced autoinfection and the resultant neurasthenia. Autoinfection showed in the blood by very marked microcytosis. While there was not such rapid improvement in the blood condition of this patient as

desired, except for entire disappearance of microcytes, there has been a great improvement in the functional disorders and the condition of the nervous system. The third case had a pelvic peritonitis, secondary to a catarrhal salpingitis. She had one nostril occluded and the other much narrowed by exostoses. Diminished hemoglobin was considered due to the difficulty of inspiration with imperfect oxygenation of the blood. The nares were relieved by operation, and improvement followed. In each of these three patients there was enlargement of the thyroid gland of varying degrees. This showed that there had been of long standing a vasomotor irritability which had resulted in this partial paresis of the nerves in this locality. This is a not infrequent complication where pelvic reflexes have been in existence for some time, and this complication, as a rule, disappears when the nerve fret is removed and vasomotor tonicity restored.

When a patient presents herself for local treatment, and on inspection we see a mucopurulent or purulent discharge escaping from the cervix, we must first decide as to its nature and cause. For treatment this leucorrhea comes into three classes:

(1) Congestive leucorrhea, caused by conditions outside the organs of generation, such as constipation or abdominal tumors, fluid collections, or plastic exudates.

(2) Due to displacements of uterus or adnexa, which would affect the circulation.

(3) Due to diseased state of the uterine mucosa and glands, or of the appendages, with or without the former conditions also.

Fortunately many patients can be readily placed in the first or second class. We can promise a more or less speedy relief of symptoms, as we are able to relieve the constipation, elevate and support the uterus, if indicated, and where accompanied by local and general relaxation, increase general and local tonicity. Where a vaginal support is indicated, cotton or wool should be used at first, but as soon as possible a firmer one of soft or hard rubber should be substituted, the latter always when it can be worn, for its greater cleanliness and firmer support. One should aim to limit as early as possible the patient's visits, having her return, however, as often as indicated to assure one's self that improvement is progressive. All support should be removed as early as can be done with safety, insisting upon a return at stated times, that the gynecologist may be sure that restoration has been secured.

The subject of this paper requires a somewhat detailed description of vaginal tamponade, and the subsidiary local measures that usually accompany it. As the vaginal tampon is an agent useful in both simple and complicated non-operative cases, they will be considered together under this head. If the patient be placed well down in the knee-chest position and the perineum raised by the left index finger, the air enters and by its own weight the whole pelvic contents gravitates toward the abdominal cavity. If this does not readily occur, the finger holding the perineum can be carried forward, and by gentle pressure against uterus or appendages, help them to move up as far as possible. No pressure should be used that causes pain. It may be that no perceptible dislodgment can be obtained, but a tampon properly placed will give comfort, and medication can be kept in contact with the tissues. If one end of a narrow strip of non-absorbent cotton or wool, 12 to 18 inches long, be carried by a long dressing forceps against the back of the index finger as it holds up the perineum, up into the posterior cul-de-sac, the tissues along the canal need not be touched. The tampon can be packed gently back and forth in the cul-de-sac more readily and with less discomfort to the patient than can be done with the aid of a Sims' speculum. The material should be soft and yielding, either aseptic non-absorbent cotton or sterilized wool. Absorbent cotton should never be used, since it tends to pack into a hard mass when wet. The whole of the posterior cul-de-sac should be filled, but not packed hard enough to cause discomfort by pressure. In introducing the tampon, the end first carried up has a string attached of firm soft knitting cotton. This end, seized by the forceps, is saturated with the medicament selected and turned over into the adjoining clean part of the cotton. It is then passed

Fig. 1. Tampon of Wool or Non-absorbent Cotton.

up quickly to the cul-de-sac, before the medicament soaks through, to be rubbed off on vulva or vaginal canal. The lower end of the string, caught around the little finger of either hand, or between the thumb and second finger of the left hand, as the tampon is introduced, prevents the entire string from being carried up with the tampon. No two patients need the same amount of cotton or wool. With the same patient the amount varies according to fullness or emptiness of the bowel, or the forward position of the uterus and adnexa. The object is to fill the cul-de-sac comfortably. One can readily tell in packing when there is enough, and the rest of the strip of cotton can be pulled off. Care should be taken that,

without giving pain, the cotton is gotten well up behind the cervix. When in place, the patient should be directed to rise straight up on her knees, while the index or packing finger holds the cotton in place behind the cervix. By this precaution the air that ballooned the vagina is allowed to escape and the tampon, held by the finger, is not crowded down by the return of the elevated pelvic organs. At the same time that the tampon is held in place, if it is not too large, the cervix will be felt to ride down over the cotton, holding it back behind it. This leaves the external os free, allowing opportunity for free escape of any discharge from the uterus. A carelessly adjusted tampon can do much harm by preventing free drainage. On removing the finger, while the patient is still straight upon the knees, the part of the string remaining outside should be cut, leaving only a piece an inch in length beyond the vulva. If it be longer, it may be drawn upon by the inner part of the thighs in exercising and cause the tampon to be displaced, as well as cause chafing. When the patient stands, the pelvic organs gravitate back again toward their former position, but the tampon now receives their weight and holds them somewhat above their former level. If only for a fraction of an inch, it is sufficient at least to take the drag off adhesions if they are present. If there is tubal involvement, I usually place a little larger amount of packing on each side of the cul-de-sac, if it can be pressed up without pain. If the distal end of the tube can be kept in the slightest degree higher than the proximal, it will favor drainage into the uterus. In rare cases large tubal collections have discharged through the uterus, the probable cause being that the exudate caused an adhesive inflammation of the tube, holding it upon a plane high enough to permit drainage. When the inflammatory swelling, which helped to produce the closure or constriction of the uterine end of the tube, has been sufficiently reduced, the escape of the fluid collection is possible. As a rule, such a fortunate termination does not result. Generally, by increased weight from its pathological condition, as well as relaxed supports, the tube has sunken to a lower level than the fundus. Becoming adherent in this new position, any evacuation of fluids into the uterus is mechanically prevented. In a catarrhal salpingitis of short standing, tamponade may make drainage through the uterus possible. And, not infrequently, vaginal treatment, with patient, judicious attention to detail, will show the entire clearing up of a case with exudations, adhesions, and tubal and ovarian complications. So long as there is progressive improvement, one is justified in continuing these methods. Whether the condition be changed by drainage or absorption, it is well to follow out the measures that show progress, although one may not always be positive about the exact course taken in the recovery. Should there be, however, recurrent attacks of peritonitis, however slight, or symptoms of retained pus, the patient should be urged to submit to operative interference and warned of the dangers of delay. The patient who is under treatment for a heavy displaced uterus, with involvement of the appendages, should wear continuously a properly adjusted tampon, to be changed as indicated. Particularly should this be the case during the menstrual period, especially if the flow be profuse or prolonged. It should be changed daily if the patient is able to be about. Many do much better to be so protected and permitted a certain amount of liberty. The tampon should also be changed daily where there is an irritating leucorrhea or an odor to the discharge. As improvement follows, its renewal may be delayed to the second, third, or fourth day, as indicated. When conditions improve, and there is no discharge, but a firmer support is impracticable, I have used wool and seen the patient only at intervals of a week or ten days. The tampon need not be removed when douches are taken, if it is placed well up behind the cervix. It becomes saturated with the water, but when the patient sits up the water is pressed out, and if wool be used it will retain its elasticity. In most patients, when the local sensitiveness is relieved, a properly adjusted support must take the place of the tampons. It is interesting to note how often, when the utricular glands are being restored by the intrauterine injections and the local circulation improved by appropriate treatment, the weight of the uterus and adnexa have greatly diminished. The ligaments, muscles, connective tissue, and the blood vessels, have participated in the general upbuilding of the whole body, and they can now give the needed support that they were intended for. Then we begin by lessening the amount of material in the tampon, after a little leaving it out after every other visit, watching effects and returning to its use at any time if indicated. It is left out altogether when it is found that the sagging does not return on its removal.

In a case where there is much sensitiveness, exercise is restricted and a douche is ordered every two to six hours, of twenty to thirty minutes' duration, at a temperature of 105° to 124° F. In some cases, in place of the douche, more rapid results are obtained in relieving pain and inflammation with the use of antiphlogistine. One-half to one ounce wrapped in the end of a small tampon, is passed quickly up into the cul-de-sac, with the patient in the knee-chest position. The rest of the tampon is packed lightly over it to keep it in place, and it is changed in forty-eight hours. At the same time a layer one-fourth inch in thickness is spread over the hypogastrium, covered with absorbent cotton, to be removed when the remedy dries and peels off. This will be twenty-four hours in some instances; in others not till forty-eight hours or more. Pure ichthyol often gives quick relief from pain. Later a solution of ichthyol, twenty-five to fifty per cent. in glycerin, may be used. As the tissues become accustomed to one remedy, change to another, which may be of no greater value, but which will serve to break up a "habit of body." Thigenol is as valuable as ichthyol, while it has the advantage of being odorless. The stains made by it on linen can be quickly removed, and it is also nonirritating and antiphlogistic. It is used in solution in glycerin in eight to twenty per cent. on tampons. A change may be made to applications of Churchill's compound tincture of iodine to the vaginal roof, using pure glycerin upon the tampon, at the same time painting the hypogastrium with this tincture if needed. To some patients glycerin is an irritant to the mucous membranes. If care is not taken commercial glycerin may be substituted by the druggist, which is irritating from a trace of sulphuric acid. If I am convinced that the fault is not in the glycerin, I substitute in its place albolene or lanoline. Where simple astringency is needed, I use upon the tampon a solution of tannin or acetate of aluminum in glycerin, ʒi-ii to ʒi. When a patient complains of constant pain, I apply a small fly blister, moving it about as fast as one heals; or the Paquelin cautery, lightly brushed over the seat of pain. Both give relief.

In my experience there is an undoubted value in the use of electricity for neurotic women and young girls, as an adjunct to the local treatment. As the patient lies upon the table, a flat pad is placed under

the neck, connected with the positive pole of a galvanic battery, another under the sacrum, connected with the negative pole. The current is made as strong as can be borne for the needed vasomotor stimulation. This treatment is emphasized while the vaginal treatment is minimized. If there are many reflexes from the pelvis, after a little the positive pole is removed from the neck and placed on the hypogastrium. Even a ten-minute application does much good. I frequently alternate at every other visit the high frequency current or the vibrator.

When we are obliged to place a patient in the third class, where the endometrium is diseased, to the preceding treatment should be added, as early as safety permits, intrauterine irrigation.

The uterus that needs irrigation is as a rule heavier than normal. The endometrial glands are diseased and the irritation has brought more blood to the organ. The interstitial tissue has greatly increased and the ligaments, blood vessels, and connective tissue packing are all relaxed and no longer furnish adequate support. "In the light of modern pathology," says W. E. Ashton, "inflammation of the uterine mucosa becomes a subject of vital importance, as it is the starting point of nearly all the inflammatory lesions of the pelvic organs." As the uterus and appendages sink in the pelvis they usually follow the curve of the sacral canal and become retroposed. The pelvic circulation is interfered with by the descent and displacement. The veins would need to empty themselves uphill, which they are little disposed to do. They become tortuous and distended, and the pelvic organs are fed by dammed-back venous blood. The increased weight and displacement lets the organs interfere more or less mechanically with the action of the rectum, allowing fecal retention. The crowded bowel, in turn, by pressing forward and downward, increases the displacement of the uterus and appendages. The fluid part of the retained fecal matter becomes absorbed into the pelvic circulation, making a blood that will take little part in any nutritive changes that are attempted. The dusky red look of the tissues must be changed to a brighter coloring, and, until we establish a clean arterial pelvic circulation in place of the dirty venous one, it is useless to expect much from intrauterine irrigation. Diet, exercise, and laxatives can do much, but better and more far-reaching results will be obtained if with them are combined colonic flushings. Since they not only empty the bowel more perfectly, but also when part of the water is absorbed, they flush the liver and kidneys, organs always more or less congested in these cases.

The weight of a heavy engorged uterus retrodisplaced, dragging upon tender and adherent ovaries, complicated by varying degrees of salpingitis, will, with every movement to be a constant source of distress. Unless the treatment inaugurated makes comparative comfort take the place of ever-present varying degrees of discomfort, it will be difficult to persuade the patient to submit to it long enough to prove its value. The first consideration is, to restore the pelvic organs to a better position and to remove the strain upon adhesions if they are present. In short, the condition calling for intrauterine irrigation in non-operative gynecology is always a complicated one, and its various divisions must receive appropriate attention. Some patients who should not be irrigated at the physician's office, may be so treated at home or in the hospital, where they are kept in bed. Such are acute inflammatory conditions, either septic or gonorrheal. Moreover, chronic cases, where the patient is very nervous, or the appendages are involved to any great degree, should not be irrigated until general and local irritability is diminished by general régime, douches, and tampons. A sedative tablet of valerian, assafetida, and sambul, two to six times a day, will often be a valuable help to control fretted nerves.

The intrauterine irrigation for postpartum and postoperative use is a procedure of long standing, and from it and its beneficent results has sprung its employment in nonoperative gynecology, originating with operating surgeons. Its rationale is well known as a cleanser and antiseptic (if medicated), as a stimulant to the vasomotor nerves, blood vessels and muscular fibers of the uterus.

The time-honored medicated cotton-wrapped probe has very little effect upon the uterine mucosa, a fact easily proven if such a probe, wet with iodine, be passed to the fundus of the uterus before a hysterectomy. When the organ is laid open after removal, the staining will be found to be confined to the cervical canal in proportion to its patulousness, and a small stain will be seen at the fundus where the probe point touched. On account of the pear-shaped character of the cavity, the rest of the wall will have escaped the staining. To treat thus a chronic corporeal endometritis or metritis, one may expect to go on indefinitely with the work, should the patient permit the treatment to continue. Intrauterine treatment by the intrauterine syringe is scarcely more effective, while not without danger. Intrauterine applications of electricity in the hands of a specialist do not enter into the scope of this paper. One with hospital experience realizes how readily all parts of the uterine cavity can be reached by an intrauterine irrigation through a double current catheter. The cervical canal must be sufficiently patulous to allow the return flow should the eye of the irrigator become clogged with thick mucus or other obstruction. It is a perfectly safe procedure to practise in one's office work, provided intelligent care is taken in selecting cases, and the same aseptic precautions are observed that are considered necessary in hospital work, fresh gowns, sterilized instruments, solutions, and accessories, but, above all, care in selecting cases. Of course, no physician who was attending a septic case would practise intrauterine irrigation any more than he would use the scalpel under such circumstances.

The technic of intrauterine irrigation is comparatively simple. The patient lies upon the table with a Kelly pad under her and the knees well drawn up. A cleansing vaginal douche is first given of sterilized water at a temperature of 105° to 115° F., and, if indicated, one and one-half per cent. of lysol or two per cent. creoline is added.

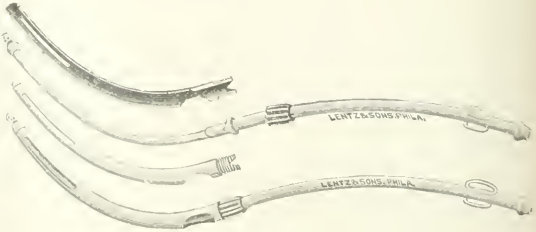

Fig. 2. The Fritsch-Bozeman Irrigator as Modified by Kelly.

The intrauterine irrigation which I prefer, is the Kelly modification of the Fritsch-Bozeman.

In most cases the medium size can be used, but

one can be had which is no larger than the tip of a Simpson's sound, still large enough to permit a small, steady stream to pass. With so small an instrument few cervices need dilating. Should, however, the internal os be so firm as not to readily admit this little instrument, I do not try to push it through, but see if a few moments' use of the negative galvanic current will not make it glide in. When giving intrauterine treatment, it is my custom to place over the hypogastrium a flat electrode connected with the positive pole of a galvanic battery. Another, with a handle attached eight to twelve inches long, is connected with the negative pole and placed under the sacrolumbar region. When desiring to dilate the cervix the stylette of the negative cord is removed from the handle and dropped into the little ring on the outer end of the irrigator. The instrument resting in the cervical canal with the tip firm against the internal os, will as a rule gradually dilate the os, and soon be felt to "slip by." If still held for a few moments longer, one can recognize that the tissues have sufficiently relaxed so that the catheter is freely movable and will permit an outflow of fluid if required. One must always be sure of a possibility for the exit of fluid, should the catheter be clogged. No risk can be run of distending the uterus by retention and the escape of fluid through the tube into the peritoneal cavity. Should the relaxation of the internal os not be so readily secured no further effort should be made in the office, certainly not by metal dilators or tents. Such a case should be dilated under ether, either at home or in a hospital. Plain sterilized water I most frequently use. The temperature may be from 100° to 118° F., according to the patient. It should always be as hot as is comfortable. One patient will have discomfort if the temperature is above 100° F., while others who have pain at 105° will be relieved if it is raised to 110°, 115°, or 118°. The temperature may be increased gradually during the douche, and from time to time. The quantity used varies from one pint to one gallon. Where there is much discharge the irrigation is continued until the water runs clear. If pain has been induced and the hot water acts as a sedative, it is allowed to flow into the uterus until the discomfort is relieved. If the continued flow does not relieve pain, the irrigator is removed at once from the uterus, and the fluid is allowed to flow into the vagina until discomfort is controlled. When the discharge has been irritating to the last pint of irrigating water some bland antiseptic remedy is added, or boric acid, ʒi to a pint, can be used. In infected cases, 1 to 10,000, or 1 to 3,000 bichloride of mercury; carbolic acid, one to two per cent.; or ten, twenty to fifty per cent. of an organic salt of silver may be employed. The last I have found specially valuable in gonorrhea. In hemorrhagic conditions such as fungoid endometritis, or after abortion or curettage, I use Churchill's compound tincture of iodine, ʒi to ʒii to Oi of sterilized water. In these hemorrhagic cases, I often supplement irrigation by cramp bark or viburnum compound tablets, two every two to six hours, according to indications. Ergot may be sometimes indicated, but most cases yield without it, and the viburnum has the advantage of causing little or no disturbance of the stomach, which cannot be said of ergot. When the pain of uterine cramp occurs, it may be managed by simple measures. While bichloride of mercury is a most satisfactory remedy where needed, perhaps with this more than any other drug one needs to be prepared for more or less pain. Local means, such as a hot water bag, the hot vaginal douche, with or without the irrigator, the positive galvanic electrode over the fundus, with negative over the sacrolumbar region, may give relief. If not quickly effected, one to three tablets of a compound of acetanilid, caffeine citrate, camphor monobromate, and sodium bicarbonate may be given. Rarely a ¼ gr. tablet of codeine may be needed. In these office cases, seldom, if ever, do I give a hypodermic injection of morphine. Occasionally it may be necessary in acute pelvic cases in hospital or at home. Then I always combine it with atropine sulphate, 1-150 to 1-200 gr., which will, in most instances, prevent its nauseating effects. I consider it a misfortune when a gynecological patient has to have a dose of opium or morphine, except in those acute conditions where it is absolutely impossible to substitute milder remedies. We all know the proneness of these patients to contract a drug habit, and loth should we be to lead one into all the horrors of its possession. A patient after an intrauterine irrigation is not allowed to leave the office with pain, and she is carefully instructed how to meet any return of it, which will be rare if asepsis has been strictly observed. Its return can, as a rule, be traced to some fault in mechanism, not in method, provided intelligent care has been exercised in selecting the case for irrigation in the office. And, moreover, if each time that the patient presents herself for such treatment the gynecologist makes sure that she is at that time in a safe condition for it. In a nervous, apprehensive patient, to prevent shock or relieve it, should it begin to appear, ʒss—ʒi of aromatic spirits of ammonia in water may be given, or whiskey (rarely), before or following the irrigation, as seems indicated. It tides over or relieves the symptoms which are not apt to appear again, when the patient realizes what she is to expect.

In conclusion, it may be said that in safe hands, intrauterine irrigation can be proved to be of great value in selected cases in office work. Old, so-called chronic cases of endometritis and metritis, with or without tubal and ovarian involvement, can be, in most instances, greatly benefited and often practically cured, provided the irrigation be supplemented by other means of treatment that are equally needed. No two patients can be treated just alike. No hard-and-fast rules can be laid down. Only experience and great care in observation can teach why one patient can be safely irrigated in the office and why another that might seem like her in many respects to a careless or indifferent observer, should only be irrigated after divulsion and curettage under ether, and where rest in bed after irrigation can be insisted upon.

In closing these notes upon some of the leading points in non-operative gynecology, it may be emphasized that nowhere does careful discrimination in diagnosis and prognosis have more value than just here. And another of the inferences from experience is that there is a large field for patient office work in this department of practice, and a field that is not over tilled.

---

**A Refinement of Asepsis** is to use at least two scalpels for every operation. The first one is used to incise the skin and is then laid aside, while the dissection is made with a fresh knife. In this way there is less danger of carrying bacteria from the skin into the wound, and the point is not without importance in many operations, such as those on the joints in which the most rigid asepsis is essential. If a tumor of the breast, for instance, is incised for diagnostic purposes and malignancy is suspected, the operation should always be continued with a clean knife.

# NON-GONORRHEAL URETHRITIS.

By HENRY G. SPOONER, M.D.,

NEW YORK.

At the present time the gonococcus occupies such a prominent position in the American medical mind, that other microorganisms have appeared too unimportant to merit consideration. Even the careful bacteriological investigations, made in France and Germany, of the microbes of the normal and pathological urethra have received little recognition in the English language.

The influence of microbes other than the gonococcus upon the genesis of urethritis was not recognized until 1883. Since then simple bacterial urethritis, secondary and mixed infections have been the subject of many controversies. When we speak of non-specific, non-gonorrheal urethritis, we designate an inflammation of the urethra without gonococci. Post-gonorrheal and mixed infections will not be considered in this article, as their study is more appropriate under the head of chronic gonorrhea.

*Historical Introduction.*—For a long time gonorrhea and syphilis were confused until Hernandez[1] in 1812 advanced the view that syphilis and gonorrhea were independent and separate diseases. As this view met with little credence, it remained for Ricord,[2] in 1838, to establish gonorrhea and syphilis definitely as two different diseases. In 1872, Hallier[3] of Vienna recognized in the pus of gonorrhea a large number of cocci, in part free, partly contained in the leucocytes, which they completely destroyed. This description is the faithful representation of our knowledge concerning the topography of the gonococcus in gonorrheal pus. It is then to Hallier that the honor reverts of having been the first to describe exactly the microbe of gonorrhea, seven years before Neisser attracted the attention of scientists to the pathogenic rôle of the micrococcus of gonorrhea (Legrain[4]).

Neisser in his important article of 1879,[5] completed by that of 1882,[6] describes the gonococcus. These microorganisms were refound in twenty-five cases of gonorrhea, in seven cases of purulent ophthalmia of the newborn, in two cases of the same ophthalmia in the adult, and finally, in the urethral discharge of nine women. Neisser also determined the absence of the gonococcus in the pus of buboes, in that of balanoposthitis, in simple conjunctivitis, and in leucorrhea. The constant presence of the gonococcus of Neisser was confirmed in Germany by Bokai[7] and Finkelstein, Haab,[8] and Aufrecht[9], in France by Bouchard[10] and Constantin Paul,[11] in England by Watson-Cheyne.[12] Thus the majority of observers thought that every urethritis was contagious, as the gonococcus was always present.

However, this idea was too exclusive, and inasmuch as the gonococcus was the cause of urethritis, the idea began to dawn that other pathogenic microbes might also inflame the urethra. In 1883 Bockhart[13] and Wolf described pseudogonorrheal urethritis, characterized by the presence of diplococci smaller and sometimes larger than the gonococcus. They described, cultivated, and even inoculated them. A sound soiled by phlegmonous pus was inserted and retained in the urethra, resulting in urethritis, in which chain streptococci were found to the exclusion of the gonococcus. Then Aubert[14] of Lyons in 1884 published cases of bacterial urethritis. He thought he was justified in concluding that urethral discharges were due to other microorganisms than the gonococcus. Also De Amicis[15] and Icard (1884) reported similar observations. The latter author in June, 1884, described a case of urethritis contracted from a woman with a retrouterine phlegmon, before the Medical Society of Lyons. In 1886 Bockhart[16] again reported cases of bacterial urethritis to which he gave the name of pseudoblenorrhagia. Castex[17] (1887) speaks of a case of urethritis without gonococci, due to yellow staphylococci, in a virgin subject, aged 16 years. This urethritis was caused by catheterism and healed spontaneously in three days.

Legrain (1888) found the micrococcus ochroleucus in the pus of urethritis during typhoid fever. In another case he found the micrococcus pyogenes aureus in a rheumatic patient addicted to masturbation. He has also reported a case, in which the pus enclosed the micrococcus cereus albus of Passet. This urethritis had been contracted by coitus with a woman who had a retrouterine phlegmon. In 1889 Legrain[19] inoculated a catheter with a culture of micrococcus pyogenes aureus and introduced it into the fossa navicularis several times, but no inflammation resulted. At the end of a week the same procedures were repeated, resulting in a scant seropurulent discharge which lasted four days. Also in 1890 Legrain[20] reports the case of a man, 22 years old, rheumatic, feeble, and anemic, addicted to onanism, who contracted urethritis, the pus of which contained no intracellular bacteria, but cultures of micrococcus pyogenes aureus were obtained. In 1891, Legrain[21] and Legay reported the case of M. W. in whose discharge they found spherical staphylococci, and on culture were found the yellow micrococcus of the urethra and the bacilli of Zopfii. Audry[22] related cases of bacterial urethritis in women. Bouchard[23] and Bazy[24] have observed urethritis as the result of masturbation. Moscato[25] mentions the case of a man who contracted urethritis during malarial fever. Finally in 1893, Janet, in his article upon the receptivity of the urethra, attached the importance to these cases of non-gonorrheal urethritis that they deserved.

Even as bronchopneumonia can be caused by streptococci or different bacilli, even as tuberculosis can be produced by bacilli of tuberculosis and by the different bacilli of pseudotuberculosis, and inasmuch as impetigo can be caused by various microorganisms, as shown by Dubreuilh,[26] so can urethritis be caused by pathogenic microbes other than the gonococcus, as the investigations of the above-mentioned authors have proved.

Gradually pathologists began to appreciate that the mucous membrane of the urethra was susceptible to inflammation under the influence of all the bacteria capable of causing an inflammation in other organs.

*Etiology and Classification.*—The classification of the various forms of urethritis is difficult, as there is little conformity of opinion among the authors, regarding their cause. Legrain divides them into venereal and non-venereal forms. Audry classes them into chemical, diathetic, traumatic, and venereal urethritis. Minguet divides them into traumatic, diathethic, and medicamental, from the etiological viewpoint.

The passage of a sound, of a calculus, or any other foreign body, by the production of lacerations, diminishes the resistance of the mucous membrane of the normal urethra, permitting of the rapid growth and extension of pathogenic bacteria.

Bockhart (1883) produced urethritis by the passage of a sound smeared with phlegmonous pus, in which streptococci of phlegmon and erysipelas were found to the exclusion of the gonococcus, as did Legrain (1888), with a second culture of micrococcus pyogenes aureus, resulting in urethritis that

lasted four days, but in this case a second attempt was necessary, owing to attenuation of the microorganisms by cultivation. Also with the microbes of yellow and white staphylococci present in the urethra, it is possible to produce urethritis by the passage of an aseptic sound.

Under the influence of rheumatism and gout, urethritis is easily contracted, as owing to the irritating action of crystals of uric acid or toxins in the urine the yellow staphylococci, normally present in the urethra, assume great virulence and the passage of salts irritating to the urethra diminishes its resistance in the same way as the passage of small concretions, but only in lesser degree.

In typhoid fever and tuberculosis, toxic substances in the urine or general circulation of the blood, may be productive of ulcerations in the urethra, predisposing it to germ invasion.

Barbellion[27] groups these cases into primary saprophytic, mixed, secondary, or postgonorrheal. Others recognize microbic and amicrobic urethritis. Eraud,[28] in a paper read at a meeting of the French Urological Association, divided them into primary and secondary and each of these divisions into septic and aseptic. This classification has the advantage of not anticipating from the pathological point of view.

As the causes that contribute to the production of urethritis are so numerous as to be beyond our comprehension, we prefer a classification based upon the clinical conditions in which cases of non-gonorrheal urethritis have been observed and would suggest the following classification:

1. *Urethritis caused by external irritation:* Coitus, catheterism, ungratified erections (?), masturbation(?), medicated injections.

2. *Urethritis caused by internal irritation, mechanical, chemical, and toxic, of constitutional origin:* Food, drinks, drugs, gout (?), rheumatism (?), arthritic diathesis (?), diabetes (?), herpes, mumps (?), syphilis (?), tuberculosis, typhoid fever (?).

*Urethritis Caused by Coitus.*—Coitus is certainly the most frequent and potent cause of urethritis, as is generally admitted. The irritation and congestion produced by this act render the most favorable conditions for germ invasion. With a healthy woman the chances of infection are very small, but are increased at the moment of the menstrual flow, as the microbes, owing to a more favorable soil, can then acquire a greater virulence, by reason of modifications occasioned in the female genital tract.

When the woman is infected by the ordinary microbes of suppuration, resulting in vaginitis or metritis, coitus, unharmful for a healthy urethra, will become particularly dangerous for the receptive urethra. Traumatisms and abrasions, caused by coitus, result in a reaction on the part of the urethra, congestion, desquamation, edema of the mucous membrane, and infection.

Cases of non-gonorrheal urethritis caused by coitus have been reported by Bockhart,[29] who reported 15 cases observed in four years. Icard observed a case contracted by coitus with a woman with a retrouterine phlegmon, in 1884. Rauzier[30] reported two cases, both medical students who had had no previous venereal infection. One case began on day of coitus, the other the day after the act, and healed spontaneously in fourteen and fifteen days respectively. Legrain[31] reported another case contracted with a woman with a retrouterine phlegmon, in the discharge of which the micrococcus aureus albus was obtained by culture.

*Urethritis Caused by Catheterism.*—The urethra is normally very resistant to germ invasion, as the microbes that normally dwell within it exert no particular action upon its epithelium, until the vitality of the cells has been lowered by irritation such as the passage of a sound. The presence of even pyogenic bacteria is not sufficient to cause inflammation, until they acquire a particular virulence, or until the vitality of the epithelium is lowered. The passage of a sound causes lacerations and circulatory disturbances that render the urethra susceptible to inflammation as the following cases will show.

Bockhart (1883) produced urethritis by the passage of a sound smeared with phlegmonous pus, in the secretion of which streptococci were found. Legrain[31] failed to cause urethritis by a first passage of a sound inoculated with a second culture of micrococcus pyogenes aureus, but succeeded in doing so a week later by repeating the same procedure. Castex caused a urethritis by catheterism in a virgin subject, aged 16 years, due to yellow staphylococci, that healed spontaneously in three days. Detan[32] (1890) related the case of a man eighty-six years old, who used a sound several times a day, resulting in urethritis, whose complications caused his death.

*Urethritis caused by ungratified erections.*—Ricord and Rodet mention cases of urethritis caused by ungratified erections. Ricord's case[2] is interesting. A physician thirty years of age, who had not had intercourse for six weeks spent the day with the girl he loved. From 10 o'clock in the morning until 7 in the evening he made vain efforts to vanquish the resistance of this lady, whose virtue would not succumb. A state of erection persisted all this time. Three days later a painful urethritis began. These cases are most doubtful, as no microscopical examinations could be made, as the gonococcus had not been discovered.

*Urethritis Caused by Masturbation.*—Bouchard and Bazy have observed cases of urethritis as the result of masturbation. During masturbation the glans penis and meatus are irritated, and may be wounded. The presence of the large number of foreign bodies found in the bladder attest to the frequency of masturbation, yet few cases of urethritis have been reported as due to this origin. Legrain[20] mentions the case quoted above, of a man, twenty-two years old, who contracted urethritis after masturbation. No gonococci were present.

*Urethritis Caused by Injections.*—When strong injections are given of corrosive sublimate, sulphate of zinc, permanganate of potash, silver nitrate, sulphate of copper, phenomena are observed, similar to those after the passage of a sound, namely simple desquamation, which is the cause of the urethritis.

*Urethritis Ab Ingestis.*—In June, 1899, a young Harvard student who had never had a venereal infection consulted me on account of a mucous discharge from the urethra. Bacteriological examination revealed the presence of numerous leucocytes, but no bacteria could be found. As the patient had been eating large quantities of asparagus, I was compelled to regard the case as due to the irritating properties of the urine caused in this way. Strong alcoholic beverages will sometimes be productive of the same affection, as evidenced by the case of a medical student, who after an evening with Bacchus, noticed a mucous secretion in the morning in which we could find only a few cocci. Legrain relates a similar case, that of a medical student who quenched his thirst with copious draughts of beer. Urethritis may also be caused by the internal administration of balsams, alcoholic tinctures, cantharides (Boutin), nitrate of potassium (Robert), iodide of potassium (Mercié), and arsenical preparations (Delacour).

*Urethritis Due to Gout, Rheumatism, or the Arthritic Diathesis.*—No incontestible case of urethritis

caused by gout, rheumatism, or the arthritic diathesis can be found in the literature.

*Urethritis of Diabetic Origin.*—No incontestible case of urethritis caused by diabetes exists, as far as the literature is known to me.

*Herpetic Urethritis.*—Urethritis may be caused by herpes. Janet reported two cases before the Congress of Urology of 1897. Fournier and Diday also describe this variety, but the case reported by Le Fur seems the only probable one.

*Urethritis Caused by Mumps.*—The authors who have reported cases of urethritis caused by mumps failed to make bacteriological examinations.

*Syphilitic Urethritis.*—Syphilitic urethritis is very rare and not acknowledged by most authors. In this connection it must not be forgoten that a urethritis may be caused by iodide of potassium.

*Tuberculous Urethritis.*—The bacillus of Koch is very rarely encountered in the urethral tract. Tuffier and Girode have found it once out of forty-one cases. Eraud in twelve suspected cases did not find it, and Guyon has shown that tuberculosis of the urethra is always secondary. Hallé never found it in the urethral secretion.

Legrain reports the case of a soldier with typhoid fever who contracted urethritis, however, micrococcus olochreucus and miscrococcus pyogenes aureus were found. No gonococci or bacilli were present.

*Pathology.*—The pathology of non-gonorrheal urethritis belongs to the study of urethral pyogenesis. The microbes that normally dwell in the urethra exert no particular action upon its epithelium, until the vitality of the cells has been lowered by irritation, such as the passage of sounds, coitus, by chemic or toxic contents of the blood and urine. The presence of even pyogenic bacteria is not sufficient to cause suppuration, until they acquire a particular virulence or until the vitality of the epithelium is lessened; as proved by the experiments of Voillemier, Legrain, and Velander, in which pus from a warm abscess, cultures of staphylococcus pyogenes aureus, and pus from fetid balanitis, were kept in contact with the normal urethra for periods of some hours without causing urethritis.

After the urethra has been chronically inflamed by a previous gonorrhea or by any other cause, indulgence in coitus renders the urethra more susceptible to germ invasion. According to Guiard toxins aspirated into the urethra during coitus with women who have gonococci can irritate the mucous membrane so as to cause a microbic suppuration. Experimentation has proved this statement to be correct. De Christmas succeeded in producing urethritis in a man who had not had gonorrhea, by injecting gonotoxin. This suggests that other toxic leucomains, when aspirated, may also produce urethritis similar to that of direct microbic origin. To explain the causes of amicrobic urethritis it is necessary to assume either that our stains do not permit us to recognize certain forms of cryptogams or to acknowledge the presence of a toxalbumin capable of producing aseptic suppuration.

The mouth is far more rich in bacteria than the urethra, yet stomatitis, tonsillitis, or pharyngitis does not develop until certain conditions modify the soil upon which the microbes live. The larynx and bronchi contain the Klebs-Loeffler bacillus, the pneumococcus, the bacillus of Koch, and other pathogenic microbes at times, yet without causing any inflammatory reaction. It is only rational to consider that the urethra should also be under the control of these general laws.

The fossa navicularis lined with stratified pavement epithelium renders a favorable soil for microbic life. The cavernous urethra lined with cylindrical epithelium renders a more unfavorable soil for the growth of microorganisms other than gonococci. The female urethra possesses similar epithelium, so that it is equally resistant to infection and it has nothing analogous to the fossa navicularis, but microorganisms are very numerous in the folds of mucous membrane at the meatus, which are bathed by vaginal and uterine secretions.

*Diagnosis and Differential Diagnosis.*—The statements made by the patients should be very cautiously accepted.

Differential diagnosis is difficult because certain claps are accompanied by even such slight discharges as are cases of non-gonorrheal urethritis. Certain patients, especially women, experience as little pain during gonorrhea, as ordinarily in non-gonorrheal urethritis, yet cases of the latter are on record in which the pain was great as in ordinary clap.

So far as duration is concerned, some cases of non-gonorrheal urethritis fail to remit to treatment and weary the physician and patient just as much as does a stubborn clap. Urethritis caused by streptococci or staphylococci can occasion complications analogous to those of gonorrhea.

From the clinical point of view differential diagnosis is therefore impossible. All that can be said is that as a rule in cases of non-gonorrheal urethritis, the incubation period and the course are shorter and less painful than in gonorrheal urethritis.

Treatment.—Cases of non-gonorrheal urethritis of constitutional origin must be treated so as to remove the exciting cause. When due to pyogenic bacteria the treatment is the same as in gonorrheal urethritis. Some cases of aseptic urethritis of unknown origin are not influenced by any form of treatment.

In conclusion it may be said: (1) The presence of pyogenic bacteria is not sufficient to cause urethritis until the vitality of the epithelium is lowered. (2) There are two varieties of non-gonorrheal urethritis of primary origin, those caused by external irritation, those due to internal irritation, chemic or toxic. (3) No incontestible cases of urethritis caused by gout, rheumatism, the arthritic diathesis, diabetes, or mumps are contained in the literature.

## THE STOMACH IN PULMONARY TUBERCULOSIS, AND THE EFFECT OF GASTRIC JUICE ON THE BACILLUS TUBERCULOSIS.

By E. PALIER, M.D.,
NEW YORK.

Recently the writer of this has come across numerous cases of pulmonary tuberculosis, and has availed himself of the opportunity to study the exact condition of the gastrointestinal canal in this disease. Every textbook and monograph on the subject devotes some space to diet in this affection, and also to the disturbances of the alimentary canal in connection with it, but to the best of the author's knowledge the subject has been treated in rather an empirical manner, without any scientific basis. If similar work has been done in this line, this work will be an addition; otherwise it will be the first.

*A priori* the writer of this surmised that hypochlorhydria or subacidity of the stomach was the prevalent condition in pulmonary tuberculosis; the more so that on being interrogated some patients affected with this disease stated that they had an aversion for meat, or at least were not fond of it. But *a priori* suppositions frequently prove to be devoid of foundation in the presence of facts, and it is then necessary to find a theory to explain the facts instead of fitting the latter into the former.

Most of the cases examined were those of men between the ages of 22 and 45, because most of the cases of pulmonary tuberculosis seen by me were in men, in the proportion of five men to one woman. The patients examined were all poor people, who applied to a certain charity organization for relief. As women apply there as much as men do, if not more, and they apply in very great numbers, it would seem that this disease is more prevalent among men than among women. But as the object of this article is not the discussion of the relative frequency of tuberculosis in the two sexes, in fact not even the disease itself, but merely the condition of the stomach in it, we shall not dwell on this point. It was mentioned solely to explain why most of the patients whose stomachs were examined were men.

Before proceeding further, it would be best to describe briefly a few cases, which will illustrate the subject better than anything else.

Case I.—A man, aged twenty-five years, born in Germany, had been in this country about a year. He had done some farming at home, and also served in the army. He was above middle size and of a very fine physique, and muscularly well developed. He had been sick with his lung trouble for about five months. A week or so previous to the examination he had a profuse hemorrhage, which afterwards continued in milder form for a few days. The patient had lost considerable flesh, was pale, weak, and had a very anxious countenance. Physical examination showed the apex of the right lung anteriorly and posteriorly affected. An examination of the sputum showed it to be literally loaded with tubercle bacilli. An examination of the stomach after an Ewald-Boas test meal, showed clapotage down to the umbilicus, and some tenderness on pressure in the epigastrium. Patient said that he had suffered even previous to the illness in question with what is usually called dyspepsia in a mild form, and he had to abstain from some articles of food, like coarse vegetables, starchy food, etc. His bowels were rather costive, otherwise there was nothing abnormal. The stomach contents, withdrawn an hour after the test meal, amounted to about 150 c.c. of well-digested food. The congo reaction was very positive, and on titration there was a total acidity of 80 and a hydrochloric acid acidity of 50.* This was evidently a case of slightly hyperchlorhydria with hypersecretion. Whether there was some pyloric stenosis in addition, or simple atony of the stomach, is of course, not easy to determine, unless the patient was kept under observation much longer.

Case II.—This was a man of thirty, born in Russia, in physique resembling the man described above. He had been well till about six months previously, when he began to feel weak and unable to continue his work as a presser in a sweat-shop. About three months later he began to expectorate, his sputum being frequently mixed with blood. When he was examined for his gastrointestinal condition, he was in the same state of depression as was the patient mentioned before. The physical signs of the lungs in this patient were quite insignificant, but his sputum was loaded with tubercle bacilli. Patient said he had never had any gastrointestinal trouble, and his bowels were regular. Several examinations of his abdomen showed no points of tenderness, and no clapotage in the stomach. An examination of the patient's gastric contents was made an hour after the ordinary test meal. The quantity that could be withdrawn amounted to about 60 c.c. It was dark, of the so-called coffee-ground color, and contained some shreds of undigested dark blood. The dark color was due to digested blood, which the patient evidently had swallowed, as he had had some hemorrhage the previous day, and his sputum was constantly mixed with blood. A chemical examination of the gastric juice showed it to be quite normal in quality, except, of course, the admixture of blood. This patient's gastrointestinal canal was then about normal so far. The quantity of 60 c.c. after a test meal might be considered a little too much, but it was not excessive, especially if we consider the patient's condition.

In this connection it may be profitable to say that the passing of black blood by the mouth or rectum does not mean that it originates in the gastrointestinal canal. Occasionally in incipient pulmonary tuberculosis the patients swallow the blood, and then they vomit it out. Sometimes one is at a loss to know whether it originates in the stomach or in the lungs, especially when one must rely on the patient for the history, and in incipient cases of consumption, where the physical signs are not marked, and when there is some tenderness in the epigastrium. But a careful study of the history, and a careful examination of the patient, should enable one to reach a diagnosis. A diagnosis should be made in such a condition as soon as possible, in order to know on what diet to put such a patient, whether the restricted diet of ulcer of the stomach, or the generous one of consumption. Of course, ulcer of the stomach may be, and is frequently found, in con-

*This is after the German method of calculating the acidity. According to the French and English method, the total acidity would be per thousand 2,920, and the HCl acidity 1.825.

nection with pulmonary tuberculosis. To this point, we shall revert.

Case III.—Man, aged 32, tailor by occupation. In physique he resembled the two men above mentioned, but was muscularly less developed. Patient had been ill with his lung trouble for about a year. He had had no hemorrhage, and though pale, yet not anxious and depressed, but felt tolerably well. He was for a few months at a sanatorium in the country. His lungs were but slightly affected at the apex, but tubercle bacilli were present in the sputum. The tuberculous process in this patient was evidently a slow one. He claimed that his gastrointestinal canal was rather good, experiencing only occasionally some disturbances. An examination of the abdomen showed clapotage in the stomach down to the umbilicus, several hours after an ordinary meal, as well as an hour after a test meal. The stomach contents an hour after a test meal exceeded 100 c.c., and reacted very slightly to congo paper. On titration the total acidity was 30, and the hydrochloric acidity 12. This was evidently a case of hypochlorhydria with atony of the stomach.

Here, then, are three tuberculous patients of nearly similar build, and yet with entirely different conditions of the stomach. We shall briefly mention two more cases, in order to present the various types of gastric trouble in consumption.

Case IV.—A man of forty, butcher, had been sick for two years, the bases of both lungs being affected. Patient was pale and weak, and complained of lack of appetite and gastric disturbances. An examination of the abdomen showed no clapotage. The stomach contents after a test meal amounted to a few cubic centimeters of poorly digested food, not reacting at all to congo. Patient could not take a full test meal owing to lack of appetite. This was a case of total absence of free HCl.

Case V.—Woman, aged 36 years. She had been sick for 18 months, both lungs being posteriorly affected. She was of small size and very weak. She said that she had frequent cramps in the stomach, and lately had been vomiting. Constipation alternated with diarrhea. An examination of the abdomen showed tenderness in the epigastrium, and a splashing sound reaching below the umbilicus. I regret to say that the patient at the last moment was overcome with nervousness and refused to take the stomach tube, and owing to her weak condition no effort was made to pass it; but from the condition of the case it seems to be one of dilatation of the stomach with pyloric stenosis, though, of course, the gastric contents would have to be studied before making the diagnosis certain.

Many other cases were examined, but the above five cases will show that one cannot tell the exact condition of the stomach in consumption before it has been thoroughly studied. It would seem that in about 60 per cent. of incipient consumption there is hyperchlorhydria, in 20 per cent. the stomach is about normal, and in about 20 per cent. there is hypochlorhydria. But these figures, of course, cannot be used for guessing as to which of the three categories a patient belongs without examining his stomach. In order to know the exact condition of a patient's stomach in consumption as well as, in fact, in other affections, it must be thoroughly examined, both physically and chemically. The above will show that the prevailing practice of prescribing a certain diet for tuberculous patients is erroneous. In fact it is altogether wrong to speak in general of diet in tuberculosis, because the diet must vary according to the individual case. The diet in the five cases described above should be entirely different in each case. Case I would be injured by a diet rich in starch and vegetables, especially raw and sour ones, whereas in Cases III and IV, owing to the lack of HCl, a diet very rich in animal food would be contraindicated. In Case II, which was normal, a generous mixed diet could be given, whereas in Case V, the diet should be altogether restricted to fluids until the condition of the patient improved. How, then, can one lay down rules for dieting tuberculous patients, as is usually done by writers on consumption? The value of alcoholic stimulants also depends on the condition of the patient's stomach. They may be good in a normal stomach and in hypochlorhydria, but they are certainly harmful in hyperchlorhydria and in catarrh of the small intestines.

In one of the patients not included in the above list examined by the writer, there was hyperchlorhydria with intestinal catarrh. The patient was treated at some institution, and he was given a mixture containing HCl for his gastric trouble. Of course, such things are excusable when they occur in a dispensary, where it is frequently impossible to make a minute examination, but when the physician desires to treat his patient scientifically, the patient's stomach contents should be examined before prescribing his diet and his medicine. From the above it will be seen that the stomach tube will do no harm in such cases, when it is introduced by experienced hands. On the contrary, in some cases the patients felt greatly relieved after the stomach was emptied. In very advanced cases one must be cautious. In such cases it is useless from a therapeutic standpoint, as the patient is doomed any way.

We shall now consider the effect of the gastric juice on the tubercle bacilli. Cases I and II, it will be remembered, had their sputum loaded with tubercle bacilli, but a careful examination of the gastric juice failed to show in it any tubercle bacilli. This was also the case in other patients where the sputum of the previous day or of the day following the gastric examination contained tubercle bacilli. In the gastric contents of Case IV, which, it will be remembered, were scanty and contained no free HCl, a few tubercle bacilli were found. Why were they not found in the gastric juice of the other patients? The gastric contents of Case II, it should not be forgotten, were black, due to digested blood. The patient evidently had swallowed his expectoration, which was loaded with tubercle bacilli; yet there were none in the gastric contents. Three reasons may be advanced to explain the above: (1) The number of bacilli swallowed were too small to be detected in the comparatively large quantity of the gastric juice. (2) The gastric juice may interfere with the staining process, and thus make the detection of the microbes in question difficult. (3) The normal gastric juice has a bacteriolytic effect on the tubercle bacilli.

We shall not attempt to discuss the first supposition; but the second and third can be proven or disproven by experiments, concerning which a few words will be said. About 10 c.c. of the gastric juice of Case II was put in a test tube and to it was added about 1 c.c. of the sputum from the same patient, and the whole well shaken up. A smear preparation on a cover glass was made therefrom, and, after fixing and staining it, tubercle bacilli could be seen. The same was tried with other samples of gastric juice and sputa, with the same result. Evidently the gastric juice does not interfere with the usual methods of staining, and when the tubercle bacilli are present in sufficient quantities they can be detected. It might be said, however, here, that the best method of fixing the smear preparation of gastric juice is by flame. Absolute alcohol, and

ether and alcohol leave a film on the preparation, which makes it opaque. The staining is by carbol fuchsin, and the decolorizing is best done by a solution of sulphuric acid, in the proportion of 1:4.

The bacteriolytic properties of the gastric juice can be determined by experiments. I have, in a previous article,* described the microbes which are usually found in the normal gastric juice, and in hyperchlorhydria, as well as in other conditions. As a rule yeast is found in the two conditions, and a small bacillus, which will be described elsewhere in detail. This would show that the normal gastric juice is bacteriolytic to a great many microbes, for in hypochlorhydria microbes are found which are never found, at least in cultures, in normal gastric juice. Whether the gastric juice is bacteriolytic to the bacillus tuberculosis, and if so, to what an extent, will be seen from the following experiments:

About 8 c.c. of natural gastric juice containing about 2 per thousand of HCl was put in a test tube, and to this was added about 1 c.c. of sputum very rich in tubercle bacilli. One must be careful not to add too much sputum, in order not to weaken the gastric juice too much; nor too little, in order to be able easily to detect the microbes in smear preparations. A smear preparation was immediately made of the above mixture, and many tubercle bacilli were detected. There were also present some streptococci and rod-shaped bacilli from the sputum. The above mixture was put away at a temperature of 38° C., and another smear preparation was made at the end of six hours, but the microbes were apparently not diminished in number. In twenty-four hours the streptococci showed diminution in smear preparations, but the tubercle bacilli did not. In forty-eight hours the streptococci had almost entirely disappeared, and there was an apparent diminution of the tubercle bacilli. The ends of some of the latter appeared ragged, as if eaten away, and some individuals were only about a third in length, as compared with the others. No such short rods were noticed at first. At the end of the sixth day not a single tubercle bacillus could be detected by carefully examining many microscopic fields, though they could be easily found at first. The streptococci disappeared much earlier.

These experiments were repeated with several samples of gastric juice and of sputum. It appeared that some tubercle bacilli of some sputum were more resistant than others. The short, thick, rod-shaped tubercle bacilli appeared to be more resistant than the long, slender forms. If, in a day or so, we add a little fresh gastric juice to the mixture of sputum and gastric juice, the bacteriolytic process is hastened. If the gastric juice is imperfectly filtered and contains a number of food particles, and also the bacteria proper to normal or hyperchlorhydria juice, namely, yeast and the bacillus referred to above, the process is much quicker, and sometimes at the end of three days the tubercle bacilli disappear. Of course, the more sputum is added the slower the process.

It must be said that in the sputum the tubercle bacilli can be detected for months. The writer has tuberculous sputa kept in well-stoppered bottles for the last six months, and the tubercle bacilli, instead of disappearing, on the contrary, seem to have increased, and are more easily detected than in fresh sputum.

Of course, animal inoculation could be made; but in the case of tubercle bacilli, this is a very tedious and uncertain process, and after all it might not be conclusive.

It thus seems from the above that the normal gastric juice is certainly bacteriolytic to the tubercle bacilli; but *in vitro* the process is very slow. The question is, how rapid is it *in vivo*? The process of digestion in the test tube is, on the whole, much slower than in the stomach, into which is constantly being poured fresh gastric juice, and in which the food undergoes a churning movement. There is no question that microbes are much more speedily destroyed in the stomach than in the test tube. It is evident from the fact mentioned above that the microbes from the sputum, which are usually found in the stomach in hypochlorhydria, are absent from the stomach in hyperchlorhydria, and also when the gastric juice is normal. But can the tubercle bacilli pass through a normal stomach into the intestines, and, if they can, are they still virulent enough to cause disease? It would seem that ordinarily they cannot, and if they do, they are no longer virulent enough to cause disease, and hence the comparative infrequency of tuberculosis of the alimentary canal. But, in hypochlorhydria, they undoubtedly can. In a normal stomach and in hyperchlorhydria also, by repeated ingestion they may find opportunities to slip through and cause disease. The writer found in the feces of some individuals suffering from hyperchlorhydria microbes which were not found in their stomachs. Evidently these microbes had found an opportunity to slip through the stomach, for it is hard to say how they penetrated otherwise into the intestines.

The frequency of hyperchlorhydria with hypersecretion in pulmonary tuberculosis, will explain the frequency of ulcus ventriculi in this disease, as these conditions of the stomach when long neglected may lead to ulcer. It is not likely that the tubercle bacilli will be able to fasten themselves to the stomach in the presence of free HCl.

By paying early attention to this organ, treating it on a scientific basis, and not at random, many grave complications can be avoided.

## THE TREATMENT OF PERFORATIONS OF THE TYMPANIC MEMBRANE, WITH ESPECIAL REFERENCE TO THE USE OF GUTTA-PERCHA TISSUE.*

By DAVID G. YATES, M.D.,

NEW YORK.

Perforations of the ear drum occur commonly as the result of traumatism, surgical procedures, and collections of serum or pus in the middle ear. Under traumatism we include the thrusting of foreign bodies through the membrane by way of the aural canal, concussion from discharges of artillery, lightning, etc., and fractures of the base of the skull. These causes necessarily determine the shape, size, situation, and to a large extent the prognosis as to healing, of such solutions of continuity. It is the purpose of this paper to indicate the methods of managing these perforations in order to secure prompt healing, with as little disturbance to the function of hearing, as possible.

Ruptures due to concussion, or to basal fractures are usually linear slits of greater or less extent, and as a rule heal promptly if let alone. The treatment is therefore purely expectant, and is directed to preventing infection of the middle ear. Such ruptures are often covered completely by a blood-clot, which acts both as a splint to keep the edges of the rent in apposition, and as a shield against infection. Healing, under these circumstances, takes place in a few

*Thesis presented at ninth annual meeting of the American Laryngological, Rhinological, and Otological Society.

hours or days, with entire restoration of function. Perforations, on the other hand, resulting from accidental puncture by foreign bodies, are slower in closing and more apt to become infected. The rupture is likely to be more extensive and irregular, and the intruding body is prone to carry with it pus producing bacteria into the tympanic cavity. The treatment of this variety of perforation depends upon the size and situation of the lesion, and its condition when it comes under the notice of the surgeon. If small, and particularly if it is situated near the lower margin of the membrane, the rupture may be covered by a small blood-clot which it would be unwise to disturb. When, however, it is large, and there is reason, from the nature of the penetrating body, to fear suppuration, or when suppuration has already begun, it is best to cleanse the parts by syringing, to inflate gently the middle ear through the eustachian catheter; and to pack the canal loosely with sterile or mildly medicated gauze. If, after removing the gauze a few hours later, we find the field clean, and can feel reasonably sure that suppuration will not occur, healing will be hastened, and the deafness and subjective noises greatly relieved, by covering the perforation with a disc or patch of tissue or sized paper, as suggested by Blake. By this means, the edges of the rupture will be kept quiet and in close apposition, and the middle ear sealed against infection from the canal. Cargile membrane (an animal tissue prepared from the peritoneum of the ox) acts very well in these cases, but is not easily handled or kept sterile. A substance which is always procurable, readily sterilized, and which approaches nearly in elasticity and texture to the drum itself, is the ordinary thin gutta-percha tissue, used in surgery for drains, dressing, etc. The patch should be cut large enough to cover the perforation and afford firm attachment to the surrounding healthy membrane. Under this plan of treatment the opening will heal in from two to five days, depending on the degree of laceration and amount of tissue lost, and will heal, moreover, with less cicatricial tissue formation, than if left to close in the ordinary course of nature. This method is only applicable in the absence of suppuration. When this occurs, and cannot be stopped immediately, it is best to treat the case as an ordinary running ear.

Perforations of the drum due to collections of serum or pus within the tympanum (acute catarrhal or acute purulent otitis media) may be divided, for our present purpose, into those of recent and of long standing. The latter may be the result of chronic suppuration, or simply remain unclosed after an acute suppuration has ceased. Ordinarily, perforations from acute otitis close, with the formation of a larger or smaller cicatrix, soon after the ear stops running. In other instances, they are slow in closing, or remain open for an indefinite period. In still other cases, the margins of the perforation adhere to the promontory, shutting off a portion of the tympanic cavity from the outer world. Or the rupture may heal with a thin cicatrix which falls inward and becomes attached to the inner wall of the middle ear.

It is vain, as it would be unwise, to attempt to heal a perforation through which pus is evacuating itself. The indication in many cases is to increase rather than narrow the channel of escape. When, however, in a subsiding acute otitis media, the opening is slow in closing, and on performing the Valsalvian experiment, nothing or only a drop of serum escapes through the perforation, it is best to take measures looking toward the closure of the rupture, since it may admit new infection to the tympanic cavity. The edges may be stimulated to new activity by the instillation of astringent drops into the ear, or by the application, on a cotton-tipped probe, of a solution of nitrate of silver in strength from twenty to sixty grains to the ounce, to the margin of the perforation, every two or three days. Here, again, the rubber discs will be found of service. Their application will promote rapid growth by keeping up a small degree of irritation, by affording quiet to the vibrating edges, and by giving support to the new epithelium. Audition will be instantly improved in many cases, and subjective sounds will disappear or be considerably lessened.

When the perforation has existed for months or years after suppuration has stopped, its edges will be found thickened and to consist largely of fibrous tissue, possessing little vitality or power of growth. To induce a new growth, it is first necessary to remove this fibrous edge, either by paring it off with a thin, sharp knife, or applying a caustic before putting on the rubber patch. The prognosis as to healing in these old cases, depends on their size, and the nutrition and age of the patient. Perforations occupying a portion of one quadrant, *i. e.* less than one-quarter of the total area of the drum, offer a good prognosis in well-nourished persons under middle age. Large, kidney-shaped perforations, occupying the major portion of both lower quadrants, on either side of the manubrium, it is practically impossible to close. No time limit for healing can be set. A perforation may show, under treatment, no tendency to close for weeks or months, and then suddenly heal in a few days.

It is in the last-mentioned class of cases that the rubber tissue has given most satisfaction. Here we have in mind the relief of the existing deafness as well as the closing of the perforation. Loss of hearing power may be due to the opening in the drum, or to the deposit of fibrous tissue about the ossicular chain, or to both. In the first case, the application of a thin, elastic, closely-fitting patch will have the effect of practically making whole the drum, and audition will be doubled or trebled instantly in many instances. Where there is ankylosis of the ossicular chain, immediate improvement will be only moderate, but hearing will increase with regular inflation by the catheter. The excursions of the drum, under inflation, with the patch *in situ* will be more extensive, and the consequent movement of the ossicles will be more effective than without it. It is not unusual to gain an immediate increase in whisper perception from a few inches to several feet. In other cases, the improvement in the affected ear will be slight, and yet the total gain in function quite marked.

In exploratory or other operations upon the middle ear the surgeon is often obliged to make large openings in the drum. In this procedure, unless the initial puncture be made with a bead of chromic acid, there is no loss of tissue, and if the flap is accurately replaced and the operation is done under antiseptic precautions, healing occurs rapidly. The flap may be held accurately in place, and protected from infection by covering it with the disc of rubber as previously indicated. When these operations are undertaken for the division of adhesive bands between the drum and the inner wall of the tympanum, it is of first importance that the inflation be carried on at frequent intervals from the very beginning, without waiting for the opening to heal, in order to prevent reformation of the adhesions. This object can be attained perfectly by the use of the rubber discs.

*Technique.*—In applying a patch to the drum, a piece of rubber is selected which is about twice the size of the hole to be covered. The canal and drum are thoroughly sterilized by syringing and mopping,

and dried. If necessary, the edges of the perforation are pared or touched with nitrate of silver. The disc is carried in to the drum by means of forceps or a cotton-tipped probe through a speculum if small, without it if too large. It is then pushed into position and the edges pressed down firmly all around. No adhesive material is necessary. The rubber is most conveniently sterilized by keeping it in alcohol or other antiseptic for a few moments, while other preparations are being made. Many patients can tell instantly when the disc is accurately in place, by the sudden improvement in audition. Inflation by Valsalva's method, or by the catheter will afford evidence as to whether or not air is passing through the perforation. The application being by these means found satisfactory, the operation is completed by dusting the field lightly with finely powdered boric acid.

To remove the disc, a sharpened probe with its point bent at right angles to the direction of its length is necessary. The point is slipped between the drum and the disc, and the latter loosened and lifted off. This must be done with care to avoid giving the patient pain or damaging the drum. The disc may also be removed by syringing, or by means of peroxide of hydrogen. Marginal perforations are covered by allowing a portion of the patch to bend upon itself and rest upon the contiguous wall of the canal. The rubber, especially if slightly warmed, adapts itself to any irregularities of surface.

After the disc has remained in place for ten days to two weeks, the improvement in hearing, first noted, begins, in some cases, to diminish. This is due to the fact that the disc has become loosened by the casting off of the superficial layer of epithelium under it and the drum is no longer "air tight;" and possibly to the circumstance that the rubber loses its elasticity after a time. At this point it is best to remove the disc, prepare the field as in the beginning, and apply another piece of rubber, when the patient will regain his former improvement. In the presence of only a small degree of stiffness in the ossicular movements, this will improve by restoring the normal vibratory movements of the drum. Regular inflation by the catheter will do much to help things along, and in cases having a considerable degree of ankylosis, this is imperative.

The advantages of using gutta-percha tissue in perforations of the drum may be summed up as follows:

1. It is convenient, easily sterilized and applied.
2. It is flexible, remains in place for a long time, and requires no adhesive material.
3. In large perforations it has the advantage over the various forms of artificial ear drums in not causing pain or irritation or setting up a discharge. It helps to heal at the same time that hearing is being improved. It is, on the other hand, useless where the drum is entirely gone, or where there is much damage to the ossicular chain.
4. Healing is rapid and the formation of scar tissue, which is likely later to give way or become the seat of calcareous deposits, is reduced to a minimum.

**Diachylon as an Abortifacient.**—Geo. J. Stone cites the history of a patient who aborted in February. She denied taking any drug. As she had amenorrhea in March and April, she repeated her doses of diachylon pills. The writer when called to see her, on April 17, found all of the cardinal symptoms of plumbism—including wrist-drop—markedly present. He then discovered the three months' lead administration.—*British Medical Journal.*

## TRANSVERSE INCISION IN ABDOMINAL OPERATIONS.

By A. E. ROCKEY, M.D.,

PORTLAND, OREGON.

Are the usual lines of incision in operation on the lower abdomen based on correct anatomic principles? We think not. Ease of access to that portion of the cavity implicated is, or was, the first thought of the surgeon. Early in the history of abdominal surgery, intrapelvic operations were done through incisions reaching nearly to, and even beyond the umbilicus. Tait was the first to advocate short incisions, and through his teachings and the general improvement in operative skill, the large incision is now reserved chiefly for the delivery of large solid tumors, other operations being done through much shorter incisions than formerly.

The same thing was true in appendicitis. Ghastly gashes were made directly through all tissues, until McBurney developed the intermuscular incision and Robert T. Morris demonstrated that the average operation in subjects not too fat could be done through an inch and a half opening.

Pelvic operations are still done through vertical, and appendectomies through oblique incisions. If ease of healing and strong and minimized cicatrix are to be considered, then these incisions are wrong for the reason that they cross the lines of cleavage in the skin instead of following them. These lines in the skin of the lower abdomen are parallel to the wrinkles, being transverse with a slight downward curve. They represent the line of least tension and greatest elasticity. For that reason, approximation requires fewer and finer sutures. Incisions for pelvic operations and appendectomy along these lines heal more readily, and there is no tendency to subsequent spreading of the scar as is commonly seen after the vertical or oblique incision. In such pelvic operations as salpingectomy, ventral suspension, etc., the short transverse incision has the additional advantage that it may usually be made through the part covered by hair and is consequently invisible except on the closest inspection. The cutaneous incision is made through the fat and to the aponeurosis of the muscles, but not through them in this line, as described by Stimson in the *Annals of Surgery* for August, 1904. When the aponeurosis of the muscles is reached, the superficial tissues are drawn forcibly upward with a curved, solid retractor, the separation being done by the gloved finger, aided if necessary, by a few snips of the scissors. The usual vertical incision through the rectus or in the linea alba is now made. Retractors with a short, slightly curved solid blade should be used. Pronged retractors should be discarded in abdominal work. It is of advantage sometimes to have a second assistant to hold retractors, though for ordinary operation it is not necessary.

A two-inch transverse incision may be stretched by the retractors to cover a two-and-a-half or even a three-inch vertical incision, and this is quite sufficient for ordinary pelvic work. Through this opening it is also quite possible to remove the appendix when desired, as I have frequently done in connection with pelvic operations. The cecum is caught with smooth-bladed sponge-forceps and drawn into the operative field. When it is necessary to have more room, it is easily obtained by extending the transverse superficial incision along the curve to the iliac spines, thus giving room for a vertical incision to or even above the umbilicus. I have done a hysterectomy for fibroids, removing masses as large as two fists, through a three-and-one-half or four-inch transverse incision.

Operations along these lines in pelvic disease have been done before, both in this country and abroad by other surgeons, to whom priority is cheerfully conceded.

I desire first to add my endorsement of the superiority of the method, and second to apply the same principle to operations on the appendix and cecum, to exploratory laparotomy on the right side, and to colostomy and resection of the colon with the anastomosis on the left side.

In operation for appendicitis, the transverse incision has a field of usefulness and points of advantage quite equal to its employment in pelvic operation. The operation for ordinary acute, unruptured appendicitis, or the interval operation is done through a transverse incision, slightly less than one and one-half inches in length, crossing McBurney's point at its center. This incision should lay bare the aponeurosis of the external oblique. Narrow retractors should be used and the incision completed on McBurney's lines. I sometimes do the entire appendix or pelvic operation with scissors, though as a rule, I prefer a small scalpel for the cutaneous incision and then finish the deeper incision of either operation with scissors.

The advantage of this incision is that it falls along structural lines in the skin. The fibers of the aponeurosis of the oblique may be readily separated to twice the length of the external incision, thus giving easy access to the transversalis, which, being the heavier and deeper, is then in line with the external opening, thus giving a maximum exposure with a minimum incision. In this operation, the peritoneum is incised transversely. In fat subjects, a two-inch incision is necessary. When it is desirable to obtain more room, it may be done first by extending all incisions along the lines described. If a very large exposure is necessary, the superficial incision is extended to the median line and the incision in the oblique carried across the rectus. The sheath of the rectus is then incised along the outer side of the muscle, both above and below the transverse incision. This incision will give ample access to the parts in the most complicated cases of appendicitis, and through it resection of the cecum and anastomosis for malignant disease may be done.

In the few cases where abdominal drainage is necessary, it may be effected either at the point where all the incisions cross, or through a small slit in the aponeurosis of the external oblique where the outer end of the cutaneous and deep muscular incisions overlie each other. For this I commonly use a twist of four, eight, or even sixteen strands of number three catgut. In mild degrees of infection, the deep tissues are better able to take care of themselves than the subcutaneous. It is my custom in pus cases of moderate severity, where the peritoneum retains a fair integrity, to clean the cavity carefully and close the peritoneum and muscular layers without drainage. In these cases it is well to introduce a twist of four strands of catgut for superficial drainage. In all clean cases, the wound should be carefully closed and a dressing of gauze sealed in position by a border of adhesive plaster, a device which I call a "box dressing." A heavy fold of sterile gauze about two and one-half inches wide and an inch beyond the ends of the wound is surrounded by a frame of one-inch adhesive strips. This may then be covered by the ordinary laparotomy pad. For suture, I use double naught (oo) black silk with a fine, sharp, half-curved needle in a Truax thumb-and-finger needle-holder, and a make a buttonhole stitch.

I recently demonstrated the amplitude of exposure through this incision on the left side, by resecting seven inches of the descending colon for malignant disease and making an end-to-end anastomosis. The man was large and the abdomen fat. There were two assistants to hold retractors in addition to the regular assistant. The exposure was sufficient and the operation was completed with facility.

Last week, I was able to prove its usefulness in a most complicated case of appendicitis. The woman had been ill two months. Recently an abscess had broken into the vagina and was discharging a most foul-smelling pus. A transverse cutaneous and fascial incision was made along the curve of the wrinkle from just below the anterior superior spine to the median line. The aponeurosis of the oblique was divided on a line crossing this a little outside of the middle and extending across the sheath of the rectus at the lower end, and well into the flank at the outer end. A vertical incision was carried upward along the outer border of the rectus. A vertical opening was made into the peritoneum. The appendix had entirely sloughed off. At the site of its normal attachment to the cecum was a hole an inch in diameter. The appendix was found behind the cecum, its tip resting at the outer side of the kidney. It was removed. The hole in the cecum communicated with a cavity in the pelvis containing milk curds and fecal matter. There was a small opening into the vagina. The vaginal opening in the cul-de-sac was enlarged and a vaginal douche given from above. The hole in the cecum was closed. Drainage was made through the vagina by a large fenestrated rubber tube, the upper end being fastened laterally to the abdominal wall back of the cecum with one catgut stitch. The abdominal incision was closed and the patient put to bed in Fowler's position. I had one assistant, and there was ample room through this incision. At the time of writing the patient is making a good recovery.

We sometimes see patients with a history of right-side abdominal pain of indefinite location. There may have been several attacks, some confining to bed for a few days or a week. One physician has diagnosed the case as appendicitis, another as renal colic, and yet another as gallstones; the patient himself thinks the trouble is all in his stomach, his appearance is that of one suffering from malnutrition; physical examination is practically negative. This is not an overdrawn or rare picture. In a recent case of this kind, the following operation was done: A three-inch transverse incision was made with center one inch above McBurney's point. A four-inch incision was made in the aponeurosis of the oblique crossing the center of the transverse incision. A three-inch vertical incision was made upward along the outer border of the rectus. A vertical incision was made in the peritoneum. The pylorus, duodenum, gall bladder and kidney were easily palpated. The fundus of the gall-bladder was exposed to view, and a portion of the stomach was drawn into the wound for inspection. They were all normal. The appendix was covered completely with old adhesions which bound it in a sharp kink. It contained three concretions. It was removed and the wound was closed.

When in doubt, explore. This transverse incision enables us to do it, and the small scar of a well-healed strong abdominal wall is not a reproach to our conscience or a reminder of uncertainty in diagnosis.

The superiority of the transverse incision in operations on the lower abdomen is becoming more evident to me as my experience increases. I have used it now almost exclusively, for over two years and have done hundreds of operations by this method.

## CONGENITAL CONTRACTIONS AND CLOSURES OF THE DIGESTIVE TRACT.

DURING the last few decades this subject has been accorded increasing attention by surgeons, obstetricians, and pathologists. The isolated cases, which until a comparatively recent date have been accounted rarities, have increased in number from year to year, so that now we are in possession of a considerable amount of statistical information on this subject. This knowledge has not, however, led up to any improvement in the prognosis, and the unfortunate children thus afflicted, who may be perfectly normal in other respects, must sooner or later succumb to their hidden anomalies. The symptomatology has now been developed to such an extent that a diagnosis need no longer wait on the autopsy knife, and the surgeon has been encouraged to resort to even extreme operative measures in the attempt to restore normal conditions. Simultaneously with the development of this practical knowledge, the pathologist has sought to shed light on the pathogenesis of the anomaly, but his want of success is shown by the large number of theories which have been advanced to account for the condition.

It is possible to divide the malformations of the alimentary canal into two classes, in the first of which must be included those met with in the various types of monsters, the organic perversities of which cannot be subjected to any rational form of embryological analysis, and also those abnormalities in the region of the mouth or anus, which are caused by some disturbance in the development of the ectoderm and its derivatives. The second class comprises those atresias and stenoses which occur in the regions of the primitive fore, middle, or hind gut, and are purely entodermal in origin. These are limited to the esophagus, stomach, and small and large intestines. Hitherto it has not been possible to explain the anomalies in the latter class by any constant etiological factor, the abnormality being usually ascribed to a mechanical or an inflammatory process. A much more satisfactory insight is afforded in a theory evolved by E. Kreuter (*Deutsche Zeitschrift für Chirurgie,* Vol. 79, No. 1), which is based on recent advances in the knowledge of the development of the digestive tract in the human fetus. His observations include the careful study of a series of ten early human embryos, and although most of the facts have already been known, their application to the explanation of the phenomenon under discussion may be justly considered original. It is not possible to present here the detailed observations, but the most important point noted is the fact that some time during a period extending from the fifth to the tenth week of fetal life, there is regularly to be found a complete closure of certain portions of the alimentary canal, which persists for a definite length of time and is then followed by the development of the lumen of the tract. In embryology, instances are not uncommon where an organ, which is later on to be provided with a lumen, is "laid down solid," as they say in German. Then again, the latter designation may also be applied to other instances where the cavity of a preformed hollow organ becomes secondarily obliterated by embryonal proliferative processes, and must be restored at a subsequent period. Such a "solid" state of the esophagus has been observed in many other vertebrate embryos and has now also been demonstrated in the human fetus. In other words, an atresia results from an overproduction of the cells lining the primitive digestive tube, but disappears when the gullet increases both in length and width, and its surface is enlarged by the development of the characteristic longitudinal folds. Similar phenomena are found to occur in other portions of the primitive alimentary tract, and Kreuter's theory is that a persistence of the phase of development alluded to will satisfactorily account for the malformations in question. If the embryonal obliteration is complete and remains so while the growth in other parts continues, then an atresia results; if the lumen is partially restored, then a stenosis, the altered entoderm being replaced in the course of time by connective tissue. There are many elements of plausibility in Kreuter's theory, and above all, it does not conflict with either clinical or pathological experience. So far as the prognosis is concerned, this necessarily must remain unchanged, for now that we have been made acquainted with the probable pathogenesis of the condition, the hopelessness of any efforts to relieve obstruction must be even more apparent.

## THE NATURAL DEFENCES OF THE ORGANISM AGAINST INFECTION.

ABOUT twenty years ago, Metchnikoff brought forward his theory of immunity against infection, which was based on the phagocytic action of certain cellular elements of the blood. Although this brilliant discovery was formerly quite generally accepted, there has been a tendency recently to discard it in favor of other conceptions, in which the normal or an acquired bactericidal property of the blood and body fluids is given the credit for resisting the invasion of pathogenic microorganisms. The factors of truth in the phagocyte theory as demonstrated by Metchnikoff and his followers, are too evident to be simply set aside for suppositions which are much less tangible, and show considerable limitation when applied to certain phenomena which characterize the defensive efforts of the body against disease. These limitations to the theories of Nuttall, Buchner, Erlich, and their adherents, need not, however, detract from their work, the results of which have been of great importance in elucidating the problems of immunity in general. Buchner's theory that natural immunity against bacterial infection is due entirely to the

presence of specific bactericidal substances in the blood, finds its strongest contradiction in the fact that in the case of certain animals which are refractory to infection by particular organisms, no such bactericidal power exists in the blood. Thus it has been shown that the great tolerance of the rat to diphtheria toxin and that of the chicken to tetanus toxin, is not due to the presence of an antitoxin in the blood of these animals, but merely to the affinity of certain cells in the body for such toxins, in this way protecting the cells of the central nervous system against the action of these poisons.

The studies of Bail have opened up another phase of the question. Infection experiments with anthrax, cholera, and typhoid fever in animals, prompted this writer to formulate his so-called "agressin" theory, according to which the disease-producing properties of a pathogenic organism are dependent upon the degree to which it has acquired aggressive powers to overcome the natural defences of the body, these being in large part cellular in their nature. This "aggressin" probably manifests some sort of a negative chemotactic action, affecting neither the life nor the activity of the leucocytes, but merely preventing them from exerting their effects. Wright and Douglas have also made investigations which demonstrate that the leucocytes themselves are incapable of taking up the invading bacteria until the action of phagocytosis has been inaugurated by a substance which is normally present in the blood serum, and which has been named by them, "opsonin." The latter exerts a peculiar effect on the bacteria, and, if the serum is heated to 50°-55° C., this property is lost and the leucocytes are apparently powerless to manifest their phagocytic properties. These observations have since then been confirmed by others.

In a recent investigation by D. H. Bergey (*University of Pennsylvania Medical Bulletin*, October, 1905), on the pathogenic properties of *Bacterium pseudodiphthericum* for guinea pigs, it is also shown how the phagocytic cells of the body exert a marked influence in preventing infection. Cultures of a low degree of virulence excite a more characteristic cellular reaction than those of a higher type, for in the latter case the cellular reaction appears to be overpowered in a short time and the animal succumbs to the inoculation. Following the intraperitoneal injection of large quantities of such organisms, there is induced a marked extravasation of leucocytes, principally polynuclear, which proceed to engulf large numbers of bacteria very rapidly. In addition there are also found the large mononuclear cells which are engaged in the act of ingesting the dead polynuclear cells filled with bacteria. These cells were called by Metchnikoff "macrophages," and in a number the bits of protoplasm from the polynuclears could be seen undergoing a process of digestion. If virulent cultures are employed for the injections, a relatively small number of phagocytes appear in the exudate, which is explained as being due to the increased "aggressive" property of the bacteria, and which, as already mentioned, is in the nature of a negative chemotaxis. In addition to this there also appears to be an inhibition of phagocytosis, and it is very probable that the acquirement of virulence by an organism rests upon these two factors. It seems not improbable from these observations that we have been a little too hasty in accepting the serum theories of immunity and defense without restriction, and that in many forms of infection, at least, the most important protective influences are exerted by the cellular elements of the body rather than by the blood and other fluids.

## THE ELECTRIC CONDUCTIVITY OF THE URINE.

The refinements which clinical laboratory methods have attained during recent years have been particularly marked in their application to the diagnosis of diseases of the kidney. In order to determine the indications for certain operations on this organ, it became necessary not only to gauge its functions, but also its functional capacity. In other words if it has been decided to remove one kidney, it is essential to know whether the remaining one will carry on the process of elimination unaided. In one class of methods this end is achieved by attempts to determine the functional activity of a kidney by testing the molecular, that is, the osmotic concentration of the voided urine. This includes cryoscopy and the estimation of the electric conductivity. The other group consists of methods for judging the character of the secreting renal epithelium, by introducing certain drugs into the circulation which act as stains and are known to impart a color to the urine after a certain length of time. The time which elapses before the apearance of the resultant stain and also its intensity afford a means for determining the condition of the kidney.

It has been found, however, that these procedures are by no means absolutely constant in their results, the latter depending on changes in the food, on exercise, etc., and no normal standard has been satisfactorily established with which they may be compared. A method is desirable which shall be sensitive and yet the end to be gained must not be subjected to the possibility of gross errors nor only to be worked out by the aid of extensive mathematical calculations. G. Kolischer and L. E. Schmidt (*Chicago Medical Recorder*, September 15, 1905) have attempted to devise such a method, in which every kidney would be a standard unto itself. They claim that the functional energy of the secreting epithelium may be tested by measuring the reaction that will occur if certain influences are brought to bear on the secreting portions of the renal parenchyma. They found that the electric conductivity would afford the most sensitive test, if a stain were used which would remain inert to the disassociating influences of the electric current. Indigo carmine was found to meet the required indications fully. It was learned that there is no absolute congruence in the electric conductivity of two specimens of urine taken at the same time from either kidney in a normal individual, but the introduction of the stain alluded to was always found to lower the conductivity. In the case of diseased kidneys, the electric conductivity was increased much beyond that observed in normal specimens and correspondingly decreased when even the slightest traces of stain appeared in the urine. This range of values could be quite accurately gauged, and among other things apparently demonstrated was that there may be cases of one-sided nephritis, a point still very much in dispute. The test proposed seems to be a truly functional one

inasmuch as the simple adding of the stain to the voided urine does not give rise to the same differences in the electric conductivity which result when the stain is brought directly into the circulation. There are many possibilities suggested by this investigation, and among others the fact that we may be able, before the administration of a general anesthetic, to tell whether the latter will produce any undesirable reaction on the kidneys. Further confirmatory researches along these lines are very desirable.

---

### Insomnia.

Sleep, as Sawyer truly says, is a function of life, and life is itself dependent upon sleep, in man, in the animals which are a little lower than he is, in some sorts of plants, in everything which lives. The organism which cannot sleep cannot live. With regard to the physiology of sleep, Dr. Waller, referring to the cerebral circulation, says: "Although there is no doubt that in coma—a pathological state similar in some respects to physiological sleep—the cerebral vessels are congested, the observations of Durham on the exposed cerebrum of sleeping dogs, and of Jackson on the retinal vessels of sleeping infants, are to the effect that vessels shrink in sleep, and we may therefore feel reasonably assured that the sleeping brain, in common with other resting organs, receives less blood than in its state of activity. Moreover, Mosso's investigations on exposed human brains affords evidence that the organ becomes more vascular during mental activity." Howell believes that sleep is caused primarily by the diminution of cerebral blood supply which results from the relaxation of tone in the vasomotor center and the consequent fall of the arterial pressure. Fatigue of the vasomotor center is supposed to be induced by the constant instreaming of sensory impulses during the day's activity. These impulses produce reflex pressure effects and keep up a constant excitement of the center. When the center is exhausted the tone of the blood-vessels relaxes, the arterial pressure falls, the brain becomes anemic, and sleep ensues. Hill coincides with these views. Foster aptly points out that sleep concerns the whole body and not the brain alone. The amount of sleep required by a healthy person depends upon age, occupation, idiosyncrasy, and the quality of the sleep. It may be stated in a broad way that for the average adult in good health, from six to seven hours' sleep is sufficient. Persons of weak intellect, the very young, and the old need in increased amount of sleep. Insomnia is a symptom of disorder or disease, and to be successfully overcome, the cause of the condition must be discovered and treated. Sawyer says there is no "rule of thumb" for insomnia, but whatever the cause of sleeplessness, a holiday, with complete change of scene and with distinct change of activities, will often do much to cure. In all cases of insomnia the bedroom should be well ventilated, and of moderate temperature. Light should be carefully excluded, and the apartment should be scantily furnished. The bed should vary according to the habits of the individual and the covering should be light but warm. The bedroom window should be open all night and all the year round, but draughts should be avoided. A little nourishment just before going to bed acts as a soporific with some persons, while sometimes sleep may be induced by the temporary application of cold to the body or head. Out-of-door exercise should be practised by those afflicted with insomnia, but fatigue should be avoided. Sleep, like food and drink, is a primal necessity, and when the appetite for it is lost, the individual should take it as a warning that something is wrong with the machinery of his mind or body, and should forthwith proceed to endeavor to remedy the defect.

---

## News of the Week.

**A Proposed Antivivisection Law in Massachusetts.**—Inspired perhaps by the author of several stories depicting the "brutality" of the vivisectionist, a Massachusetts legislator proposes introducing this winter a bill "to prohibit all experiments under any circumstances and for any purpose whatever, with or without an anesthetic, upon dogs or cats." A petition is now being circulated through the State, and the parties behind the measure hope to present many thousands of signatures in favor of the bill when it comes before the Legislature. We suppose the friends of scientific progress are equally alert to prevent the passage of such a foolish measure.

**How the Pneumococcus May Acquire Virulence.**—In the weekly bulletin of the Health Department of Chicago, Dr. Bielin gives the substance of the report of his investigations in regard to the pneumococcus, as follows: "Rabbits injected intravenously with the sputum of a single healthy person failed to develop pneumonia; injections with the mixed sputa of two or more healthy individuals never failed to produce a typical pneumococcus infection. These results demonstrate, among other things, the wide diffusion of the pneumonia germs; they are present in the secretions of the mouth and throat of the vast majority of healthy individuals, usually lying dormant and inactive. Mixed with the germs of others, they develop the disease. The practical point for prevention is the necessity of avoiding all unnecessary contact with a pneumonia patient, and the further necessity on the part of other members of the family, nurses, and attendants, for sterilizing their throats during the course of the disease."

**The Medicolegal Section of the Fifteenth International Medical Congress.**—The committee in charge of the International Medical Congress, which will be held in Lisbon from April 19 to 20, 1906, requests contribution of papers on the following medicolegal subjects: The signs of virginity and of defloration in medicolegal relations. Hand marks and finger prints; their medicolegal importance. The medicolegal importance of the carunculae myrtiformes. The mechanism of death by hanging. The value of bacteriological examination of vulvovaginal discharges in the determination of venereal contagion. The signs of death by drowning. Ecchymoses in legal medicine. Spontaneous and criminal abortions from a medicolegal point of view. Medicolegal investigation of blood stains. The relations between the seat of cerebral contusions and the point of application of the agent which produced them. Epilepsy in legal medicine. The induction of abortion; when is it permissible? The value of legal medicine in the study of criminal law. The best legislation for the protection of the "medical secret." The effects of the civil and penal law towards the newborn living infant. Distinction between the natural openings in the hymen and tears of this membrane. Criminal vulvar copulation. Organization of medicolegal services. Anyone who may intend to take part in the discussion of any of these topics is requested to communicate with Dr. Ramon Guiteras, Secretary of the American National Committee, 75 West Fifty-fifth street, New York.

**Tuberculosis in the Public Schools.**—The Minnesota State Board of Health has issued a circular to county superintendents of schools forbidding the employment as teacher of any person suffering from tuberculosis and debarring children suffering from that disease from admission to the schools. The order was issued not only to safeguard the public health but also for the benefit of the sufferers themselves, who could not be in a worse place than closely confined to a schoolroom.

**Tuberculosis in Ireland.**—The U. S. Consul in Dublin reports that the deaths from all forms of tuberculosis in Ireland during the quarter ended June 30, 1905, numbered 2,984, a figure which represents an annual rate of 2.72 per 1,000 of the estimated population of the country, and is 15.2 per cent. of the total number of deaths (19,616) registered during the period.

**Medical Reciprocity.**—As was stated in these columns two weeks ago, at a conference held between the Board of Regents of New York and the State Board of Medical Examiners of New Jersey, at Trenton, October 16 it was decided to indorse each other's examined licentiates without further examination, beginning January 1, 1906. The medical license of New Jersey is indorsed, at this time, in lieu of further examination by Maine, Vermont, Delaware, Virginia, South Carolina, Texas, Ohio, Illinois, Michigan, Minnesota, Wisconsin, Kansas, and Colorado. New Jersey will indorse the medical license issued by any State, after examination, whose educational, examining and licensing requirements are substantially equal to, or higher than, those of New Jersey, irrespective or reciprocity, provided the applicant complies with the conditions of indorsement. The Standard of Requirements of New Jersey consists of a high school diploma issued after four years of study, and a medical diploma issued after four courses of lectures of at least seven months each, in four different calendar years, in a medical college of approved standing.

**The Hippocratic Oath for Nurses.**—At the thirtieth annual commencement exercises of the New York City Training School for Nurses held last Saturday at the Nurses' Home on Blackwell's Island, a class of forty-one young women received diplomas. It was the first class that has graduated since the present course of three years was established. After listening to a good deal of excellent advice from clergymen and physicians, the members of the graduating class all took the hippocratic oath to preserve inviolate the secrets of the sick room.

**An Addition to St. Vincent's Hospital.**—A seven-story addition to St Vincent's Hospital, affording accommodation for 100 more patients than the institution has been able to receive, was opened on November 1. Archbishop Farley presided, and speeches were made by Dr. Frederick S. Dennis, John D. Crimmins, and Father O'Flynn, of St. Joseph's Church. About 300 men and women, who have assisted the hospital financially, were present.

**In Honor of the President.**—In a dispatch to *The Tribune* it is said that on the day following the visit of Mr. Roosevelt to New Orleans, to show the faith of the people in the Roosevelt anti-race-suicide doctrine, the city produced the highest birth rate in its history.

**Workings of the New Medical Law in Vermont.**—Seventy-eight physicians in seven of the northern counties of Vermont were recently summoned before the State Board of Medical Examiners in Burlington for examination, having failed to have their diplomas recorded within the time limit fixed by the new State law. All but five of these appeared for examination and several others also appeared who had recorded their diplomas, wishing to take the examination because of the reciprocal relations it would establish with other states. The board will begin immediately to get a list of those physicians in the remaining six counties who have not had their licenses recorded, and an examination will be conducted in Rutland in December for their benefit. Another examination will be held in Burlington in January.

**Changes in the Faculty of the Maine Medical School.**—Drs. Frederick H. Gerrish and Alfred King, both of Portland, who for many years have taught anatomy in the Maine Medical School, have been transferred to the Portland branch of the institution. Dr. Gerrish will be professor of surgery and Dr. King assistant professor of clinical surgery. Their places have been taken by Dr. Walter E. Tobie of Portland, as professor of anatomy, Dr. Hiram L. Horsman of Augusta as instructor and assistant demonstrator in anatomy, and Dr. Wallace W. Dyson of Portland assistant demonstrator of anatomy.

**The Cornerstone of the New Eye and Ear Hospital** was laid on November 2 by Mr. John T. Agnew, brother of the late Dr. C R. Agnew, one of the founders of the institution. The new building has a frontage of 125 feet on Sixty-fourth street between Second and Third Avenues, and will eventually run through to Sixty-third street. It is to be occupied in about a year from this time in place of the present quarters in Park avenue. The hospital is to be nine stories high, with an administration building in Sixty-third street, when completed. At the ceremonies the Rev. Howard Duffield delivered an address, and Dr. Frank Van Fleet spoke for the physicians.

**The Vermont State Medical Society.**—The ninety-second annual meeting of this Society was held at Burlington the second week in October. The following officers were elected: *President*, Dr. M. L. Chandler of Barre; *Vice-President*, Dr. E. S. Albee of Bellows Falls; *Secretary*, Dr. Geo. H Gorham of Bellows Falls; *Treasurer*, Dr. B. H. Stone of Burlington; *Auditor*, Dr. J. H. Blodgett of Saxtons River.

**The Medical Society of Virginia.**—The thirty-sixth annual meeting of this Society was held the last week in October in Norfolk The following officers were elected: *President*, Dr. Lomax Gwathmey, Norfolk; *Vice-Presidents*, Drs. S. T. Kent, Ingram, Greer Baughman, Richmond. T. C. Wuick, Falls Church; *Recording Secretary*, Dr. Landon B. Edwards, Richmond; *Corresponding Secretary*, Dr. John F. Winn, Richmond; *Treasurer*, Dr. R. M. Slaughter, Theological Seminary. The next meeting will be held at Charlotteville in October, 1906.

**The Kentucky State Medical Association.**—At the annual meeting of this Society, held the last week in October in Bowling Green, the following officers were elected: *President*, C. Z. Aud, Cecilia; *Vice-Presidents*, Drs. Murison Dunn, Richmond, M. Coleman, Paducah, J. M. Salmon, Ashland; *Secretary*, Dr. James B. Bullitt, Louisville; *Treasurer*, Dr. W. M. McClure, Lexington; *Orator in Medicine*, Dr. Wm. A. Jenkins, Louisville; *Orator in Surgery*, Dr. W. O. Bullock, Lexington; *Delegate to American Medical Association*, Dr. J. Garland Sherrill, Louisville. The next meeting will be held at Owensboro in October, 1906.

**The Colorado State Medical Society.**—At the annual meeting of this Society held in Colorado

Springs in October, the following officers were elected: *President*, Dr. H. G. Wetherill, Denver; *Vice-Presidents*, Drs. E. T. Boyd, Leadville; Perry Jaffa, Trinidad, and C. A. Ringle, Greely; *Secretary*, Dr. Melville Black, Denver; *Treasurer*, Dr. S. E. Solly, Colorado Springs; *Publishing Committee*, Drs. Edward Jackson, J. M. Blaine, and J. N. Hall, all of Denver; *Delegate to the American Medical Association*, Dr. Hubert Work, Pueblo; *Alternate*, Dr. H. R. Bull, Grand Junction; *Councillors*, Drs. A. S. Boyd, Leadville, and Frank Finney, La Junta. The next meeting will be held in Denver beginning the first Tuesday in October, 1906.

**Dr. Edward Fletcher Brush**, independent candidate for Mayor of Mount Vernon, carried that city in the election on Tuesday of this week by a plurality of 1,000 over the Republican and Democratic candidates. There were about 5,000 votes cast, Dr. Brush receiving 2,500.

**The Beth Israel Hospital** has received an offer of a donation of $5,000 from a friend of the hospital, with the provision that an additional $10,000 be raised in donations and membership dues, through the efforts of the directors and their friends, before December 1, 1905.

**The Jersey City Hospital.**—The cornerstone of Jersey City's new City Hospital, which is being built on the site of the present structure in Baldwin avenue, was laid by Mayor Fagan, on Wednesday afternoon of last week. Dr. F. D. Gray, a member of the Board of Hospital Trustees, made a short address.

**A Tuberculosis Hospital in Richmond Borough.**—The Board of Aldermen approved recently the appropriation by the Board of Estimate of $800,000 for a tuberculosis hospital to be established on Staten Island.

**To Drain the Staten Island Marshes.**—A number of men were put to work the first of the month draining the marshes near South Beach, Staten Island, to prevent the further propagation of mosquitos. For this and similar work on Staten Island an appropriation of $17,000 has been made by the city.

**Obituary Notes.**—Dr. George Benson Dunmire died at Philadelphia on November 2 at the age of sixty-eight years. He enlisted in the 125th Pennsylvania Regiment in 1862 and served as hospital steward with the command during the nine months of its service. Subsequently he received a commission as First Lieutenant in the Forty-sixth Pennsylvania Militia. At the close of the war he took up the study of medicine and was graduated from Jefferson Medical College in the class of 1865. He was for many years treasurer of the Medical Society of the State of Pennsylvania.

Dr. Frank K. Owen of Ypsilanti, Mich., died suddenly on October 14 in St. Mary's Hospital, Detroit. He was born near Knoxville, Tenn., in 1841. At the close of the Civil War he began the study of medicine and was graduated from the Medical Department of the University of Michigan in 1872. He served during the Spanish War as assistant surgeon to the Thirty-first Michigan Volunteers.

Dr. Richard M. Kerley of St. Louis died suddenly on October 29. He was a graduate of the Jefferson Medical College, Philadelphia, in the class of 1869.

Dr. George Johnson of Frederick, Md., died at the home of his son, Dr. William Crawford Johnson, on October 26, at the age of seventy-five years. He was educated at the Frederick Academy and Princeton College, graduating from the latter institution in 1851. He then entered the medical school of the University of Pennsylvania and received his degree in 1854. Returning to Frederick he established himself there in practice and continued actively occupied in his profession until 1891, when he retired, owing to ill health.

Dr. W. H. Walthal, aged seventy years, died at Roanoke, Va., on October 18, after an illness of nearly a year. He was a native of Prince Edward county, but had been living in Roanoke since 1880. He was surgeon in the Stonewall Jackson brigade during the Confederate war and was afterwards transferred to the hospital corps in Richmond.

Dr. Robert H. Harrison, Sr., of Columbus, Tex., died October 20 at the age of seventy-nine years. He was a graduate of the Cincinnati Medical College in 1846 and of the Medical College of Alabama, Mobile, in 1873.

Dr. Alexander Powe Hall of Mobile, Ala., died October 24, at the age of sixty-nine years. He was graduated from the University of Virginia and served during the entire war as a surgeon in the service of the Confederacy. After the fall of Richmond he returned to Mobile, where he resumed his practice.

Dr. Charles E. Dever of Lynn, Mass., died of apoplexy on October 25 at the age of forty-three years. He was a graduate of the University of Maryland School of Medicine in the class of 1891, and had practised in Lynn about ten years.

Dr. Charles G. McKinley died at his home in Kansas City, Mo., on October 24, at the age of eighty-four years. He was a graduate of Starling Medical College, Columbus. He had practised in Ohio twenty-two years and in Olathe, Kan., twenty-five years. He had lived as a retired physician in Kansas City for ten years.

Dr. John Robinson Buist of Nashville, Tenn., died October 24, at the age of nearly seventy-two years. He was born in Charleston, S. C., and was graduated from the New York University Medical School in the class of 1857. He served as surgeon in the Confederate Army in Col. Meaney's First Tennessee Regiment. From 1874 to 1880 he was a member of the Nashville Board of Health, and was one of the pioneers in the cause of improved sanitation in that city. For a while he was Professor of Surgery at Sewanee, and since 1895 he had held the chair of Diseases of the Nervous System and Mental Diseases. He was a member of the Edinburgh Medical Society of the American Medical Association, the Southern Surgical and Gynecological Society, the Medical Society of Tennessee, the Nashville Academy of Medicine, and the Alumni Association of Bellevue Hospital, N. Y. During the later years of his life he was associated in practice with his son, Dr. William E. Buist, who survives him.

Dr. Francena E. Porter died in Lynn, Mass. on October 23. She was born in Lynn, and for some time was employed as a clerk in a drug store, after which she entered the New England Hospital in Boston to study for a nurse. Some time later she entered the Women's Medical School, Philadelphia, and she graduated from that institution with the degree of M.D. After a year's experience gained in the hospital of the Drs. Blackwell in New York city, Dr. Porter went to Kansas and practised her profession in that State for some years. Returning to Massachusetts, she opened an office in Worcester and for a few years was one of the visiting physicians at the Lancaster Industrial School, but eight years ago failing health compelled her retirement from practice, and she moved to Reading Center, where she had since resided.

## THE HARVEY SOCIETY LECTURES.

The third lecture of the series, held under the auspices of the Harvey Society was delivered at the New York Academy of Medicine, by Prof. F. G. Novy of the University of Michigan, on Saturday evening, November 4, 1905. The subject was "Trypanosomes," a field with which Dr. Novy is familiar from his extensive experimental studies in animals. He has also been successful in obtaining pure cultures of this organism by means of a special medium. Before proceeding to the description of the trypanosomes, he outlined briefly the history of our knowledge of the subject.

The discovery of the protozoön of malaria by Laveran furnished an impetus to further researches on the parasitology of the blood, and soon afterwards Evans described a flagellated organism which he found in the blood of certain animals in India affected with a disease known as surra, which disease he attributed to the presence of the parasite. Although nagana or tsetse fly disease was faithfully and accurately described by Livingston in his book of African travels, the etiology of the disease was unknown until Bruce demonstrated that a native fly was the carrier of the infection and that the organism which he found in the blood of the affected horses and cattle was apparently identical with that previously discovered by Evans in India. A third form of epidemic disease was then described as occurring along the African shores of the Mediterranean and attributed to a similar organism. In 1901 the flagellated organism found in these animal epidemics was accidentally discovered in the human species, the patient being an inhabitant of the West Coast of Africa who was believed to be suffering from malaria. The immunity which was claimed for man was thus shown to be erroneous, and in 1903, Bruce and the English Government Commission established definitely the fact that the so-called African sleeping sickness was due to infection by trypanosomes.

Trypanosomiasis has been found to be widely distributed among nearly all the lower animals, although in most instances unattended apparently by any ill effects. Novy even found the organism in many species of our own native birds where it was demonstrated more readily in cultures however than in blood smears. It was found to affect more particularly the younger birds and nestlings.

The main part of the lecture consisted of the display of excellent lantern slides, which the speaker employed as the basis for his remarks. On a map of the world the wide distribution of trypanosomiasis was well shown, the disease being found in most parts of Africa, Asia, South America, and the Pacific Islands. An idea of its ravages may be gained from the statement that over 200,000 persons are believed to have died from its effects in Central Africa alone during the recent epidemic. Prof. Novy's personal observations were conducted mainly on trypanosomiasis in rats. In certain localities these animals were found to be invariably infected with the disease while in others they were completely free from it. He was able to cultivate the organism successfully in a medium composed of agar and blood serum from the animals. The growth and development of the trypanosome were vividly shown in a series of slides. A great and growing interest attaches to this parasitic protozoön, which has assumed such an important rôle as a cause of disease in both man and animals of the tropics. Through the acquirement of tropical possessions, American must necessarily take a more extended interest in this subject, and although we have thus far escaped at home, we cannot tell how soon we may be forced to be on the defensive.

---

# Correspondence.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

LONDON TROPICAL SCHOOL—POST-GRADUATE EDUCATION—PROFESSOR OSLER—SIR THOMAS BROWNE—PROFESSOR CROTHERS ON NORMAN KERR—COLLEGE OF SURGEONS—VON BEHRING'S SENSATION.

London, October 13, 1905.

Wednesday was a red letter day at the London Tropical School, when a distinguished audience of doctors and gentlemen connected with the Colonial government assembled to hear an address by Professor G. H. Nuttall, the Professor of Tropical Medicine and Hygiene in the University of Cambridge. The chair was taken by Sir Alfred Maloney, who suggested that he was perhaps requested to occupy it as a sort of live exhibit in natural history—as one who had served for thirty years in the worst climates of the Empire, and successfully got out of them all. He also testified that he had always found the Colonial office give hearty thanks to suggestions to improve sanitary conditions in the tropical colonies, though sometimes local agents were not active in adopting measures on the spot.

Professor Nuttall, in his address, spoke of the benefits to mankind which resulted from recent discoveries, especially with regard to yellow fever and malaria. Research, he said, was a word heard on all sides, and it was the enemy of authority, that tyrannous spirit which retarded the advance of scientific medicine for centuries. It was experimental medicine which had made the great progress in our knowledge of disease—its causes, prevention, and cure. The majority of important discoveries of all kinds had but slight, direct influence at the beginning; their full significance was hidden for a time. Most of them were made by those engaged in research in the realms of pure science; and pure science was unselfish, not aiming at profit, but it was the forerunner of applied science. To study disease we should do so for the sake of knowledge, in the scientific spirit and though the practical man might not enter into that spirit, he was ready enough to use its discoveries. All are not born with the instincts of research, but it should be the function of educational institutions to detect them where they are present, and lead the men who possess them to do the work for which they are fitted. Too often such men drift into other pursuits from lack of means, for to succeed in research a man needs an assured income. Could it be that those who were anxious to help on human progress could ignore the devotion of those who had laid down their lines in the study of tropical medicine? Medical research needed endowment, and it was grievous that in a country where so much charity abounds, so pitiably little was done for its advancement. To teach science as it should be taught in fully equipped institutions, was more expensive in the case of medicine than in other professions. It did not suffice to build laboratories—they must be provided with funds to help them to become working entities.

The progress of the London School of Tropical Medicine had been an upward struggle from its inception, six years ago. This and the sister institution in Liverpool, were now known throughout the world for the excellent work accomplished by their staffs and students. The London school had a great mission to fulfill, to train men in methods they would have to employ in distant parts, and it was to be hoped that the public would second the noble efforts made to establish a center for the study of those diseases which affected the people of so many parts of this vast empire. The professor concluded by noticing the recent progress in parasitology, and showing that immunity would only be expected through the researches of experimental medicine.

Mr. John Tweedy, President R. C. S., addressed the West London Post-Graduate School on Wednesday. Remarking that medical education was a question always to the fore, he declared that the curriculum was increasing in complexity, but notwithstanding its higher requirements he was sincerely convinced that the system of to-day did not afford the same guarantee of competency as the less exacting curriculum of twenty-five years ago. The proper object of preliminary training was to qualify the student to begin his medical work. Scientific training should be removed from the medical curriculum, and delegated to

scientific institutions, and many subjects now crowded into the qualifying course should be transferred to the post-graduate period. No matter how well a doctor might have been equipped five or six years ago, if he had ceased his connection with his hospital and school and isolated himself, he would find great strides had been made in medicine, knowledge, and technique. Left to his own resources a man was apt to tend towards routine, and then thoroughness, and intellectuality diminished or even disappeared. He congratulated those who had the courage to leave their practices for a time, and take post-graduate courses, in order to acquire fresh knowledge and correct antiquated opinions. It was not the number of cases seen, but the reasoned consideration given to them which constituted intellectual experience, and that was the kind which post-graduate work obtained through the cases brought under the criticism of experts. The teaching of the medical schools dealt with principles. The post-graduate course applied these principles to practice, and this was on the true lines of medical progress.

Prof. Osler yesterday gave an address at Guy's Hospital, to the Students' Physical Society, which dates from 1830, and is in a way the child of an older society in connection with Guy's, dating from 1771. Dr. Osler took for subject Sir Thomas Browne, that 17th century doctor and literary man, whose career has lately been several times before the public. The professor said he had in early life studied the works of the author on whom he was about to speak. Born in October, 1605, Thos. Browne was educated at Winchester and Oxford, but did not seem, in after life, to entertain a high opinion of his alma mater as a school of medicine, for in one of his letters he wrote that he should as soon think of sending a lad to Oxford to learn shoemaking as to study medicine. In 1637 he settled at Norwich as a physician. Although he had previously professed antipathy to the sex, and thought it unfortunate that some less mean method had not been selected for the perpetuation of the species he took unto himself a wife, who proved a fruitful branch, and bore him ten children. He was a staunch Royalist, but did not suffer much inconvenience from the Civil War. He encouraged his children to cultivate self-reliance, and actually sent one boy alone to France at the age of fourteen. Sir Thomas was master of six languages. His first and greatest work, the "Religio Medici," was at first circulated in manuscript among his friends, and five copies now exist. The first edition was issued surreptitiously in 1642, but next year the second edition was published with a statement on the title page that it was a true and faithful version. It was thought by Dr. Johnson that the first issue was published with the author's knowledge, if not his authority.

The lecturer mentioned various editions and exhibited copies of several, relating interesting facts respecting them. He also referred to other works by Sir T. Browne, and presented the society with a complete collection. A number of pictures were thrown on the screen, including portraits and the church of St. Peter Mancroft at Norwich, which he attended for so many years and from which he was buried.

Next Thursday, being the 300th anniversary of the birth of Sir T. Browne, has been selected as the day for unveiling his statue at Norwich, the ceremony being performed by Lord Avebury. On the same day a memorial service will be held in the Church of St. Peter Mancroft, mentioned above. An address is to be given by the Master of Pembroke College—the representative now of Broadgate Hall (Browne's College). The anniversary of his birth is also that of his death, as he died on October 19, 1682, the day on which he completed his 77th year. More editions of his works have lately appeared, and others will follow. We are also certain to be entertained with numerous Browniana and appreciations of an author whose admirers seem continually increasing. The new volume of the "English Men of Letters" Series, is on Sir T. Browne, by Mr. Gosse.

Prof. T. D. Crothers is here, and on Tuesday he delivered the first Norman Kerr lecture before the Society for the Study of Inebriety, which has now a roll of 800 members. Dr. Crothers had a very warm reception, and as an old friend of Dr. Kerr and an ardent worker in the same cause, was able to impart a personal interest to his address. Norman Kerr devoted his life to the promotion of the scientific study of inebriety; he was not the first in the field, for Dr. Rush of Philadelphia took it up in 1809, and others followed. In 1844 the British Lunacy Commissioners spoke of it as a disease, but without attracting special attention to this point. Dr. Turner of New York established an asylum in 1863, the first of the kind, and the first effort to demonstrate that it should be treated as a morbid condition. Much controversy followed. In 1874 Kerr settled in London, took up the subject, and worked at it until his death in 1899. He advocated the establishment of institutions with legal measures for control, and succeeded in establishing the Dalrymple Home, opened in 1884.

In the same year he founded this society and was its president until his death. Its proceedings had influenced public opinion in a great degree. In 1887 he organized the international congress on the subject. Two years later he issued his "Inebriety; Its Pathology and Treatment," which remains a recognized authority. Its particular value the lecturer attributed to its giving a general survey of the whole subject, without exhausting any one phase. Dr. Kerr was a graphic writer, a great organizer, a leader of men, who, if he did not always convince his hearers, invariably secured their respect. In all his writings he urged the scientific study of the alcohol problem in the most practical way along conservative lines. He set men thinking, turned the tide of philanthropic temperance into new and broader channels, gave it new vitality, the result of which was already felt in all the civilized world.

At the quarterly meeting of the council of the Royal College of Surgeons, held yesterday, the best thanks were voted to Lieutenant-Colonel Havelock Charles for the presentation to the college of his collection of skulls and other specimens, representative of many castes and tribes of India, and other parts of Asia. The council pronounced it a most valuable addition to the museum, not only on account of the great number of specimens, but also on account of the authentic particulars attached to them.

We have, of course, had some excitement this week, and much food for conversation on account of von Behring's statement at the Paris congress about a cure for consumption. A small man would not attract international attention, but his previous achievements seem to entitle him to a hearing. Here, at present, so far as one can see, medical men are sceptical, though many profess to be unable to follow his statement, and dismiss the subject with a sigh for past disoppointment. Most of us are satisfied if we can keep an open mind. We agree, too, that the atmosphere of a congress is hardly suitable for so momentous an announcement.

---

SOCIETIES BEGIN WORK—BRUNTON ON PROGRESS OF MEDICINE—CARCINOSARCOMA — ECTOPIC GESTATION — CYSTOSCOPIC APPEARANCES IN RENAL DISEASES—DIVERTICULUM IN A HERNIA CASE—CAISSON DISEASE—SIR T. BROWNE'S TERCENTENARY—DEATH OF COLLIER OF MANCHESTER.

LONDON, October 20, 1905.

WITH the early frosts our societies are getting into working order for the winter session. At the Medical Society of London the new president, Sir Lauder Brunton, having been inducted into the chair, delivered an address, describing advances in medical science that had been made within his own experience, and forecasts of other advances which seem probable. Passing on to more recent discoveries regarding the causation of disease, he instanced that of one protozoon as the germ of malaria, another as that of Texas fever, a third as that of tsetse fly disease, and a fourth as that of sleeping sickness. Then he mentioned as most remarkable the discovery that elephantiasis is due to a disease of a disease germ. The study of such germs may prove one of the most profitable fields of research. Carriers of infection have been made known, and this knowledge is already leading to the limitation, and perhaps the suppression, of several diseases. Some diseases of animals, exceedingly fatal in South Africa, have been shown to be caused by inoculations with protozoa by the bites of ticks, and the destruction of these pests bids fair to lessen the spread of those diseases. The tsetse fly conveys the protozoon from antelopes, in whose blood it seems pretty constantly present without injuring them, but it is very destructive to horses and cattle. When antelopes are destroyed the disease vanishes. In the case of sleeping sickness, which is spreading to so alarming an extent, it is not an animal, but human beings that supply poison to the flies, and what we need is some drug to act on the protozoon, as quinine does in malaria.

One of the chief difficulties in discovering the cause of tsetse disease was the fact that the antelopes were not themselves affected. It is not long since we learned that diphtheria germs may be present in the pharynx and those of typhoid in the urine of a patient who is apparently well, and that Malta fever may be conveyed by the milk of apparently healthy goats. In Australia rabies is not present, and the most stringent quarantine is enforced to protect the huge flocks. But here there are people who object to having their dogs muzzled for the protection of others, just as others refuse to protect their own children from smallpox.

At the Clinical Society, on Friday, Dr. David Newman gave a demonstration of the cystoscopic appearances of the mucous membrane of the trigone and openings of the ureters in certain renal diseases. Among the specimens shown were a recent tuberculous deposit close to the neck of the bladder, encysted stone, papilloma, sarcoma, calculus

impacted in the ureter, another coming through the muscular wall of the bladder and pushing the mucosa before it, so as to simulate a tumor, ascending ureteritis from septic infection, "shoots" escaping from the ureter, showing the escape of blood, stone, and clots. Differences between the two orifices, the mode of escape of the urine, the character of escaping fluid, and deformity of the orifices supply various indications. When one orifice is normal and the other abnormal, the lesion of the kidney will be found on the side of the morbid ureter. After the demonstration Messrs. E. M. Corner and C. W. Rowntree reported a case of operation for a supposed irreducible inguinal hernia in a boy eighteen months old. No sac was found, but a diverticulum of the bladder holding a few drachms of urine was excised. The bladder and inguinal canal were sutured and healed by first intention. Two months later the boy was readmitted for tuberculous peritonitis, laparotomy performed, and much fluid evacuated. The viscera were covered with miliary tubercles, but the boy steadily improved, and is now well, twelve months after the first operation.

Mr. Clutton said he had several times seen the bladder in operating for hernia, but never a case like this, which seemed unique. He had seen tuberculosis of the sac once, and the operation was followed by peritonitis; perhaps the diverticulum was the result of the tuberculous lesion. But on this Mr. Corner said the lump had been present since birth, so that it was not likely to be secondary.

The Obstetrical Society began its session with a paper by Dr. Herbert Spencer on carcinosarcoma uteri, a term applied to cases in which cancer and sarcoma coexist in the same uterus. Cases of malignant growth which are partly cancerous and partly sarcomatous in structure are to be distinguished as sarcoma carcinomatodes. He described a case in which two growths occupying the body of the uterus differed much in appearance. Under the microscope one was a typical glandular carcinoma, the other a small-celled sarcoma. He had met with the coexistence of the two diseases once out of ten cases of sarcoma, and thought careful examination would show the association to be less rare than published records indicated.

Dr. Handley suggested that the coexistence might be due to simultaneous invasion by the two parasites; but he thought it more likely that any lump in the uterine wall might so irritate the endometrium as to cause cancer. It was possible in this case the sarcoma might have originated in a fibromyoma. Dr. Spencer admitted this, and it was possible examination of additional sections might determine the point.

Captain J. C. H. Leicester, I.M.S., reported a case of ectopic gestation in which the sac appeared to have ruptured twice. The second time the abdomen was opened and a distended Fallopian tube and clots were removed. The patient, a Hindostani, made an uninterrupted recovery.

Mr. H. J. Paterson described a case admitted for, as was supposed, ruptured extrauterine gestation with peritonitis. But the woman improved rapidly. Swelling increased slowly and regularly. Six months after the last normal period the abdomen was opened and a fetus of eleven and one-half ounces removed, which died in a few minutes. The placenta was found on the front and upper wall of the sac, the deeper portion being slightly detached. The free hemorrhage was controlled by packing with dry gauze. After an interval this was removed and the sac irrigated with hot water. Many bleeding points were clamped and ligatured. About two pints of clots were taken from the bottom of the sac, but much was left, as it was adherent. The sac was secured to the wound and packed with sterilized gauze. Severe vomiting followed, and on the third evening the patient's condition seemed desperate, but calomel was given and a turpentine enema. Relief followed, and slow recovery, the sinus into the sac persisting above a year.

Mr Doran said packing the sac and ligaturing its vessels were often necessary, but, unfortunately, the ligatures were apt to get infected, especially when the deeper part of the sac was formed by the large intestine.

Dr Galabin said there was a great advantage gained when it was in any way possible to remove the whole placental site, and he related a case in illustration of this.

Dr Amand Routh thought packing was almost always followed by infection of the ligatures and a resulting sinus. Calomel was more likely to allay vomiting than morphine.

Mr. Paterson, in his reply, said the removal of the sac was impossible in his case, on account of the extensive adhesions to the intestines. The ligatures were necessary, as the bleeding vessels were large. He believed the old clot at the bottom of the sac became infected, owing to its proximity to the rectum.

On Wednesday Prof. Thomas Oliver, physician to the Newcastle Infirmary, concluded a course of lectures at the Royal Institution here on maladies caused by the air one breathes in the home, factory, and mine. Caisson disease was his concluding subject. He showed on the screen illustrations of various types of caisson, and stated that during compression the results were not serious. Imperfect ventilation, caused by passing through various strata, such as soft coal, and muscular fatigue were contributory causes of the disease; but the one essential cause was the sudden liberation of the gas in the blood which had previously been in the state of solution. On the appearance of symptoms the treatment was to recompress by putting the patient again into the airlock, and afterwards decompressing very slowly. Of twenty cases admitted into the Newcastle Infirmary only two had had their lives threatened and the others recovered the use of their limbs in a few days.

It is a great thing for a doctor to be remembered for more than two hundred years after his death, even though his literary work is the occasion. Yesterday the statue to Sir Thomas Browne was unveiled at Norwich, the day being the tercentenary of his birth and the 223d anniversary of his death. We claim him as a Londoner by birth, but he lived so long in Norwich, being knighted as her most representative citizen, that it seems appropriate that the long-delayed statue should be placed there. He is the most distinguished of a long line of learned literary physicians, beginning in the sixteenth century, which proves that medical practice is by no means incompatible with the highest culture in literature and arts. The names of Dr. Caius, Sir R. Blackmore, Sir Hans Sloane, Sir W. Petty, Sir Richard Garth, Arbuthnot, Akenside, Smollett will occur. We may continue to our own time, if we include those who somewhat deserted medicine for literature, as Goldsmith, Crabbe, Keats, and Oliver Wendell Holmes. In some respects the autocrat of the breakfast table reminds one of the author of "Religio Medici," though if I cited instances you might think them rather far-fetched.

The ceremony of unveiling the statue was performed by Lord Avebury, whose scientific reputation is appreciated by the profession. He said Sir T. Browne held a unique position, not only in English libraries, but in the literature of the world, and Lowell regarded him as "our most imaginative mind since Shakespeare." The statue, cast in bronze, represents Sir T. Browne sitting in an antique chair, contemplating a piece of ancient pottery, which he holds in his right hand. The figure, of heroic size, stands on a massive granite pedestal. The memorial has been subscribed for by people in all parts of the civilized world.

At the luncheon Lord Avebury, responding to the toast by the High Sheriff of Norfolk, dwelt on the value to the nation, and the world in general, of Browne's works, their profound thought which charmed Johnson, who wrote his life, and Peter, who compared him to Jean Paul Richter among Germans and Montaigne among Frenchmen. The toast to his memory, proposed by Professor Stuart, was drunk in silence. Sir R. Douglas Powell replied in the name of the Royal College of Physicians, and Mr. Edmund Owen in that of the Royal College of Surgeons. In the evening a memorial service was held in St. Peter Mancroft Church.

Joseph Collier, M.B., F.R.C.S., surgeon to the Royal Infirmary, Manchester, and lecturer in the university, died on the 13th inst., aged 50. His early death is a great loss to the school, and is very deeply lamented by his colleagues and pupils. He was for many years surgeon to the Children's Hospital (Pendlebury), and in 1869 came on the surgical staff of the Infirmary. He had served as president of the Pathological Society, and was long a teacher of practical surgery at Owen's College. The vice-chancellor of the university said: "In Mr. Collier they have lost a very brilliant surgeon and inspired teacher, to whose influence many medical men looked back with gratitude, and to many of whom he was one of their most valued friends."

## OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

DECREASE IN CHOLERA—A MIRACLE WORKER—A DESTRUCTIVE TYPHOON—STUDY OF BERIBERI.

MANILA, P. I., Sept. 29, 1905.

THERE has been a most gratifying decrease in the number of cholera cases reported in the city of Manila during the past week. From Saturday, September 23, up until this morning there has not been a single case of cholera reported in the city of Manila. There was, however, a suspected case that occurred to-day; the result of the autopsy, however, has not yet been learned. The total number of cases in the city of Manila to date has been 196, of which 170 died.

The disease is still present in the provinces, and so far the health authorities have not succeeded in stamping it out. About ten days ago there was discovered what, in all

probability, was one fertile cause of the spread of the disease in the provinces. In the little town of Tay Tay, about fifteen miles from Manila, it was reported that a Filipina woman was engaged in performing miracles in the cure of disease. Her fame was spreading rapidly, and people were flocking from all directions to consult her; among others were persons who, in all probability, had cholera; at any rate, it was only a short time until the disease made its appearance in Tay Tay.

The alleged miraculous cures are said to have been performed by the application of water by the means of a leaf which grew in the immediate neighborhood. It was reported that the alleged curative water was obtained from a nearby estero, placed in a tank, and afterwards the woman bathed in it, in order to give it its healing properties. The applicants for relief then had the particular portion of the body which was supposed to be diseased washed in the water, and afterwards this water was drank. Among her patients there were, no doubt, some who had cholera, and it seems quite probable that at times the tank in which the water was stored became infected. For those who were bedridden, or otherwise incapacitated from "consulting" the miracle worker in person, samples of water were bottled and sent to them at their homes. In view of the fact that the water was obtained from an estero (small canal or creek), along the banks of which cases of cholera were occurring, it can be readily seen that it is quite possible that the water may also have become infected in this manner. The assembling of people in large numbers was in itself a distinct menace, and there seems but little doubt that a number of the cases of cholera which occurred in nearby towns were correctly ascribed to having received their infection from Tay Tay.

One feature of the situation which gave particular cause for anxiety was the fact that the town of Tay Tay is situated very close to the watershed of the Manila water supply, and at any moment the same was liable to become infected at a remote place, and become a source of great danger to the city of Manila. The health authorities have, however, taken the matter in hand, and the alleged miracle working has been stopped.

Cases of cholera continue to occur on the watershed, and particularly at San Mateo, which is a small town situated very close to the banks of the Maraquina River, above the intake of the Manila water supply. The river, at that point, is well guarded by the military, and so far there has been no infection, yet the presence of the disease at that place continues to be a serious menace. The total number of cases in the provinces since the beginning of the outbreak is 288, with 234 deaths. Bilibid Prison has continued to remain entirely free from the disease since the sanitary control of the prison was transferred to the Board of Health. So far cholera is still confined to within a radius of forty miles of Manila.

On September 26 Manila was visited by one of the worst typhoons that has occurred in the past twenty-five years. Ten lives were lost in the city of Manila by the falling of electric wires charged with heavy currents. The damage to the city has been estimated at about a million dollars. So far but meager reports have been received from the provinces, but it is feared they have suffered very heavily. Considering the great network of wires in Manila, and the heavy currents which pass through them, and the great number of them that were blown down during the storm, it is remarkable that no more persons were killed.

Dr. Maximilian Herzog, of the Bureau of Government Laboratories, went to Japan several weeks ago, for the purpose of studying beriberi. The necessary material for a scientific study of that disease in Japan is most abundant. It is understood that in one hospital alone several hundred cases of beriberi are being treated at the present time.

Dr. William J. Mallory, formerly resident physician at the Civil Hospital, has been appointed attending physician and surgeon of the Benguet Sanatorium at Baguio, Benguet.

## OUR BERLIN LETTER.

(From Our Special Correspondent.)

BERLIN September 22, 1905.

ALTHOUGH peace has been established between Russia and Japan, nevertheless the results of the late war are now being felt in Germany. Even in times of peace it is not expected that strict hygienic measures will be enforced in Russia on account of the inferior character of the lower grade of officers. Still worse are these conditions in time of revolution. Surely the statement of the Russian Government that no case of cholera had been observed in Russia since April 21 is absolutely untrue, and Germany has to pay the penalty of being neighbor to these infected districts. It is well known that the congress of physicians which was held in the first part of April at Moscow discussed the subject of cholera. But the government suppressed the publication of the proceedings. Russia signed the regulations which were drawn up by the Paris International Sanitary Convention in 1903; she agreed at this time to inform at least once a week all of the neighboring countries concerning all epidemics. Russia has neglected her duty, and Germany has to bear the consequences of this neglect. The first cases of cholera were found in the smaller towns of Prussia; that is, in west Prussia. All of these towns were situated on the Weichsel, a river, the longer part of which lies in Russia. All of these cases were Russian raftmen. As the writer was born not far from the Weichsel, he is well acquainted with this class of people. Accepting the fact that cleanliness is the first principle of hygiene, these people offer a most excellent starting point for infectious diseases. Their dress is disgustingly filthy; their hair matted together like felt, bulges out under a small, round, dirty hat. Water is a stranger to them. A shirt covers the body down to the knees. This garment is never changed, and over it is worn a coat of dirty fur. The legs are swathed in filthy rags. These people are accustomed to live in stables like animals. Their food consists mostly of salt herring and sauerkraut. It is never cleaned in any way. Potatoes are a rare addition to their meals.

The first three cases occurred at Kulm. In the meantime many new cases broke out in other small places on the Weichsel and on another small river tributary to the Oder, but communicating with the Weichsel by a much traveled channel. At Hamburg a Russian emigrant, perhaps after having drunk Weichsel water in the course of his journey, fell sick on August 24, and died of cholera on the following day. Hamburg succeeded in stopping the further spread of the disease, but in the provinces situated on the infected river new cases of cholera were reported almost daily. Up to date statistics show two hundred and seventy-six patients and eighty-five dead. All kinds of precautions were taken at once. Sixteen stations have been established in the infected territories. The attention of the people was called to the official notices, bathing places were closed, and establishments for good water were instituted. Berlin is directly connected with these infected quarters by a water route. The most stringent measures are observed. A station was established about ten miles east. As is customary, a military physician was appointed supervisor and the necessary bacteriological examinations are made. A government steamer controls the river traffic of Berlin so that there is no possibility that any vessel passing this way will not be carefully examined. Not only are physicians stationed here, but also policemen. Dr. Schuster most courteously gave the writer a great deal of information concerning these hygienic measures. The plan of employing military physicians is an excellent one, chiefly because these physicians are accustomed to carry out their instructions without any wavering. And a certain severity is almost necessary in carrying out hygienic measures, especially among this uneducated class. All vessels are obliged to stop at a certain distance from town. Without any exception, all passengers are examined. The straw stables have been burned. When there is the slightest suspicion of illness the suspect is taken on board the government vessel and brought to land. Cholera patients are put in a hospital and suspects are placed on a ship in the river not far from the Government station. Up to this time no cases of cholera has occurred here, and frequent bacteriological examination of the water proves that no cholera bacilli have yet infected the river. Up to this time also no case of cholera has occurred in Berlin, although several suspects have been examined. The Government has given special instructions to every physician in Berlin. The utmost precautions are taken. The writer declares that he sees no chance of the spread of this epidemic in Germany. It is possible that certain cases will be discovered in the larger towns of the neighborhood, Breslau, Posen, and so on. But the vigilance of the government, the activity of the physicians, and the winter season now near at hand will entirely exterminate the epidemic. Since writing the above the writer has heard, after leaving Berlin, that the first case of cholera in that city was detected by the examination of Professor Gaffky. The family of the dead seaman was isolated. Berlin has been divided into one hundred and sixty sanitary departments which have already instituted hygienic measures.

**Spinal Anesthesia.**—Freund says that now that its probationary period is over and the proper technique has been learned by experience, spinal anesthesia has been placed on a secure footing as one of the greatest advances in surgery. The author describes a number of hysterectomies and other major abdominal operations performed to great advantage under this anesthesia, and he lays great stress on its superiority over inhalation anesthesia in marantic individuals.—*Zentralblatt für Gynäkologie.*

# Progress of Medical Science.

*Boston Medical and Surgical Journal, November 2, 1905*

**The Active Treatment of Muscular Rheumatism.**—B. B. Cates emphasizes the necessity in this malady of quickening the circulation, opening up freely all the excretory channels, and eliminating all waste material. He finds that nearly all patients with muscular rheumatism have torpid livers, heavily-coated furred tongues, offensive breaths, constipation, and frequently headaches; in other words, they often show the classic signs of a condition we are wont to term "biliousness." Moreover, chronic rheumatics are often heavy eaters. They eat fast, chew their food improperly, are sluggish in thought and action, and complain much of indigestion. Treatment calls for proper muscular exercise, preferably on rising, cold tubbing, and brisk rubbing. Sufficient time must be spent in masticating the food, and the first step to insure this is to see that the teeth are in good condition. Special directions are given by the author as to exercise. He declares that a rigid adherence to the rules he lays down will not only cure the most obstinate case of muscular rheumatism, but will develop the muscles, bring back the bright eye, banish indigestion and constipation, give elasticity to the step, and soon your patient, unless he has his daily exercise and cold plunge, will feel uneasy all day long.

*New York Medical Journal, November 4, 1905.*

**Three Vices of Blood Pressure.**—These are summarized by L. F. Bishop as follows: First, primary low arterial tension, met with in all enfeebling disease, in great physical emergencies, and following either to diseases of the heart structure, or to a failure of the vital force and tissues of the body. Second, high arterial tension, indicating that the circulation is laboring under stress, and due to nervous causes, such as overwork, excitement, and dissipation, or chemical causes, such as the over ingestion of food, or the failure of kidney elimination; indeed all the causes which can arise from a life of mental hardship combined with physical luxury. Third, secondary low arterial tension, which represents the final outcome of pre-existing high arterial tension.

**Status of the Fetus in Utero.**—H. Hughes makes a strong plea against the present legal status of unborn children. If, she says, regarding murderers, we were lax in obeying the law, failed to report cases of murder, received the murderer into good society, forgave his offense and read scientific papers on the expediency of destroying one life that another may reap the benefit, how many papers read before a select society whose doors are practically barred to the public, would make life safe in our midst? This is exactly the protection we extend to unborn children. The young and strong who are able to defend themselves, the old and feeble whose life is nearing its completion, are safeguarded, but the seeds of the race, the tender young shoots, the hope of the future, are unprotected. The lawmakers who discriminate between the legal status of the born and the unborn are particeps criminis in the awful destruction of the young that is going on to-day. It is not higher education, nor religion, nor moral persuasion, nor natural affection, that we depend on for our own safety, but the strong arm of the law. Why should only these virtues be called upon in the case of the unborn? Let the law, she says, require that every birth, no matter at what stage of gestation, be registered and the cause of death reported to the civil authorities, as is done in the case of every human being, and the people will soon awaken to a proper understanding of the status of the fetus in utero.

*Medical News, November 4, 1905.*

**The Treatment of General Peritonitis.**—A thorough consideration of this subject is made by A. J. McCosh, who discusses in detail the several points of anesthesia, incision, rapidity of operation, methods of cleansing, drainage, evisceration of intestines, removal of lymph, enterotomy and enterostomy, injection of magnesium sulphate and post-operative position. His conclusions are as follows: (1) No one plan of treatment is applicable for all cases; (2) the majority of cases are best treated by operation, but there are also many cases where operation diminishes the chances for recovery; (3) Undoubted cases of general peritonitis recover without operation; (4) Rapidity, gentleness, and removal of the cause are the most important features of the successful operation; (5) irrigation with saline solution is generally recommended. All chemicals and mechanical irritants are to be avoided; (6) drainage should be provided, but the drains should be smooth, nonadhesive and of small diameter. The cigarette drain is preferred; (7) enterostomy is not advocated; (8) gauze packing is injurious; (9) Fowler's position after operation is most advantageous.

**The Duodenal Ulcer, by one of its Victims.**—This paper is a general discussion of the subject by F. E. Cooke. Concerning etiology he reminds us that it is a well established fact by the modern theories of immunity that intestinal parasites are protected from the digestive ferments in which they live by antidigestive ferments found in their skin. It has also been proven that the alimentary walls are able to protect their tissues from self-digestion (autolysis) by certain antibodies contained in their epithelial cells. Any diminution of these bodies may, and a marked diminution does result in autolysis, or self-digestion. The author suggests that it is conceivable that in external burns, toxic substances are absorbed and are specific and destructive to the antibody in the epithelial cells of the duodenum. As soon as the antibodies are diminished to a sufficient quantity, an ulcer results. He further notes that any disproportion between the composition of the blood and gastric juice may give rise to ulcer, either in the stomach or duodenum. How does it do this? By diminishing the antibodies in the epithelial cells. The disproportion may be due to two causes, viz., anomalies in the composition of the blood, as chlorosis, anemia, suppression of menses, etc., or an increase of secretion of the gastric juice, particularly the hydrochloric acid. In case of the former it is a matter of lowered resistance; in the latter, an increased virulence. This explains the greater frequency of gastric ulcers in women, and duodenal in men. It also accounts for the fact that gastric ulcer, which is more common in the female, is usually not associated with hyperchlorhydria, whereas in the male the reverse is the case.

*American Medicine, November 4, 1905.*

**Examination of the Leucocytes as an Aid to the Diagnosis and Prognosis of Disease.**—Thomas R. Brown states that a thorough appreciation of the exact significance of leucocytosis will not be possible until we have definitely determined the mode of origin of the various forms of the white blood cells and their relationship to one another. It seems proved beyond doubt that the determination of the leucocytes by careful investigators under proper conditions is of real value in the diagnosis and prognosis of disease, and that the more careful and more systematic the studies of the blood, the more help we may hope to derive in drawing correct inferences. Leucocyte counting has not and never will reach the point at which it and it alone will furnish us without possibility of error with correct diagnosis and prognosis, but it has been in the past a great, and it will be in the future an even greater, help to the physician and surgeon who value correctly its possibilities and its limitations.

**Mercury in Syphilis.**—Otto Lerch explains why mercury is more effective when given by inunction than other methods. By inunction it is absorbed by the lymphatics and comes in direct and immediate contact with the virus. Enlarged glands will yield to inunction after resisting every other treatment. Lesions of blood-vessels and viscera of bones and of the nervous system follow the lymphadenitis. Enlarged glands are found early in the disease and they may be palpated when every other symptom has disappeared. They contain the virus and a late secondary infection may be explained originating from them when the resisting power of the organism is lowered. Deep-seated glands cannot be inspected and it is therefore impossible to say when a patient is cured. Dr. Lerch urges that in tabes and paresis antiluetic treatment should be tried, as it is often impossible to make a positive diagnosis. A certain analogy between syphilis and tuberculosis has led him to give inunctions of iodoform in tuberculosis. He has had good results.

**Nasal Septum in Children.**—Arthur Ames Bliss believes that traumatism is the most frequent cause of deflections in the nasal septum in children, and that, when this is the case, the resulting deformity should be corrected as soon as possible after its production. Congenital deformity of the nose is the cause in a minority of cases. In cases of deflection of long standing it is not necessary to defer the operation of resection and replacement until the development of the nose is complete, at about the twelfth or fourteenth year. Dr. Bliss prefers the operation devised by Dr. Harrison Allen, or that of the Gleason-Watson method, but believes that no special form of procedure will apply in every case, the method of operation depending upon the character and extent of the deformity. As a splint, the author prefers to use a section of rubber drainage tubing, cut to fit the nares, in each case, rather than the usual hard rubber or metal tubes. Those cases of deflection,

in which distinct symptoms are produced by the bend of the septum, are the only ones referred to as needing operation. Mouth-breathing results from deflections causing occlusion, quite as serious as that from adenoids and hypertrophied tonsils; while the facial deformity caused by efforts to open the occluded nares by the local muscle supply, becomes very pronounced Reference is made to the nerve reflexes, caused by intranasal pressure, in the sympathetic nerve system and in the branches of the fifth nerve.

**The Corroding Action of the Ovum in Ectopic Pregnancy.**—J. Riddle Goffe calls attention to recent researches that have demonstrated the destructive action of the impregnated ovum in its implantation on the uterine tissues. He utilizes this fact to explain certain cases in which, with the symptoms of ectopic pregnancy and the presence of more or less extensive pelvic hemorhrge, microscopic examination reveals no traces of the products of conception, or of the source of the bleeding. The effect of the corrosive action above mentioned, he says, ir readily conceived in cases in which the implantation of the ovum is transferred from the uterus to the thin-walled Fallopian tube. While generally successfully accomplished, it must frequently happen that the corrosive process extends completely through the tubal wall or brings the intervillous spaces so near the surface that the blood pressure ruptures the peritoneum and causes serious hemorrhage. He gives an account of a case in which this seems to have occurred, and refers to another reported by Paul Zweifel, in which hemorrhage occurred eight days after the first omission of the menses and the ovum was found to have eroded completely through the tube and serosa into the peritoneal cavity. It would be a fair inference, he thinks, that when a woman has missed one menstrual period and is attacked with sharp hypogastric pain, collapse and vomiting, with marked feeble pulse, and without rise of temperature, that an erosion has occurred through a gravid tube, and the need of prompt operation should be at once suggested.

**Extrauterine Pregnancy.**—J H. Carstens remarks the occasional occurrence of cases of extrauterine pregnancy not manifesting the usual symptoms and rendering possible mistakes in diagnosis, even by very well-posted diagnosticians. Two such cases are reported by him, and he draws from them the following conclusions: (1) Extrauterine pregnancy must always be in the physician's mind in cases of sudden onset of pelvic trouble; (2) the least irregularity of menstruation is suspicious of extrauterine gestation; (3) inflammation and sepsis following a supposed miscarriage often are due to ruptured ectopic pregnancy; (4) prompt operation is always indicated; the choice of the vaginal or abdominal route depending on circumstances."

**Non-Gastric Diseases with Gastric Symptoms.**—J. H. Musser enumerates the principal diseases in which gastric symptoms are prominent without there being necessarily any organic disease of the stomach whatever. First among those mentioned are the disorders of the eyes, ears, and of the nose and throat, the gastric symptoms of which are familiar to all. In the diseases of the nervous system he refers to the gastric crises of tabes, the vomiting attending apoplexy, meningitis and brain tumor, and especially to the gastric symptoms of epilepsy, which are sometimes misinterpreted in obscure cases of this disorder. Acute affections of the cardiovascular system may have gastric symptoms as their sole expression, and they are still more pronounced and continuous in failure of compensation. Among lung diseases apex pneumonia and tuberculosis are examples, and in children with severe vomiting the possibility of the former infection should be borne in mind. The gastric symptoms of liver disease, or disorders of the intestines and appendix and of the genitourinary organs are well known, and in blood disorders the vomiting, etc., of chlorosis is a familiar example. Among the infectious disorders, special mention is made of tuberculosis, gonorrhea, and syphilis, and among the intoxications, those of tobacco and lead, exophthalmic goiter, internal suppuration, Addison's disease, and uremia. The gastric neuroses of hysteria and neurasthenia sometimes cause special difficulties of diagnosis. Non-gastric diseases generally require the closest examination of all the organs and study of all the secretions and excretions, as well as of the clinical course and history. The symptoms bear more or less relation to pathological or physiological fluctuations of the primary cause in eye, heart, kidneys or whatever other organs may be affected, and have not the constancy of those of organic gastric disease.

**Gonorrhea in the Female.**—L. H. Dunning concludes that the estimate of some high authorities as to the importance of gonorrhea, as a cause of sterility in women and of severe pelvic disease, is too high. He claims that while acute gonorrhea is easily diagnosed in the female, both smear and culture being available, in the chronic and subacute cases the diagnosis is often impossible, even with the use of all secondary aids, such as questioning the patient, sudden onset of inflammatory conditions without other causes, etc., and that in many cases of gonorrhea in women the patients recover quickly, leaving no traces so far as physical examination can detect. As proof of this, he gives the account of a patient whom he treated in a severe attack of gonorrhea contracted from her husband. When, nine years later, he was consulted by the same woman on account of her sterility, he could find no pelvic disease whatever, and she had no symptoms beyond somewhat painful menstruation. This difficulty of diagnosis makes it impossible to say just what part gonorrhea plays in the production of female sterility. His belief is that the most frequent cause is the intentional prevention of pregnancy, and that next to this come errors of development of the reproductive organs of women. He finds also that the records of his private practice show no such preponderance of gonorrhea as the cause of severe pelvic lesions, as is claimed, and the same is true of those of the only charlty hospital of Indianapolis. He admits, however, that there is a great difference in the prevalence of gonorrhea in different communities, and that studies covering a wider field will be required to settle the question.

*The Lancet, October 28, 1905.*

**A Case of Emphysema Occurring During Parturition.**—F. H. Sprague reports the case of a healthy primipara with normal head presentation and prolonged labor due to deficient liquor amnii. When the head began to distend the perineum (chloroform being used), swelling was noticed on the right side of the mother's face and neck. Later the swollen area involved the whole front of the right chest down to the fourth rib; the supraclavicular fossa was distended as well as the cervical triangles. The characteristic crackling was evident on palpation and the voice had sunk to a whisper. The child had in the meantime been delivered. Dyspnea and dysphagia were both present. For two days the patient was in great discomfort, but then all symptoms began to abate, and by the eighth day conditions were normal. The emphysema did not interfere with the progress of the puerperium. No treatment was adopted beyond the protecting the chest and neck with cotton wool restraint of cough and of all respiratory effort.

**Multiple Abscesses of the Kidney Due to Ascending Infection of the Normal Urinary Tract by Bacillus Coli Communis.**—One personal case is reported by H. L. Barnard, and reference is made to cases previously reported by Rigby, Brewer, Lennander, Wilms, and Blake. The author notes that in each case the affection has been unilateral. He advises the exposure of the kidney through the loin, and, if the organ is engorged and covered with subcapsular hemorrhagic abscesses, its rapid excision. In two of the cases quoted, however, recovery followed splitting, partial resection, and drainage. This method should probably be reserved for slight cases in which the infection is restricted to one or two small areas and for bilateral cases. After nephrectomy the temperature falls to normal, the pyuria ceases, the toxemia disappears, and the wound does not suppurate. The kidney may be infected through the blood lymph, urine, and by extension of a neighboring suppurative process, such as the colon or a retroappendical abscess. Ordinarily the urethra protects the bladder from infection. The short urethra in women is undoubtedly the cause of the more frequent occurrence of (non-gonorrheal) cystitis in women. The male urethra normally protects the bladder from its length, the passage of urine scours it out. Moreover, its muscular fibers clear it out thoroughly by a peristaltic wave at the end of micturition. Similarly the ureters protect the kidney and are even better adapted for their purpose, being emptied some fourteen times every minute. But all of these safeguards are circumvented by any obstruction which leads to a dilatation of the urinary cavities and channels. In the author's case urethritis and cystitis existed at the time of operation, and the only exciting cause of these that could be ascertained was overindulgence in coffee and beer.

**Membranous Colitis.**—A study of sixty cases is made by W. Hale White. A tabulated record is made of findings in sixteen cases that, although not fatal, did not recover; of six cases much improved, of twenty-one cases that recovered, of twenty-one cases with some disorder of the female generative tract, and of eight cases associated with appendix disease. The author declares that the most important part of the treatment is to keep the large bowel empty. Castor oil is the preferable remedy and should be given as soon as the patient wakes. Often this will cure the patient. If the oil is not well borne magnesium sulphate may be given in its place, or calomel may answer. Should these methods fail, the bowel should be washed

out with plain water at blood temperature. In very severe and intractable cases the bowel may be kept clear by a right-sided colotomy. This entails, however, an awkward state of affairs. The opening must remain patent for one year and its closure may be difficult. Should it be done there is no need regularly to wash the bowel through from the artificial opening to the anus. All that is necessary is for it to be empty and to start it in this condition. One washing may be given at time of operation. High-frequency electric currents through the abdomen are of uncertain value. The so-called intestinal antiseptics are worse than useless. The abdomen should be warmly clothed. Improvement under any plan is not infrequently delayed until it has been continued for months.

*British Medical Journal, October 28, 1905.*

**Graves's Disease.**—Hector Mackenzie thinks it probable that the parathyroids play an important part in the pathology of Graves's disease, and that their atrophy may be the cause of some of the more serious symptoms. In speaking of the presence of the thymus in fatal cases of this disease, he states that perhaps every case of persistent thymus is one of potential or latent Graves's disease. Although there are no obvious naked-eye changes in the nervous system, certain microscopic lesions have been found after death in some cases. The writer believes that it is most probable that the hypertrophy and over-activity of the thyroid is the cause of the symptoms of the disease and of most of the changes in the organs of the body. It is not known what it is that starts the hypertrophy of the thyroid. The disease is more common in the female than in the male. It may occur at any age but it is rare in children or over the age of fifty. The four cardinal symptoms are well known to all —goiter, palpitation, exophthalmos, and tremor. Progressive emaciation may well cause anxiety, and with it goes loss of strength. Slight degrees of pyrexia are not uncommon. Edema is occasionally seen. Looseness of the bowels, alternating sometimes with constipation, is another trouble. Irritability is nearly always present; and even insanity develops in some cases, the type being either melancholia or mania. There are two varieties of the disease, the acute and the chronic. The prognosis should be guarded in all cases, but especially in the acute ones. Time is a most important element in combating the disease. Massage, which is beneficial in certain cases, as in patients who are confined to bed, must be judiciously employed. There is no rule as to the climate that will suit one of these patients. Peaceful rest and quiet are most essential. Wholesome food, pure and bracing air, and pleasant and cheerful surroundings are indicated. As to drugs, Mackenzie has found potassium bromide useful. Belladonna also affords relief. In certain cases, treatment with thyroid gland is beneficial, but usually makes the patient worse. Local treatment also has its place. On the whole, the risk attending thyroidectomy is too great to justify the adoption of the operation save in exceptional circumstances.

**Open-Air Treatment of Addison's Disease.**—Byrom Bramwell gives the history of a patient who was suffering from Addison's disease. He had been ill for eighteen months. There was a good covering of fat, although the patient had lost in weight. This loss evidently had to do with muscle and not with fat. There was extreme asthenia. There was some degree of anemia. The hemoglobin equaled 70 per cent. There was considerable excess of lymphocytes (40 per cent.) which was suggestive of a tuberculous lesion. There was deep pigmentation of the skin of the parts which had been exposed to the air. There was some pain in the back over the region of the suprarenal capsules, but there was no tenderness on pressure in the lumbar region. After the patient had been in the hospital for three weeks, it was decided to try the effect of open-air treatment. Although the weather was most inclement and cold, the patient stood the exposure well. He did not complain of the cold and felt quite comfortable. At the same time, suprarenal extract, five grains, three times daily, was administered. Improvement was remarkable. The patient, after his discharge, came for inspection from time to time and declared that he felt well. Eight months after his discharge from the hospital, he returned to work (he was a ship steward) without asking permission of the physician. In three months he complained of great weakness and inability to work. The next day he was better, but in two days he was dead. The final attack and death seemed to be due to rapidly developed asthenia and failure of the heart's action, perhaps the result of autointoxication. There was no post-mortem examination. Bramwell emphasizes the fact that the life of a patient with Addison's disease, even when marked improvement takes place, is an extremely precarious one. This is due to the abolished function of the suprarenal glands. Such patients, even if they have apparently recovered, should lead inactive lives, as anything likely to depress the heart's action may be attended with great danger.

*Berliner klinische Wochenschrift, October 16, 1905.*

**The Local Effects of Tubercle Bacilli at the Portal of Entry.**—Von Baumgarten combats the theory that tubercle bacilli can pass through the superficial coverings of the body without causing local lesions at the point of entry. In a long series of experiments such lesions were constantly present, although a microscopic examination was sometimes necessary to determine their existence in rapidly fatal cases, or where, as the result of a diminished virulence in the organism, the disease was limited to the regional lymphnodes for a long time. Inoculation of bacilli into the abraded skin or mucous membrane is invariably followed by the development of tubercular lesions at the site of inoculation. Similarly the administration of milk containing tubercle bacilli to rabbits is followed by typical tuberculosis of the intestinal mucosa, the mesenteric lymphnodes and the liver. Frequently the lungs, throat, and cervical lymphnodes are also affected. Here also in rapidly fatal cases, although the cervical and mesenteric lymphnodes were microscopically involved, the lesions in the mucosa were often microscopic. Tubercle bacilli can pass through the intact intestinal mucosa only at the site of the lymphoid follicles, whence they pass to the mesenteric lymphnodes. Here they are collected in large numbers, and the nodes may therefore in the early stages of the disease present a more advanced stage of tuberculosis than the mucosa. Later the mucosa is broken down by the action of the bacilli in the follicles and typical ulcers result. The author thus explains the infection of the mesenteric nodes in the presence of an apparently intact mucous membrane. Pulmonary infection as the only result of feeding experiments is due to the aspiration of a portion of the bacilli, while the inhibitive action of the gastric juice or the rapid expulsion of the remainder from the intestine prevents an infection of the intestinal canal. Baumgarten has further shown by experimentation that the injection of tubercle bacilli into the trachea is followed by tuberculosis of the lung tissue, and that the bacilli are unable to pass through the alveolar endothelium to the bronchial lymphnodes without infecting the former.

**A Contribution to the Pathogenesis of Diphtheria.**—Scheller and Stenger call attention to the frequency of diphtheria of the throat arising from the extension of the specific organism from the nasal cavities. Rhinitides, especially rhinitis fibrosa, is often due to the presence of diphtheria bacilli. Pharyngeal diphtheria is often ushered in by a mild rhinitis that the authors regard either as an initial process in the disease or as a factor predisposing to infection with the diphtheria bacillus. Mechanical, chemical, or infectious agents affecting the nasal mucosa may give rise to a diphtheritic infection of the pharyngeal mucosa where diphtheria bacilli are present, although dormant, in the nose, even though the organism has not previously been lodging on the tonsillar or pharyngeal mucous membrane. The writers record a case in which an operation upon the nose was followed by a tonsillar diphtheritis. Diphtheria bacilli had been found in the nasal, but not in the pharyngeal cavity, before operation.

**Fever During Menstruation in Tuberculous Women.**—Franck believes that in the absence of disease of the genital organs even a mild pyrexia during menstruation is to be regarded as a sign of probable tuberculous infection. Anemia, sweats, a tendency to contract colds, and a tuberculous family history tend to strengthen the assumption of the presence of tuberculosis, and warrant the institution of the customary treatment, even though the lesion cannot be found by examination of the patient.

*Deutsche medizinische Wochenschrift, October 12, 1905.*

**Multiple Scelerosis and Trauma.**—Grossman first reviews the literature relating to the subject, which appears to show that authorities are divided in regard to the possibility of traumatic origin of multiple sclerosis. Strümpell, Krafft-Ebing and Pierre Marie are all opposed to a belief in trauma as an etiological factor, while such authors as Leube, v. Leyden, and v. Jaksch think it must be reckoned with as a possibility. Grossman's own case was that of a man of 28, who was alleged to have been in perfect health until he fell from a height while washing windows and struck on a bench below. He was unconscious when picked up and suffered from general pains all over his body, so that after staying in bed for two days at home he went to a hospital, where the diagnosis of multiple sclerosis after trauma was made on account of the already existing optic atrophy, nystagmus, intention tremor, unequal patellar reflexes, vertigo, and forced laughing. The man's comrades attested that he had been in perfect health and able to do hard work up to the

time of the accident, so that it would appear that this was an excellent case of post-traumatic multiple sclerosis. Closer analysis shows, however, that the symptoms described could not possibly have developed so promptly, and the author believes that the patient had the disease in a latent form for some time without suffering from any impairment of his faculties until suddenly the process was started into activity by the accident.

**Ligation of the Ovarian and Internal Iliac Veins in Puerperal Pyemia.**—Haeckel recommends this procedure highly in cases of puerperal pyemia, particularly if of chronic course. Through extension from the dilated vessels of the placental site the venous plexus on either side of the uterus becomes choked with infectious material. From time to time portions of this are carried into the general blood stream and cause the typical pyemic chills and temperature. By ligating the ovarian and the internal iliac veins in each side a stop is put to this process of deportation of septic emboli and prompt improvement follows in the patient's general condition. Of course the septic products are left in the occluded vessels, but they no longer can enter the general circulation, and the best opportunity is afforded for their gradual absorption. The author describes one case of chronic pyemia in which he carried out the measure with great success, and another of the acute form in which it did not seem to influence the course of the disease appreciably. He considers the operation as representing a valuable addition to the surgeon's resources in dealing with this complication of the puerperium.

*French and Italian Journals.*

**Senile Trembling in the Nursling.**—Raymond writes that besides the tremblings due to intoxications or to the diverse lesions of the nervous system there exists another special form. It is hereditary and may descend from father to son. Aside from this symptom, the patients are healthy. There is no other morbid symptom. Senile trembling is the term applied to that symptom when it is observed in old age, but it is encountered at every period of life. The writer reports the case of a child seven months old. From the time he was two months old he presented all the characteristics of senile trembling. The head alone was affected, no other part of the body taking part in the trembling. The oscillations of the head were slow and were made from side to side, indefinitely repeated. The child was placid and looked well. It had never suffered from convulsions. As to the etiology of this affection only one factor could be discovered: the mother had suffered during four months of her pregnancy with whooping-cough. The maternal infection, without a doubt, had caused certain degenerative changes in the brain of the child, hence the trembling. In the treatment of these cases all offensive medication ought to be rejected. Baths, certain preparations of the valerian, and careful attention to the digestive tract are the most important features. Nothing else is of any consequence.—*Journal des Praticiens*, September 2, 1905.

**Two Nephrectomies for Renal Tuberculosis.**—Carlier reports two cases of this kind that have recently come under his care. The first patient was a young woman twenty years old. Failing to determine with certainty the integrity of the left kidney from the separation of urine, Carlier did a nephrotomy on the right kidney. This operation resulted in the outlet of from four to five hundred grammes of pus, which had been dammed up in three different pockets. The general condition being so much improved after this operation a secondary nephrectomy was done. Numerous adhesions about the kidney necessitated a subcapsular nephrectomy. The patient is now almost well. The left kidney is healthy although the bladder is not yet normal. Section of the kidney which was removed showed four large empty cavities. A fifth was filled with caseous material. Nephrotomy does not bring about the cure of such lesions. The second case was that of a little girl ten years old. The affected kidney was completely riddled with cavities. The ablation of this organ, together with its capsule, was easily accomplished by the lumbar route. The patient made a perfect recovery after operation.—*Le Nord Médical*, September 1, 1905.

**Action of Massage on the Precordial Region in Affections of the Heart.**—Cautru declares that massage effects arterial pressure. It may be soothing in its effects, lowering the pressure which is accomplished by manual vibrations and gentle movements, or it may be exciting, raising the pressure, as brought about by petrissage. Whatever the nature of the massage, the indication for its variety is based on the condition of the arterial pressure. By massage the number of the pulse beats may be regulated. The rhythm, also, may be influenced. This effect may be permanent after several treatments. The writer has obtained sphygmographical tracings in his work, which definitely demonstrate his results. Besides its effect upon the arterial pressure and upon the pulse, massage also influences the volume of the heart. However, in cases of pericarditis with effusion and in pericardiac symphysis the absolute dullness is not changed by means of massage, and this fact offers an important element in diagnosis. Aside from its action on the heart the good effects of massage have been noted in relation to intercostal neuralgia, which occurs so frequently in cardiopathies, and on the general condition—diminution of dyspnea, increase of diuresis, sensation of well-being—especially if the action of cardiac massage is combined with that of abdominal massage.—*Le Progrès Médical*, September 2, 1905.

**The Alimentary Régime of Epileptics.**—Jules Voisin and Roger Voisin, after discussing the advisability of the lactovegetarian régime in epilepsy, conclude that this treatment is based on a faulty theory. They believe that the ideas concerning the phenomena which accompany the digestion of meat which the advocates of the lactovegetarian régime have advanced are probably false. The consumption of meat or of nitrogenous elements, whatever may be their nature, provided that such food is not taken in excess, does not result in the increase of the number of epileptic attacks. It is useless to prescribe in such cases then the lactovegetarian regime, or even the hyponitrogenous régime. It is sufficient that the epileptic, along with his ordinary bromide treatment, follow the rules of good general hygiene, avoiding digestive troubles.—*La Presse Médicale*, September 2, 1905.

**Statistics of 731 Laparotomies.**—Casati has done 731 consecutive laparotomies, among which he finds the greatest mortality in cancer of the stomach and of the uterus, and of these in cases of occlusion of the intestine. In such cases, of 164 patients, 47 have died, that is a mortality of 28.65 per cent. Of all the other cases, 567 in number, among which there were 176 abdominal tumors, 122 removals of the adnexa, 24 appendicitis operations, 11 removals of the spleen, 19 removals of the kidney, there have been only 28 deaths, that is a mortality of 4.93 per cent. The author believes that in case of appendicitis the operation should be undertaken in the acute stage of the disease.—*La Riforma Medica*, August 26, 1905.

**Tumors of the Sella Turcica.**—Umberto Parodi tells us that there have been observed typical adenomata of the hypophysis, as well as sarcomata and ghiomata; on the other hand, there have been found in many cases tumors that are not clearly adenomatous; these have been called angiosarcomata, and have also been ascribed to the epithelial adenomata or adenocarcinomata. Other tumors have no adenomatous structure and are still considered adenomata. A diagnostic element consists of the chromphyl cells characteristic of the hypophysis. The author describes a tumor examined by him, which occurred in an old woman who was entirely blind and deaf, but otherwise was entirely healthy, having no signs of acromegaly. She died of pleuropneumonia. The tumor occupied the sella turcica, and the region covering it. The optic chiasma and nerves were compressed and atrophied. There was found a small band of tissue that resembled atrophic tissue of the hypophysis. The hypophysis was destroyed and functionless. The tumor included tissue of two distinct types: perivascular tissue, and a portion having an irregular alveolar structure. It was not a typical adenoma, nor a sarcoma; the location of the tumor, the absence of transitional forms from residual hypophyseal tissue, and the absence of likeness to tumors produced by the bones, nerves, or meninges, make it probable that it was derived from parahypophyseal embryonal germs.—*Archivio per le Scienze Mediche*, Vol. XXIX, Fasc. 4.

**An Unusual Case of Rheumatic Arteritis.**—Andrea Conti describes a case of rheumatism in a boy of seventeen years, who, two years previously, had had an attack of articular rheumatism, which had produced marked lesions in the heart. There were mitral systolic and aortic murmurs, a very much enlarged heart, and visible pulsation in the great vessels of the neck and in the upper intercostal spaces. During the attack described, in combination with high fever and dyspnea, there was severe pain over the abdominal and thoracic aorta, and these could be felt, and were very tender to pressure, and their pulsation could be felt through the abdominal walls. The author believes that there was an arteritis of rheumatic origin involving the arch of the aorta and its thoracic and abdominal portions. Under treatment the symptoms of arteritis disappeared, and the patient recovered as far as could be expected in one with so severe a heart lesion.—*Rivista Critica di Clinica Medica* September 16, 1905.

# Book Reviews.

Vital Questions. By Henry Dwight Chapin, M.D. New York: Thomas Y. Crowell & Co., 1905.

The author of this little volume of sociological essays has done a good work for his fellows. The thoughts here expressed are not revolutionary, the work proclaims no panacea for the ills of humanity, the several chapters contain no great truths that have not been expressed before, yet some lives will be better for the book having been written, some ills will be assuaged, some of the idle who are wasting their talents because they do not know how to employ them will be stimulated to work for others, and in relieving the sorrows of their fellows will find real happiness for themselves. Though the truths discussed are not new, the author deals in no platitudes; he regards his subjects from a fresh view-point and treats of them in a dispassionate and practical way that brings them home to the reader. The keynote of the book is sound common sense without a trace of radicalism or striving after the sensational. The questions discussed in the several chapters are "opportunity," relating to individual inequality; "survival," dealing with the unfit; "subsistence," having to do with poverty; "hope," the child; "vigor," health; "training," education; "achievement," as expressed by success; "contentment," the basis of happiness; "faith," dealing with religion; and "the final question"—death.

But altogether apart from the vital importance of these questions and from the interesting way in which they are presented, the book contains a lesson for the physician which he should take to heart. Dr. Chapin offers no apology, in the modern English sense of the Latin *apologia*, for entering, as a physician, upon a discussion of purely sociological questions, but boldly asserts that, as a physician, he is better qualified than the average layman to treat of such subjects. "The public may," he says, "and can get from the medical profession much more than the mere healing of their physical ills," and if they do not, the fault lies with the profession. Physicians as a class are narrow, they concern themselves too much with the physical and neglect the vast opportunities which their training and experience give them for promoting the welfare of the community. Here is a vast body of educated, thinking men brought into intimate daily contact with the poor and the wretched and the criminal, yet how seldom does one of them come out of the rut and give the world the benefit of his sociological experience. No "settlement worker," and no priest even, can ever get so close to the real life of the poor as the physician who sees them with the mask thrown off, to whom they reveal all their misery and their pain, and to whom their very souls are laid bare in the intimacy of professional confidences. Who, then, is better fitted to discuss the prophylaxis and treatment of social ills than the one to whom their nature and their causes are so familiar? Dr. Chapin has done a good work in emphasizing the fact that the physician owes more to the community than he gives in treating the physical ills of the individual. To him is also given the opportunity of laboring in a broader sense for the betterment of mankind. The medical man should be a power working for the elevation of humanity; he should come out from his retirement and take the part in the work of the world that his education and his opportunities peculiarly fit him to take. The author of this little book has shown what can be done in a modest way by every physician, and it would be well did others follow his example.

Krankheiten des Verdauungskanals. Von Dr. Paul Cohnheim, Berlin: S. Karger, 1905.

The newer methods of examination in diseases of the digestive tract are of great importance in this special field of medicine. In many of the every-day cases, however, a diagnosis and a rational line of treatment can be well established by taking into consideration the history of the disease and the physical examination of the patient—without a thorough investigation of the gastric secretion. This fact is adhered to through the present volume. Cohnheim's book is, therefore, a useful addition to medical literature.

A Guide to Anæsthetics for the Student and General Practitioner. By Thomas D. Luke, M.B., F.R.C.S. (Ed.), Instructor in Anæsthetics (University Surgical Classes), Royal Infirmary, Anæsthetist to the Deaconess Hospital, and the Dental Hospital, Edinburgh. With 45 Illustrations. Second Edition, 135 pages. Edinburgh: William Green & Sons; Philadelphia: J. B. Lippincott Company, 1905.

The growing popularity of ethyl chloride as a general anæsthetic has been the reason of this new edition. The author prophesies that in a few years it will be the most frequently used anæsthetic in England. The work, as a whole, covers the subject of local and general anæsthesia in a practical and thorough manner.

A Treatise on the Nervous Diseases of Children. For Physicians and Students. By B. Sachs, M.D., Alienist and Neurologist to Bellevue Hospital; Neurologist to the Mt. Sinai Hospital; Formerly Consulting Physician to Manhattan State Hospital, East and West; Formerly Professor of Mental and Nervous Diseases in the New York Polyclinic; Ex-president of the American Neurological Association. Second Edition. New York: William Wood & Co., 1905.

That the medical world appreciates the value of this work is evidenced by the fact that it has been translated into German and Italian and a French edition will soon follow. This popularity is well deserved since the author has produced a work distinctly original, the material of which has been supplied by a large personal experience in hospital and private work in the department of neurology. Moreover it has a breadth of scope not always noticeable in special treatises.

The present edition differs from its predecessors mainly in compactness and in its being thoroughly brought up to date in a specialty in which there have been important advances in the last few years. The author has omitted those chapters, present in the regular text-books on neurology, and having no special bearing here, such as the anatomy and physiology of the nervous system; detailed histories and bibliographies have also been dropped from the text.

The work is meant as much for the general practitioner as for the specialist, and its direct style, helpful therapeutics, and useful diagnostic hints will be appreciated by all who have to treat convulsions of all types, chorea, paralyses, etc., and enable him better to advance a prognosis when requested by anxious parents. The one critical remark that might be made against this volume is that its index is too limited and makes much valuable material difficult to obtain for ready reference.

Clinical Diagnosis. The Bacteriological, Chemical, and Microscopial Evidences of Disease. By Rudolf v. Jaksch, M.D., Professor of Special Pathology and Therapeutics, Director of the Medical Clinic in the German University of Prague, Ordinary Member of the Supreme Sanitary Council. Fifth English Edition. Based upon the Fifth German Edition, but containing additional matter and illustrations. Edited by Archibald E. Garrod, M.A., M.D., F.R.C.P., Assistant Physician to and Lecturer in Clinical Pathology at St. Bartholomew's Hospital, Physician to the Hospital for Sick Children, Great Ormond Street. With 172 illustrations (many in colors), including one colored plate. London: Charles Griffin & Co., Ltd.; Philadelphia: J. B. Lippincott Company, 1905.

Owing to the death of Dr. Cagney, the original translator, Dr. Garrod's name appears upon the title page of the new edition of this authoritative work. Among the more important additions to be noted are a section on trypanosmata with a colored plate, and one on cryoscopy. The author states that he has given up the use of Beckman's apparatus for freezing point determinations and is now using his own modification of Zikel's pectoscope. The interpolations of the English editor are numerous and contribute their share toward keeping the work fully abreast of the times in this most progressive branch of medical literature.

The Diagnostics of Internal Medicine. A Clinical Treatise upon the Recognized Principles of Medical Diagnosis, Prepared for the use of Students and Practitioners of Medicine. By Glentworth Reeve Butler, Sc.D., M.D. Chief of the Second Medical Division, Methodist Episcopal Hospital; Attending Physician to the Brooklyn Hospital, etc. With five colored plates and two hundred and eighty-eight illustrations and charts in the text. Second revised edition. New York and London: D. Appleton & Company, 1905.

This handbook of clinical diagnosis met with such a warm reception almost immediately upon its first appearance that it is not surprising that a second edition has been required so soon. In this issue the author has taken advantage of the opportunity to add many more of the instructive diagrams and other illustrations which are so prominent a feature of the book. In addition to minor changes in the body of the text two new sections have been added, one of 14 pages by Dr. Paul M. Pilcher on the use of the *x*-ray in diagnosis, and another of 33 pages by Dr. W. A. White on diseases of the mind. Other notable additions are found in the lists of infectious diseases which now includes discussions of such recently studied conditions as paratyphoid fever, Malta fever, trypanosomiasis, spotted or tick fever, milk sickness, glandular fever, etc. A section on cryoscopy has also been introduced. The subject of diagnosis is of itself one of the most interesting departments of medicine, but when pursued by the aid of so original and attractive a guide as this, its study becomes doubly fascinating.

# Society Reports.

## NEW YORK COUNTY MEDICAL ASSOCIATION.

*Stated Meeting, Held October 16, 1905.*

DR. FRANCIS J. QUINLAN, PRESIDENT, IN THE CHAIR.

THE evening was devoted to a discussion on the Dispensary Abuse.

**History of the Dispensary Law.**—Dr. E. ELIOT HARRIS presented the salient facts connected with the history of the law. He quoted a learned economist who had said that civilized communities had enacted laws having for their object the enforcement of certain restraints upon the appetites; the so-called benevolent impulse of our nature which moved us to give relief to those who appeared to be in distress might often be the cause which created a new lot of beggars. The Dispensary Law, which required all dispensaries to obtain a license, was enacted to restrain such impulses and to act as a deterrent to the fraud so easily practised on this form of medical charity. Scientific workers in the field of charity had educated the press and the public to the full danger of the moral degradation consequent upon misdirected charity. Dr. Harris quoted a number of excerpts from newspapers, to show that when the first dispensary bill was introduced into the Legislature, in 1897, the press and the public were alive to the questions at issue and ready to cooperate to secure the enactment of the law. Notwithstanding the general support of the press, the Dispensary Bill was vetoed by Governor Black in 1897; and in 1898 it was again defeated, although supported by a joint committee representing thirteen medical societies. In 1898 the Dispensary Bill was placed in the hands of the Committee on Legislation of the New York State Medical Association. In the investigation which followed, the Governor stated that every person had a right to establish a dispensary, so long as he used his own money in maintaining it, but if he used other money he could properly be subjected to State supervision. Dr. Harris said he could not see what privilege was gained when Section 23 of the law read as follows: "Nor shall any person, corporation, institution, society, association, or agent thereof, except a duly licensed dispensary, display or cause to be displayed, a sign or other thing which could directly or indirectly or by suggestion indicate the existence of the equivalent, in purpose and effect, of a dispensary." Certain unincorporated clinics, as those connected with medical schools and hospitals, had to be cared for in the bill, in order to avoid their opposition, hence the following Section: "A license shall be issued on application to all dispensaries legally incorporated and to unincorporated dispensaries connected with incorporated institutions at the time of the passage of this Act." The fears of some of the schools of medicine were quieted by Section 21 of the law: "The State Board of Charities shall make rules and regulations, and alter and amend the same, in accordance with which all dispensaries shall furnish, and applicants obtain, medical and surgical relief, advice or treatment, medicine or apparatus. But such rules and regulations shall not in any case specify the particular school of medicine in accordance with which a dispensary shall manage or conduct its work or determine the kind of medical or surgical treatment to be provided by any dispensary." The Governor objected very decidedly to giving the State Board of Charities power to revoke the license of incorporated dispensaries for disobedience of its rules. To meet these views Section 22 of the bill was added, which is now the law: "The said board is hereby directed to apply to the Supreme Court to revoke the license and annul the incorporation of any dispensary legally incorporated or conducted in connection with an incorporated institution at the time of the passage of this Act for wilful violation of the rules and regulations made by said board." The Dispensary Bill was introduced into the Legislature on February 24, 1899, and was signed by Governor Theodore Roosevelt on April 18, 1899.

**Dispensary Rules Adopted by the State Board of Charities and the Policy of the Board in the Enforcement of the Dispensary Law.**—Dr. STEPHEN SMITH reviewed Chapter 368 of the Laws of 1899, which was "An Act to Amend the State Charities Law, relating to the Licensing and Regulation of Dispensaries, by the State Board of Charities." This law went into effect on October 1, 1899. He also presented the Report of the Board's Special Committee on the Rules and Regulations for Dispensaries; together with the Rules and Regulations, the form of Application for a License, and the Form of License Adopted by the Board, Pursuant to the Provisions of Chapter 368, Laws of 1899. In this report it was stated that the form and manner of application for a license of a dispensary consisted of issuing to parties desirous of a license a circular, which Dr. Smith submitted in full, which was designed to secure, in writing, such information in regard to the institution as would enable the board to form a correct judgment as to the propriety of issuing its license. The form of the license issued was that usually employed by the State authorities, which granted license. In preparing the rules and regulations a circular of inquiry was first sent to the managers of all the dispensaries in the State, and to persons known to be interested in their reform, requesting opinions and suggestions as to the rules and regulations best adapted to the objects contemplated by the law. A large number of replies were received, containing many suggestions which were useful to the committee. The committee endeavored to create as little embarrassment as possible in the management of existing dispensaries and yet secure the needed reforms. Rule I. required that each dispensary should post a notice conspicuously in the waiting-room, announcing the fact that the dispensary had been duly licensed by the State Board of Charities to furnish medical and surgical relief to the sick poor who were unable to pay for the same. Added to this notice was the penalty for false representations by applicants in their efforts to obtain medical or surgical relief. This penalty stated that any person who obtained medical or surgical treatment on false representations should be guilty of a misdemeanor, and on conviction thereof should be punished by a fine of not less than $10 and not more than $250. Rule II. created the "Registrar," a new office in the dispensary, or, rather, a new title to the officer known as the "House Physician." The advantage in this provision would appear in the appointment of a competent person to have charge of the daily management of routine duties, keeping records, etc. Rule III. was the most important, because it aimed directly to control the alleged abuse of the indiscriminate treatment of applicants. It prescribed the rules governing the admission of individual applicants. Two classes were to be admitted at once, emergency cases and those evidently poor and needy. Those about whom there was doubt were to be given one treatment and then investigated. The results of investigation had to be filed in the dispensary. Any who refused to sign the card of admission were rejected. On the admission card was printed the representations to which the applicant subscribed and which covered those subjects most liable to conceal the frauds hitherto practised upon the dispensaries. The committee regarded this card as the most important of the rules, as it brought directly to the applicant the responsibility which he incurred in signing the card containing his representations. Rule IV. provided for a matron, who, in addition to her general duties, should attend women who had to submit to gynecological examinations and operations. Rule V. gave force and effect to existing rules of most dispensaries against the treatment of contagious diseases in these institutions. The enforcement of the rule had, however, been so lax that dispensaries had come to be regarded as prolific means of spreading diseases. Rule VI. governed the utilization of the dispensary for purposes of instruction and was designed to prevent the use of harsh and compulsory methods of compelling reluctant patients to submit to examinations and operations. Rule

VII. would eliminate from dispensaries druggists who had had no training for their responsible duties, and would prevent the dispensary being the medium for the refuse stock of wholesale dealers. Rule VIII. insured periodical sanitary inspection by the local health boards and immediate compliance with their orders. Rule IX. was designed to prevent an inadequate number of seats in the waiting-room, the indiscriminate mingling of the sexes. The committee suggested, in conclusion, that there should be at least two women in the Board of Managers of all dispensaries operating under their own charter and which received and treated women and children. It also suggested that there should be two classes of physicians and surgeons, visiting and assistants. The term of service was limited to three years in a division. The members of both classes should be elected annually by the Board of Managers. Physicians and surgeons should be held more rigidly responsible for the proper treatment of the patients of the classes to which they were respectively assigned. After the rules were prepared a public hearing was given, to which all the managers of dispensaries in the State were invited. On October 10, 1900, these rules and regulations were amended. One of the amendments provided that the "Registrar might select a deputy to perform his duties or to assist him;" instead of "every applicant," the phrase, "or parent or guardian of such applicant," was inserted. Several other minor changes were also made. In 1901 a special report of the Committee on Dispensaries, in relation to the enforcement of the Rules and Regulations of the Board was made in April, 1901, after the amended rules had been in operation for five months. In the opinion of the Board the time had arrived when action should be taken to secure compliance with the rules. At this time tables were presented, showing the results of the inspection of the dispensaries of the State and how far the Rules and Regulations on the State Board of Charities were complied with.

**The Practical Application of the Law to the Dispensaries.**—Mr. W. N. Beck, Chief Inspector New York State Board of Charities, after briefly reviewing the history of the dispensary law as already outlined, said that the question had recently been raised whether the dispensary law had not been a failure. He then compared conditions in 1899, before the dispensary law was in effect, and those of the present time, as revealed by a special inquiry made by the Board's inspector of dispensaries, Mr. John B. Prest. He took up each of the rules noted in Dr. Smith's paper, and showed that these rules had been complied with to a great extent. He summed up his detailed statement by saying that a condition of anarchy had been replaced by one of law and order; dispensaries had been driven from drug stores and tenement houses, and their location restricted by law and the requirements of the State Board. The dispensary buildings were now usually suitable and clean and their equipment adequate. The responsibility of dispensary managers had been consistently emphasized. Women patients were no longer examined or treated alone. An officer was provided to make and preserve accurate accounts of the work done and statistics were collected yearly of this work. Faithful and thorough medical service was now usually the rule. In a majority of dispensaries care was taken in the admission of applicants. The system of regulation provided had resulted in a diminution in the number of dispensaries from 136 in 1899 to 119 in 1904, and that in spite of the marked increase in population. The number of beneficiaries had increased only slightly in this period, from 932,172 to 1,009,334, or about 77,000, while the number of treatments given had increased from 2,106,723 to 2,825,640, an increase of more than 800,000. This would seem to indicate that the number of persons receiving charity in dispensaries was not increasing in proportion to the population, and that more attention was given to the individual patient than formerly. The statement showed, however, that much remained to be done. A uniform system of keeping records and accounts of dispensaries should be adopted, and more care in the admission of applicants, and the subsequent investigation of doubtful cases was imperatively needed. Inquiry at the office of the Charity Organization Society developed the fact that doubtful cases were often not reported by the dispensaries until several days, or even weeks, after the application was made. These cases were not investigated until after more pressing cases were disposed of, and the reports did not reach the dispensaries in time to be of much use. The interest and cooperation of dispensary officers, physicians and managers was essential if further progress of a lasting character was to be made. The Dispensary Law was not the creation of the State Board of Charities, or of a few physicians, or of any one group of people, but it was the expression of the serious purpose of the community to safeguard its social interests by restricting the bestowal of medical charity and by insuring the actually poor, prompt, careful and considerate treatment.

**The Experience of the Special Inspector of Dispensaries of the New York State Board of Charities.**—Mr. John B. Prest said that his qualifications to speak on this subject consisted of five years' service for the State, during which time he had visited every dispensary from New York to Buffalo from five to upwards of twenty times, and had investigated a considerable number of unlicensed dispensaries, medical companies, and medical institutes; he had studied the growth and operation of the dispensary from many points of view. He said that when he first began the work of inspection he met with considerable opposition, but the attitude on the part of those in authority in the dispensaries had changed. While some years ago the law was little thought of by the medical men in charge of dispensaries, now, to a large extent, these same persons looked upon the law with favor. At that time they seemed to care nothing at all for a State license and considered the formalities necessary to acquire one an unnecessary bother. Many of them now looked upon the license as a valuable asset, and they indicated that they believed applications for new licenses would be closely scrutinized and issued only in most desirable cases. The records kept were now very complete and were compiled each month. This was accomplished by asking at each inspection for the number of cases treated month by month. Of all regulations governing dispensaries those which were designed to restrict the dispensary privilege to the needy poor, and the requirement that doubtful cases be investigated, have caused the most opposition. Hospital superintendents had told him that if registrars should restrict the cases admitted to those who were clearly too poor to pay, the clinics would be so reduced that they could not retain the most experienced specialists on their medical staffs. However, this much-abused regulation was now more generally observed than formerly. He spoke of the reforms in the drug departments of dispensaries, but related instances that went to show that second-hand bottles and those brought by the patient were frequently used. He believed that in the State of New York, where the regulation of dispensaries by statute had been tried for six years, the problems that the dispensary presented were nearer solution than anywhere else. In conclusion, he said that the law had resulted: (1) In placing a permanent and desirable check upon the indiscriminate establishment of dispensaries throughout the State of New York; (2) it had, to a large extent, weeded out the institutions not having real merit; (3) it had secured the adoption of more uniform methods of administration; (4) it had greatly improved the record systems at the several institutions resulting in more trustworthy statistics; (5) it had secured better cooperation between dispensary officers and charitable societies; (6) it had strengthened the institutions now existing and closed the less desirable ones. The law had failed to effect a permanent check upon the total volume of medical and

surgical relief given at the dispensaries. He did not think this was the fault of the law, but was due to other causes: (*a*) The growing competition for cases, fostered by the medical schools, and the operation of dispensaries as feeders for hospitals; (*b*) the commercializing of the dispensaries to make them self-sustaining; (*c*) the subsidizing of the dispensaries by the public authorities.

**The Practical Value of the Investigation of Dispensary Cases.**—Prof. Edward T. Devine of Columbia University said that, so far as he could see, there was but very slight change in the dispensary abuse of to-day, comparing it to what existed a few years ago. If one judged by any effect which was produced upon the dispensaries by the reports and investigations of the Charity Organization Society, he would say desirable, material and direct effects of such reports and of such investigations were very slight indeed. There were 34 dispensaries in New York city, out of a total of 119 in the State; during the past year these 34 dispensaries had asked for reports of 1,500 cases, *i. e.* not more than one out of every 200 or 300 reported for investigation. He said that many of the registrars were not of a suspicious nature, and no doubt many that should be investigated escaped him. Professor Devine said he was far from being as pessimistic about dispensaries and their abuse as a whole, and that excellent effects could and would be produced by the enactment of dispensary laws. It was a simple thing for the dispensaries to cooperate with the State Board in the literal and complete enforcement of the law. The cost of these investigations was very reasonable, about $200 being paid for looking into these 1,500 cases. Professor Devine then considered the question, why the practical effect was so slight. The cases were apt to come in bulk after dispensary treatment was finished; there were two and a half times as many treatments as patients. Again proper records were not kept in the dispensaries and information was not obtainable. Of the 1,500 patients investigated only a very slight proportion were people who would be able to pay for services. Quite a number of the people said that they had gone to the dispensary at the suggestion of their own physician. The question of dispensary abuse was not so simple as many believed, especially those who have so much to say on the subject. The difficulty lay in the fact that with the best of intentions to restrict free medical treatment, they had not yet agreed upon standards as to who should pay for the medical treatment.

Dr. Joseph D. Bryant spoke of the manner in which records of cases were kept, or unkept, in the dispensaries a few years ago, and the scribbling that was done in such a hurried manner; to-day a great change had occurred, so far as the patients and the service were concerned. Dr. Bryant said he had much experience in a general way with dispensaries, especially in the appointment to the dispensary staff of young men who were, as a rule, first-class men, able, competent, with hospital experience in the majority of the cases. To be sure, many were late, detained, or did not come at all. He was not disposed to blame the visiting or attending physician or surgeon so much as those who were over them. Many claimed dispensary treatment because they were taxpayers. The question arose, Where should the line be drawn? The abuse of dispensary treatment he did not believe was so great as those opposing it would have us believe. Dr. Bryant believed in the dispensary law; he believed in rules, and practical rules, that had been established by the Commission, and he believed that they should be reasonably enforced. But he could not understand why Dr. Smith should feel so discouraged because the reports of those who followed him seemed marked with great improvement and created a strong incentive to continue the work. Dr. Bryant closed by saying that he was willing to influence, and aid in carrying into effect rational rules, and such aid would be given cheerfully, materially, and promptly.

Dr. G. W. Gay of Boston said that the Massachusetts Homeopathic Hospital was managed upon strictly business principles, the physician sharing with the hospital in whatever the patients were able to pay. A patient occupying private rooms and paying $15 or over had to pay the attending physician a reasonable fee. A member of the staff might take a private patient to the hospital and charge a fee if the patient paid $7 a week for board. The Boston Dispensary had over 40,000 patients annually. Its doors were wide open, and there was no inspection of any kind. In fact, with the exception of the Children's Hospital, so far as he knew had any system of inspection or of exclusion. For more than a quarter of a century a portion of the profession, for various motives, had educated the public to the idea that the hospital was the cheapest and best place to obtain advice and treatment in time of accident or sickness. The trend of the people toward the free clinics was never so universal as at the present time. It devolved upon the profession to correct this. There was no concerted action among hospitals and dispensaries in Boston looking to an abatement of the evil, yet considerable was being done by certain institutions. The Boston City Hospital received over 9,000 house patients, and more than 60,000 out-patients annually, and had no system of exclusion. At the Massachusetts Charitable Eye and Ear Infirmary during the three months that it had been in operation over a thousand patients had been directed elsewhere as not being worthy recipients of charity. Over 300,000 persons received practically free treatment in the hospitals and dispensaries of Boston every year. The surgical operations approximated 25,000. A conservative estimate of the commercial value of this work would be about ten million of dollars annually. That the profession was alive to the evils resulting from this wholesale, promiscuous and unrestricted charity was made evident recently when the reader sent a series of questions to over 400 physicians in his vicinity of all grades and schools and in all social and professional circles. The first question was this: "In your opinion is medical charity abused in the hospitals and dispensaries in Boston and the vicinity?" One gentleman, a noted pathologist not in active practise, answered in the negative; two replied, "Not much!" and 302 replied in the affirmative. Another query of the series: "Do you think that the patients who are able to pay for a private room in a hospital should, as a rule, pay the physician who takes care of them?" Eighteen said no, four were doubtful, and 205 said yes. Again: "Do you think that physicians who give their services to the poor should be required to treat the rich and well-to-do patients in our hospitals and dispensaries for nothing?" Ten said yes, two were doubtful, 310 said no, and most of them said it in italics. Massachusetts had no dispensary law; that she needed one was shown by the fact that the number of persons who annually received free treatment in the seventy-five hospitals and dispensaries in the city of Boston was equal to one-half of its entire population. After making all due allowance for repeaters and rounders and for the out-of-town patients, it would be safe to say that at least one-fourth of these people were able to pay for the necessary services and were unworthy of the charity which they received. In Philadelphia more than one-fifth of the population were annually treated as charity patients; in New York, with about ninety hospitals and nearly as many dispensaries, approximately one-fourth of the people received free medical treatment every year. Sir Henry Burdett was authority for saying that one-third the inhabitants of London depended upon charity for medical services. Boston seemed thus to hold the unenviable position of having the largest number of mendicants in proportion to her population of any of the cities under consideration. As she was said to be one of the richest cities *per capita* in the country, it was difficult to explain this peculiar condition, unless it was that a considerable number of these people were able to pay for what they needed and abused their privileges. Common sense and common honesty

were the requisites needed, and it was our duty to insist upon their ruling the management of our charitable medical institutions.

Dr. Frederick Sturgis spoke of a paper on this same subject that he had read several years ago before the New York State Medical Society, when he stated that the dispensary would control the physicians and not the physicians the dispensary if care was not exercised. In order to better understand the dispensary abuse, he applied for a position on the staff of one of the largest dispensaries in the city. In 1897 and 1898 there were some patients at these dispensaries who could pay the doctor a small fee, and in those days charity did mean something. The board did not want to make a business of charities, but Dr. Sturgis told the board that if they did not charge a small fee they would have to shut the doors. In a short time after the adoption of his suggestion this institution netted $12,000 a year and only ten per cent. of the applicants paid this money. The result of the dispensary law enacted and carried out seemed to have done extremely well. He believed the whole thing depended upon the doctors, and not upon anybody else. The general pith of the thing was this: you could not mix charity with business. The dispensaries should conform to certain rules. A dispensary should be only not alone in name, but in fact, and the State Board of Charities should insist that no remuneration should be received from any patient that applied for treatment or medicine; it should be purely a charitable affair, and the patients should not be charged even ten cents, as was done in some institutions to-day. He said he had been struck by the strong desire evinced by some physicians to start a dispensary. He did not entertain such a hopeful view of ever being able to cut off treatment of persons in dispensaries who were able to pay.

Dr. Egbert Le Fevre said that he had been connected for twenty years with dispensaries, and he could bear testimony to the efficiency of the present State law in many respects. At one time he investigated thirty-five patients that applied for treatment at the dispensary who seemed able to pay, and in every case he found they were worthy objects of charity. He asked what should be considered medical charity, and how could they discriminate between the deserving and the undeserving ones. These were most difficult problems. Many who really needed medical charity were those who were trying to live respectable, and trying to keep above the poor conditions which surrounded them. To all appearances they were unworthy objects of charity, yet, when investigated, they were found to be worthy. He said that the claim was made that medical colleges and institutions were the causes of charity abuse, and to this he took exception. Dispensaries were a necessary part of medical colleges to day, just as much so as the anatomical or the laboratory. Medical schools could not get along without this material for teaching. Most dispensaries connected with medical colleges provided the teaching material, and these patients gave something for the advancement of medical science, and were not objects of charity in the broad sense of the word, and they should be looked upon in a different light. The question of medical abuse should be thought of in another manner. How many physicians would care to be bothered with these charity patients? In this city it was absolutely impossible; therefore, the dispensaries for the poor would always be with us. Many of the physicians overestimated the abuse of medical charity when taken in its broad sense. We should look at it not only as a charity which covered a multitude of sins.

Mr. Edward T. Devine said, in answer to Dr. Le Fevre, that the danger was just as great among the dispensaries connected with the medical schools as elsewhere, and it was particularly true in the obstetrical practice, lying-in hospitals and allied institutions. The feeling was becoming widespread that there was no disgrace in accepting entire medical treatment in such cases. They were encouraged to expect not only medical treatment, but nursing treatment as well. These confinement cases presented dangers which were subtle and attacked the integrity of home and family life of society.

**Officers Elected.**—*President,* Dr. Francis J. Quinlan; *First Vice-President,* Dr. John A. Bodine; *Second Vice-President,* Dr. H. H. Seabrook; *Secretary,* Dr. William Ridgely Stone; *Corresponding Secretary,* Dr. Charles G. Child, Jr.; *Treasurer,* Dr. Charles E. Denison; *Member of Executive Committee,* Dr. Frederick P. Hammond for one year, Dr. Alexander Lambert for two years, Dr. H. A. Dodin for three years.

---

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, Held October* 19, 1905.

Dr. Charles L. Dana in the Chair.

**Wesley M. Carpenter Lecture: The Etiology of Syphilis.**—Dr. Simon Flexner delivered this lecture. He said that we could not definitely maintain that the etiology of syphilis had been certainly and wholly resolved, yet we were permitted to hope that this great event had possibly been achieved. We had in any case as a permanent addition to the knowledge of syphilis many important facts which came to us on established grounds, and which could not be affected by any fate overtaking the recent discovery of a special organism in syphilitic products. He thought that the successful inoculation of monkeys and apes with syphilis might be an aid to the study of the difficult and tangled subject. He gave a brief history of the experimental work done in the attempt to inoculate monkeys with the virus of syphilis, and he thought these experiments might be taken as proving not only the susceptibility of certain monkeys to the local lesions of syphilis,, but also the possibility of successive transmissions of the virus from animal to animal. However, since in the greater number of tests the results were *nil,* the positive results partook of the nature of accidents. The use of animals had already partially answered certain questions relating to the manner of entrance of the virus into the body, and the comparative virulence of different products of the syphilized animal; and it might also help to explain better than we now knew, the important question of reinfection in syphilis. Cutaneous inoculations with primary syphilides and primary lymphatic glands caused lesions; subcutaneous injections of chancre and condyloma produced no specific manifestation; insertion of infected glands directly in the peritoneal cavity was without effect. Defibrinated blood and blood serum from cases of recent syphilis in man, were innocuous when injected subcutaneously and intraperitoneally. Blood serum from syphilitic men was also without protective action against subsequent inoculation with active virus. The internal organs of recently infected monkey and ape possessed neither infective nor protective properties of high degree. These were some of Neisser's results, which if not conclusive, had yet a bearing upon the relative infectiousness of the blood and internal organs of syphilities, and bore on the questions of the avenue through which the virus ought to enter the body, and its capacity to enter directly into the interior of the body, and cause the secondary lesions of the disease without first having undergone incubation at some local superficial site. It had been ascertained that the poison was easily injured or destroyed by low degrees of heat. Particles of chancres and condylomata suspended in salt solutions or in aqueous humor, were rendered inactive upon the monkey and chimpanzee after heating for one hour at 51° C., and one-half hour at 60° C. Glycerin did not deprive the virus of its power to set up specific lesion in the ape. He said that evidence would seem to indicate that the microbe of syphilis was microscopic, not ultra-microscopic. He related the early experiments which revealed the existence of a spirillum in the interior of a chancre and in a mucous patch, and the points of interest connected with the discovery of the *Spirochæta pallida.* This organism was described by the discoverers as measuring from four to ten

microns. In width it varied from immeasurable thinness to one-half a micron. It had from three to twelve curves which were sharp and regular, and resembled the curves of a corkscrew. The organism was motile and the motions consisted of rotations on the long axis, forward and backward movements, and bending of the entire body. Flagella had not been seen. The character of the curves and the tenuous form made its identification relatively easy. As it was frequently the only spiral organism present in the preparations, there was usually no difficulty surrounding its identification. Its detection was not entirely easy since, with most stains recommended, it was tinged so lightly that it required practice in order to see it. The fluids obtained from the interior of syphilides were most favorable for examination since, in this location, the organism was scarcely ever attended by the coarser kinds of spirilla or with extraneous bacteria. The spirilla might be entirely missed among the saprophytes of the surfaces of ulcerating lesions. Dr. Flexner did not doubt that *Spirochæta pallida* occurred on the surface of these lesions, but evidently its growth was more restricted. This organism seemed not to thrive so well on dead as on living tissue. There was evidence that the pallida type might be simulated more or less closely by spiral microorganisms occurring in other pathological conditions than syphilis. Until a method of cultivation was found, we had to rely upon superficial characters. He was, however, convinced that the morphological characters of *Spirochæta pallida* were sufficient to identify it in specimen made from specific lesion; but he would not be surprised if similar morphological forms occurred in nature among the saprophytic organisms. The lesions that had been studied chiefly were those that appeared on the skin and mucous membranes, but nevertheless a small number of observations had been made on the blood and deep organs, while a fairly large number had been carried out with material obtained from the superficial lymphatic glands. The evidence was conclusive that primary lesions contained the spirochete either constantly or in the majority of cases. The later papers recorded fewer failures in finding the organism in chancre, condylomata, and mucous patches than the earlier ones. This was probably due to increased experience. The ulcerated papules of the mucous membrane of the mouth and throat seemed from his experience to contain the spirochetes in good numbers, and to be particularly suitable for demonstrating the organism. He assumed that should *Spirochæta pallida* be established as the cause of syphilis, for which he thought the evidence still inadequate, its presence would be sought systematically to confirm or prove the diagnosis. He thought it not improbable that valuable time might be saved in this way, but possibly some of the distressing and disfiguring stigmata of the disease might be avoided. His experience taught him that the spirochete occurred in gland juice, but that long search might be required to discover it. He had always endeavored to obtain aspirated fluid which contained masses of gland cells since the blood alone was not likely to yield the organism. He related a case in which the origin and nature of an eruption was in doubt in which he applied the test and found the organism. He did not claim that this case proved anything definite, but it showed possibilities. The finding of the spirochete in the regional lymphatic glands was imperative, if the organism was to have any position as the probable cause of syphilis. His experience did not suggest that the enlarged inguinal lymphatic glands contained an indiscriminate mixture of organisms. The question arose as to whether this organism invaded the deeper parts of the body, and as to whether it inhabited the circulating blood. Our knowledge on these questions was still highly defective. One experimenter had found the organism in aspirated splenic juice from a case of recently acquired syphilis; Hoffmann had obtained it from the juice of a submental gland in a case in which chancre of the lip existed. The circulating blood had been studied by a few investigators, but with a very small number of successful findings. He had studied the blood from two cases, but in neither were organisms found in the centrifugalized specimens. The blood should be selected from a part of the skin which was free from the lesions of the disease. There was abundant evidence of the distribution of this microorganism by the general circulation, from which it would appear to be taken out by the blood-vessels of the skin and mucous membranes, and possibly the internal organs. It seemed permissible to assume that the inflammatory and productive lesions were associated with, and perhaps caused by, this localization, although it must, for the time being, remain unsettled, whether the direct causes of the local reaction were vascular emboli or perivascular infections. He thought it would be of interest to learn whether the pallida existed in the vaccine pustule. He had made two experiments for this purpose, but conditions were not favorable and results were negative. The great length of time during which the microorganism of syphilis must, under some conditions, endure in a living state in the body, constituted a fact of high importance in the history of the recurrences and the congenital transmission of the disease. Hence, the question arose whether there was reason to believe that congenital syphilitic manifestations were associated with the occurrence of *Spirochæta pallida*, whether the number and distribution of this organism were such as to explain the lesions and the infectiousness of this disease, and whether the spirochete existed equally in those cases of congenital syphilis which were the offspring of a parent suffering with florid syphilis, and of another in whom the disease had not manifested itself for many years. The evidence at hand indicated that the organism survived in the body for many years, and was transmissible by a parent, herself free from the usual signs of the disease. He cited several cases illustrative of this point. The literature already contained the records of a sufficient number of examinations of infants, the subjects of congenital syphilis, to show that the organism regularly occurred in the disease. It had been detected in the lesions of the skin and intestinal organs, sometimes in large, sometimes in small numbers. In several cases studied after death, a general infection with the spirochete could be demonstrated. That congenitally syphilitic children were capable of infecting with syphilis healthy persons was, of course, established, and it was in conformity with this fact that Bakes and Panea could demonstrate the spirochete in the pharyngeal secretions of a congenitally syphilitic child. They also found them in the conjunctival secretion. So far, therefore, as a study of congenital syphilis could serve to establish *Spirochæte pallida* as the cause of syphilis, this had been done in part only. Perhaps data could be secured bearing upon the question whether the placental circulation was or was not previous to syphilitic virus, and thus to shed light upon those cases in which the child had become infected from a post-conceptional infection in the mother, and some light might be shed on that remarkable condition of supposed immunity. Dr. Flexner did not wish to be accused of having assumed that the spirocheta was the immediate cause of syphilis, for he said he was far from having this conviction. In regard to tertiary syphilis he said that a small number only of gumma and other tertiary syphilides had been studied for the pallida with almost constant negative results. The exceptions to the rule he thought must be viewed with suspicion for the present. He thought that the finding of the pallida in experimental primary syphilides in monkeys might have some significance. He had had three successful inoculations of syphilitic virus upon two macaco species of monkeys. Thus far, only one of the series had been studied for the pallida which were found present in small numbers. Kraus of Vienna had since followed the organism through two monkeys, the second monkey having been successfully inoculated with the virus from the first. One or two writers had claimed to find the pallida type of spiral in ulcerated tumors, and in a non-syphilitic papilloma. The question of similarity of species found in these growths with the pallida was a disputed one. The means at our command at present upon

which to base a classification, were too few and inadequate to settle so important a discussion. There would doubtless be described among the host of spiral microorganisms that must exist in nature forms which approached more or less closely to the pallida type. Until cultivation could be secured and experimental inoculation tested, we would have to be content with such considerations of their morphology staining reaction and relation to specific lesions, upon which data we would have to place our faith or disbelief that a great and epoch-making discovery had been made.

## AMERICAN PUBLIC HEALTH ASSOCIATION.

*Thirty-third Annual Meeting, Held in Boston, September 25, 26, 27 and 29, 1905.*

(Concluded from page 636.)

**Pathology and Pathogenesis of Smallpox.**—Dr. W. T. COUNCILMAN, Boston, presented a general consideration of the pathology and pathogenesis of this disease. He discussed the cause, mode of infection, mode of production of exanthema, immunity, secondary infections, and concluded with an experimental study of smallpox in monkeys.

**The Pathology and Etiology of Human Vaccina.**—Dr. WILLIAM TRAVIS HOWARD, Jr., Cleveland, O., discussed this subject under three heads:

*Material and Methods.*—The material upon which this study is based consisted of twenty-three pieces of skin excised from successful vaccinations on twelve men, each of whom was vaccinated in three places at the same time. The vaccinated areas were excised at various periods, from forty-eight to 168 hours after vaccination. As controls, skin was also excised from three unsuccessful vaccinations. The skin was fixed in Zluker's fluid, cut in paraffine, and sections were stained by various methods, eosine and methylene blue and Borrell's stain giving the best results.

*Pathology.*—The skin lesions of vaccina closely resemble those of variola, but are in general of more rapid growth and more constant. Contrary to the current belief, destruction of the epidermis and the formation of the vesicle are well-nigh complete in forty-eight hours after vaccination. The vesicle at this stage is composed of a reticular meshwork of coarser and finer strands of a hyaline fibrinoid material, formed from degenerated epithelial cells. The meshes of the reticulum contain fluid and fine, granular material, and but few cells. Swelling and reticular regeneration comprise the earliest cytoplasmic changes. Later, larger and smaller hyaline droplets appear, and the cells are transformed into hyaline fibrinoid material. Invasion of one epithelial cell by another, a conspicuous occurrence in vaccina of the rabbit's cornea, is also seen here. Nuclear degeneration is marked and takes several forms, the earliest being (1) swelling with increased prominence of the reticulum, (2) massing of the chromatin in the center and along the nuclear rim, and (3) wrinkling and retraction of the nuclear rim. Later, the nuclei becomes condensed and shriveled, and often fragment, with the dispersion of chromatin dust in the cytoplasm and intercellular spaces. Comparatively few blood corpuscles are found in the epidermis at this stage. The internal changes in the corium consist of edema, leucocytic infiltration, and swelling and proliferation of endothelium of the blood and lymph vessels. These changes are much more marked than in the corresponding stage of variola. In the 72-hour lesion all the epithelial cells below the horny layer are necrotic or have disappeared. The spaces of the reticulum are smaller and the strands coarser. In the mild and deeper parts of the lesion fibrin and leucocytes are prominent. The leucocytes are of the large and smaller mononuclear and eosinophilic types. On each side of the original vesicle, early secondary vesicles (analogous to those occurring at the margins of the variola vesicle) are conspicuous. Here the earliest changes in the epithelium may be traced; they are identical with those seen at the margins of the 48-hour lesion. The changes in the corium are still more intense. From seventy-two hours on, the chief additional changes are (1) condensation of the reticulum into a dense, hyaline material, containing broken-down leucocytes, (2) further necrosis of epithelial cells at the margins of the primary vesicle, and (3) persistence of the inflammatory changes in the corium. The scab or crust is formed by the condensation of the reticulum and exudate of the vesicle. It is thrown off on the renewal of the epidermis, the cells of which proliferate at the margins of the lesion and push their way under the scab.

*Etiology of Vaccina.*—No bacteria were found in any of the lesions. There were found in the early lesions structures corresponding to the primary cytoplasmic stage of cytoryctes variolæ, as described by Councilman and his coworkers and by Howard and Perkins in the early stages of variola and by Tyzzer in vaccina of the calf and rabbit. There was entire absence of the secondary cytoplasmic and the intranuclear stages of cytoryctes variolæ, which is in accord with Tyzzer's experience in vaccinia of the calf and rabbit. Therefore it is believed that vaccinia of man, the calf, and the rabbit, is caused by the primary cytoplasmic stage of cytoryctes variolæ, which is to be regarded as the asexual cycle of this organism.

**Experiments with Vaccine Virus.**—Dr. W. F. ELGIN, Glenolden, Pa., discussed this subject under various heads. In concluding, he called attention to two important questions in connection with the production of vaccine virus—purity and potency. It was shown that, up to the present time, no sure method had been universally accepted which would accomplish both in virus prepared for general distribution. Attention was also called to the fact that many of the laboratories, particularly those under state control in this country and abroad, had practically given up bacteriological control as a routine procedure. The question that was propounded to this association last year was again emphasized, as to "How far we are justified in clearing vaccine of bacteria at the expense of its potency?"

**The Dissemination of Tuberculosis as Affected by Railway Travel.**—Dr. CHARLES B. DUDLEY, Altoona, Pa., stated that during the past few years the railroads had been called quite sharply to account for their remissness in sanitary matters. It was obvious that if the spread of tuberculosis was largely due to contact of the healthy with those who were affected, the railroads under present conditions could hardly be held responsible, since there was no means by which ticket agents or conductors could be sure as to diagnosis, and to refuse transportation on an erroneous diagnosis would lead to serious trouble. If, on the other hand, the spread of tuberculosis was largely due to pulverized dried sputum, the railroads might fairly be regarded as responsible, and be required to take greater precautions. The danger of infection from dried sputum on cars had, however, been greatly magnified. As items pointing in this direction, he mentioned: (1) The length of time of passengers on cars was small at the longest, while prolonged exposure seemed to be agreed upon as a marked characteristic in the acquisition of this disease; (2) tuberculous sputum was extremely difficult to dry; (3) even though artificially dried, it was extremely difficult to pulverize; (4) although artificially dried and pulverized, it was heavy, and did not readily remain suspended in the air; and (5) cars, from their construction, afforded very great advantages to the access of sunlight and air, which were more or less fatal to this form of disease germ. Furthermore, if cars were such a menace as had been supposed, it would seem that employees of the sleeping car companies and of the railroad companies, whose occupation required that they spend much time on the cars, would be largely affected. The statistics gathered at the last census, as reported by Dr. George M. Sternberg in his book, "Infection and Immunity," showed that railroad men were less affected by tuberculosis than the average of persons of the whole country. Furthermore, information from

the Pullman Company did not show that the colored porters who were supposed to be predisposed to tuberculosis, and who spent a large portion of their lives on sleeping cars, were more affected than others. Also the records of the Pennsylvania Railroad, in connection with its Relief Department, showed that passenger conductors and brakemen were not as infrequently affected with tuberculosis as were the freight conductors and brakemen. Again, bacteriological examinations of the air from cars known to have transported tuberculous patients, the results of which had been recently published by Dr. J. J. Kinyoun, did not indicate any alarming prevalence of tubercle bacilli in these cars. Finally, experiments made for the purpose, as to the behavior of tuberculous sputum on carpets and plush, showed that analogous material was less likely to become dry and to be pulverized and disseminated in the air than if this material was on a hard, non-absorbent surface.

**A Few Points in Regard to Car Sanitation.**—Dr. HENRY M. BRACKEN, Minneapolis, Minn., said that to advance car sanitation it was not only necessary to improve the methods of car construction, but to instruct railway employees in the proper care of cars. Special duties should be imposed upon them as to ventilation, car cleanliness, etc. Their instructors should be medical men connected with railway companies and familiar with sanitary problems. He pointed out the dangers from spitting upon the floors or furnishings of cars. He discussed car cleaning, and said more attention should be given to this subject. The drinking water for railway cars should be of unquestionable quality, distilled or equally pure, and should be kept out of reach of passengers except as drawn from the faucet; it should be stored in well-cleaned cans or coils, and iced with well-selected ice that had been handled in a cleanly manner. He advocated improvement in the toilet rooms of the day coaches.

**The Restriction of Contagious Diseases in Cities.**—Dr. CHARLES V. CHAPIN, Superintendent of Health, Providence, R. I., said that municipal sanitary practice was at first based on the filth theory of disease. During the last twenty-five years it had been largely determined by the recognition of the contagiousness of the infectious diseases. Future practice would be modified by specific knowledge as to the etiology of each disease. The chief sanitary discovery of recent years was that unrecognized foci of infection were the principal factor in the spread of contagious disease. This was bound to modify present methods, rendering them less burdensome. Stringent measures could not stamp out disease. All that could be hoped for was to limit extension from the recognized cases. This could be done substantially as well by moderate means. No restriction of personal liberty was advisable in influenza, pneumonia, typhoid fever, or cerebrospinal meningitis. In measles and whooping-cough there should be some restriction of school attendance and the occasional closure of school. In scarlet fever and diphtheria the patient should be isolated for three or four weeks, other children in the family kept from school. Wage earners should rarely be interfered with. The use of cultures to terminate isolation in diphtheria as ordinarily practised was illogical. Hospital facilities were needed only for the poor. Official disinfection did more harm than good. When the above diseases appeared for the first time in small places, or, rather, when rarer diseases appeared in large cities, the most energetic measures were called for.

**Modification of Present Port Inspection.**—Dr. A. H. DOTY, Health Officer, Port of New York, pointed out the necessity for a change in the present method of quarantine inspection, which would insure a more thorough examination of passengers and crews on incoming vessels. He called attention to the necessity of a closer observation for the detection of mild or ambulant cases and recognition that this type of disease was commonly the cause of outbreaks, the origin of which was unknown, and which were frequently improperly attributed to infection by cargoes, clothing, etc. While five days might be regarded as the maximum period of incubation of yellow fever, the fact that a person had been five days away from an infected area should not permit him to pass quarantine without having his temperature taken and the use of other means to detect the presence of mild cases. This should also be applied to the examination of those held to complete the period of incubation of other diseases. Furthermore, the possibility of occasional cases having a longer period of incubation than that generally accepted must be remembered. He spoke of the detention, annoyance, and expense to commerce caused by unnecessary disinfection.

**Communicability of Cerebrospinal Meningitis and the Means of Controlling Its Spread.**—Drs. WILLIAM H. PARK and CHARLES BOLDUAN, New York City, stated that fifteen hundred cases of cerebrospinal meningitis occurring in New York City investigated by Dr. Bolduan revealed the fact that 200 of the patients had been in direct contact with other patients, and that many of these latter showed evidence of infection from still others. These 200 represented eighty-eight families. Bacteriological examinations conducted by Dr. Goodwin in the laboratory revealed that about half those sick with meningitis had abundant meningococci in the nasal cavity during the first two weeks of the disease, and that the nasal cavities of five attendants were badly infected. The conclusion was drawn that the meningococci were spread by the discharges from the nose and mouth of the sick and those in immediate contact with them.

**Method of Securing More Uniform Instruction and Co-operation in Health Work.**—There was a symposium on this subject. Drs. F. C. ROBINSON, Brunswick, Me., and W. T. SEDGWICK, Boston, discussed educational cooperation with the general public in public health work. Dr. H. C. ERNST, Boston, spoke of graduate and undergraduate instruction in hygiene in universities and medical colleges. Mr. W. D. FROST, Madison, discussed the teaching of hygiene in the public schools. Dr. S. H. DURGIN, Boston, pointed out the present regulations and laws as to the qualifications and methods of appointment of executive and technical health officers; while Dr. H. D. PEASE, Albany, emphasized the importance of sanitary conferences and schools of instruction for health officers.

**Lessons to be Learned from the Present Outbreak of Yellow Fever in Louisiana.**—Dr. JAMES CARROLL, Washington, D. C., read a paper on this subject, in which he drew the following conclusions: "(1) The methods now in vogue for handling and reporting cases of yellow fever in cities exposed to the importation and epidemic prevalence of yellow fever in the United States are generally lax and need to be changed. (2) It is time to acknowledge that many cases of yellow fever cannot be diagnosed with certainty in the early stages, and the only real safeguard in the epidemic zone, during the epidemic season, is to handle all recent cases of fever, not diagnosed, as if they were yellow fever. (3) Bilious remittent fever, occurring in the yellow-fever zone, should be regarded as yellow fever, unless it is shown by microscopical examination that the infection is one of malaria, relapsing fever, etc. (4) Physicians who make an early diagnosis of yellow fever are often subjected unjustly to severe criticism, and as the result they naturally hesitate to commit themselves even when the diagnosis is fully justified. They should be relieved from this duty by a special diagnosis commission in every city exposed to the danger of infection. The commission should be composed of three eminent diagnosticians who should be controlled by the department of health, and whose duty it would be to examine promptly and report in writing upon every case of fever occurring during the season from about May 1 to October 31. Practising physicians should be required, under penalty, to report promptly to the health authorities during the season in question every case of fever coming under their observation, whether in a patient or not. The health authorities should immediately notify the members of the commission, whose duty it would

be to visit the case at once and every day following until the diagnosis was made clear or the case shown to their satisfaction to be not one of yellow fever. All cases suspected of being yellow fever should be treated in a mosquito-proof ward or hospital set apart for the purpose and under the control of the diagnosis commission. Appointments of resident physicians or clinical assistants to have charge of the patients should be made only on the recommendation of the diagnosis commission. The decision of the commission in the matter of diagnosis or the removal of a patient to the hospital should be final. (5) In exceptional cases, to be decided by the commission, certain patients might be retained in their homes, protected by mosquito nets and wire screens, awaiting a final decision. The responsibility for the proper disposition of such patients should rest upon the commission, who should be aided, when necessary, by sub-commissions appointed upon their recommendation. (6) The members of the commission should be paid a stated fee for each visit to a patient necessary to establish the diagnosis or decide upon his removal to hospital. In this way the expense to the city would be trifling, the responsibility for diagnosis and treatment would rest upon the commission, and the occurrence of an epidemic would be impossible, if the law were rigidly enforced."

**Yellow Fever in Mexico.**—Dr. Eduardo Licéaga, Mexico City, discussed this subject under the following heads: Isolation of the patients; disinfection of the home occupied by the patient; destruction of the mosquito larvæ. Since they had instituted modern methods in Mexico, yellow fever had been diminished to a marvelous extent. He predicted that at no distant date this disease would be completely exterminated, as it had been in the Island of Cuba.

**Etiology and Prevention of Yellow Fever.**—Dr. John Guiteras, Havana, Cuba, confined his remarks to new points that had arisen in the struggle with yellow fever during the past year. The French Commission from the Pasteur Institute, experimenting in Rio Janeiro, had produced a case of yellow fever by applying to a non-immune mosquitos raised from eggs laid by an infected mosquito. This raised a very interesting question as to the transmissibility of yellow fever by the progeny of infected mosquitos. The speaker thought in Havana that they had by experimentation settled this matter, that an infected mosquito could not transmit infection through its progeny or eggs. He was inclined to believe from a perusal of the experiments of the French Commission that there was some mistake. Marchoux, the French experimenter, acknowledged that he had only one such case. He worked in an infected locality, and it was possible. Dr. Guiteras thought, that the man was accidentally bitten by another infected mosquito without Marchoux knowing it. There was another argument against the transmission of yellow fever by the progeny of infected mosquitos. It seemed to him that it would have been impossible to have eradicated yellow fever in Havana as they had done if the theory of the French Commission of the transmission of the disease by the progeny of infected mosquitos was true. In getting rid of yellow fever in Havana, they began to attack the epidemic in the beginning, so that it was comparatively easy to wipe out the disease in that city. This would have been impossible if the progeny of infected mosquitos had been also infected. Another interesting point to which Marchoux called attention was that one source of infection was to be found in young children affected with a mild form of yellow fever. Dr. Guiteras said this was not new, as Blair, Chaillé, and himself had pointed this out in their investigations at Key West and in Havana, and they had shown that there were many cases of unrecognized mild yellow fever among children who became sources of infection through the mosquito. It was a study of the problem of yellow fever in young children in the yellow-fever zone that led him to call attention to and insist upon the great danger of mild cases of yellow fever. He had been calling attention to this for many years, not only in cases of young children but also in young adults, especially of the colored population, who were apt to develop mild cases of the disease. These he had always considered the most dangerous transmitters of the infection.

*Early Diagnosis.*—Special attention was directed to the high percentage of hemoglobin found in yellow fever cases, which he said was an important differential diagnostic point between this disease, typhoid fever, malaria, and influenza, three affections that were frequently confounded with yellow fever. In influenza, typhoid fever, and malaria the percentage of hemoglobin was low—70, 75, and perhaps 80. In malaria and typhoid fever, on the second day of the disease, one noticed a decline in the percentage of hemoglobin in the blood. On the other hand, in yellow fever the percentage of hemoglobin was high, very often 100, sometimes above 100, during the first three, four, and five days of the disease, and rarely below 90. If the percentage of hemoglobin went below 90, and the case proved to be one of yellow fever, he considered that there was a complication, or the patient previously suffered from malaria. Another point that had been of considerable aid to him during the present epidemic of yellow fever, especially in Florida, where they were confronted with the existence of an epidemic of dengue, and where the question came up as to whether or not yellow fever was present, was the diazo-reaction of Erhlich. The diazo-reaction of Ehrlich was an important diagnostic sign in typhoid fever, but it might be present in other infectious diseases. He could say positively, however, that this was never present in uncomplicated cases of yellow fever, and on two occasions his mind was completely relieved as to the existence of yellow fever during the past summer in the South by finding the Ehrlich diazo-reaction in the urine. He was therefore able from his experience in Havana to exclude at once yellow fever in these two cases. Another diagnostic point was the presence of albumin in the urine. Albumin in the urine was a characteristic sign of wellow fever. He insisted more than he had ever done before upon the importance of this symptom, and upon a certain interpretation that must be given to the presence of albumin in the urine. After a careful study of many kinds of fever in Havana, he had found that albumin in the urine was more common in other infectious diseases than he had thought. It was common in cases of influenza and of typhoid fever, but not so common in malaria. It was only occasionally found in cases of malaria. Albumin in the urine was found in cases of dengue. The special point he brought out was that the quantity of albumin found in the urine in cases of yellow fever was out of all proportion to the other symptoms present.

Dr. Guiteras concluded his remarks by referring to the methods of disinfection that were being employed in New Orleans, and complimented the physicians in charge of yellow fever cases in Louisiana on the efficient work they were doing. He spoke of the use of superheated steam for the destruction of mosquitos, saying that this agent was being used to great advantage in the present epidemic in Louisiana, and it was a valuable and efficient adjunct.

**The Collection and Preservation of Samples of Sewage for Analysis.**—Mr. Stephen De M. Gage and Mr. George O. Adams, Massachusetts, stated that in collecting samples of sewage and the effluents of sewage filters for analysis, more representative samples would be obtained if each sample was the average of a number of small samples taken at short intervals. The preservative used must prevent chemical changes. Two preservatives which best met these conditions were chloroform and carbon bisulphide. Both would destroy the bacteria and prevent all bacteriolytic decomposition; both were sparingly soluble in water, and, being heavier than water, they did not evaporate rapidly, requiring small amounts to be used in each sample. Both

were comparatively inexpensive, and neither interfered with any of the usual analytical methods.

**The Cause, Course, and Treatment of Beriberi.**—Dr. HAMILTON WRIGHT, Beriberi Research Commissioner, London School Tropical Medicine, referred to previous publications on this subject. The cause of the disease appeared to be a bacillus which gained entrance to the alimentary canal in contaminated food and drink, choosing for its active site the stomach and small intestine, *i. e.* chiefly the pylorus and the duodenum. The disease began in necrosis of the mucosa; congestion; small-celled infiltration; seemingly an extracellular toxin was formed which poisons the peripheral terminations of the fibers in the systems of neurons, inducing symmetrical, bilateral, sensimotor, cardiac, and vasomotor paralyses. A description of the symptoms, of the microorganisms which seem to be the cause of the disease, and the course of the disease were given, together with a working theory of the cause and nature and treatment. Reference to preventive measures, such as care in the disposal of feces, etc., with statistics in jail beriberi before and after the adoption of such measures, were given.

**Methods of Bacteriological Examination of Milk.**—Dr. FRANCIS H. SLACK, Boston, Mass., described the apparatus and methods in use at the Boston Board of Health Laboratory for collecting, plating, incubating and counting; also for direct examination of milk sediments and the microscopic estimate of the number of bacteria present, together with pus and streptococci determination. The methods of examination described were recommended as a system which had been reasonably successful in practice for city laboratory work where quick reports were needed as well as the accurate examination of large numbers of samples.

**Consideration of Some of the Problems and Difficulties of Bacteriological Diagnosis.**—Mr. BERT R. RICKARDS, Boston, discussed some of the everyday problems and difficulties met with in making bacteriological diagnoses. Each disease discussed was considered, first, in relation to any special points connected with the preparation of the specimen submitted; secondly, in regard to those problems which have to do with accuracy in diagnosis; and, thirdly, with reference to results and their relation to the clinical aspect of the case.

**Longevity of the Bacillus Typhosus in Surface Waters and Sewage.**—H. L. RUSSELL and C. A. FULLER, Madison, Wis., contributed a paper on this subject. From their experimental work it appeared that in relatively pure waters of a surface character the typhoid bacillus was capable of retaining its vitality for about eight days. The results of their experiments confirmed and extended on a broader basis the data obtained in the investigations made on the Chicago Drainage Canal. They had been carried out under sufficiently diverse conditions to warrant the belief that the typhoid organism in natural sewage did not live as long as it would in relatively pure water.

**Mosquito Transmission of Yellow Fever.**—A committee consisting of Drs. John Guiteras, Frederick Montizambert, P. H. Bailhache, James Carroll, William Bailey, and Eduardo Licéaga, presented the following preambles and resolutions:

"*Whereas*, The results obtained during the present epidemic of yellow fever in New Orleans by the methods of mosquito extermination, and by the prevention of the access of the mosquito to the patients, have been far in advance of the results obtained by the older methods; and

"*Whereas*, It has been possible by the new methods to hold in check and gradually to reduce an epidemic that has taken a firm foothold in the midst of the largest non-immune population that was ever exposed to yellow fever; therefore, be it

"*Resolved*, (1) That the association sees in these results a further confirmation of the view that yellow fever is naturally transmitted only by the bite of an infected mosquito. (2) That the association is of opinion that an efficient plan of defense against the propagation of yellow fever at the beginning of an epidemic can be easily established upon the basis of this doctrine. (3) That the successful carrying-out of such plan depends upon a thorough understanding of the mosquito doctrine by the people, and the support that they may give to the prompt and frank reporting and to the proper handling of the first cases and of all suspicious cases. (4) The association wishes further to congratulate the Public Health and Marine Hospital Service for the brilliant work done by Dr. Joseph H. White and his colleagues in New Orleans, and to urge upon all concerned that the said service be called upon to take charge permanently of maritime quarantine along the Gulf Coast."

These resolutions were adopted.

**Officers.**—The following officers were elected: *President*, Prof. F. C. Robinson, Brunswick, Me.; *First Vice-President*, Dr. J. J. Kinyoun, Glenolden, Pa.; *Second Vice-President*, Dr. Domingo Orvananos, Mexico City, Mexico; *Third Vice-President*, Dr. Richard H. Lewis, Raleigh, N. C.; *Secretary*, Dr. Charles O. Probst, Columbus, O.; *Treasurer*, Dr. Frank W. Wright, New Haven, Conn.

Mexico City, Mexico, was chosen as the place for holding the next annual meeting, in 1906.

---

## Books Received.

*While the* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

IMMUNITY IN INFECTIVE DISEASES. By ELIE METCHNIKOFF. Translated from the French by Francis G. Binne. 8vo, 591 pages, illustrated, muslin. The Macmillan Company, New York. Price, $5.25.

THE NATIONAL STANDARD DISPENSATORY. CONTAINING THE NATURAL HISTORY, CHEMISTRY, PHARMACY, ACTIONS, AND USES OF MEDICINES. By various authors. 4to, 1,858 pages, illustrated, muslin. Lea Brothers & Company, Philadelphia. Price, $7.25 net.

CLINICAL DIAGNOSIS: THE BACTERIOLOGICAL, CHEMICAL, AND MICROSCOPICAL EVIDENCES OF DISEASE. By RUDOLPH V. JAKSCH, M.D. Fifth English edition. Edited by ARCHIBALD E. GARROD, M.A., M.D., F.R.C.P. 8vo, 602 pages, illustrated, muslin. J. B. Lippincott Company, Philadelphia.

ARBEITEN AUS DEM PATHOLOGISCHEN INSTITUT DER UNIVERSITÄT HELSINGFORS. Herausgegeben von PROF. DR. E. A. HOMEN. Bend 1, Heft 1-2. 4to, 378 pages, illustrated, paper. S. Karger, Berlin.

A TEXT-BOOK OF DISEASES OF WOMEN. By BARTON COOKE HIRST, M.D. Second Edition. 8vo, 741 pages, illustrated, muslin. W. B. Saunders & Co., Philadelphia. Price, $5.00 net.

LECTURES UPON THE PRINCIPLES OF SURGERY—Delivered at the University of Michigan. By CHAS. B. NANCREDE, A.M., M.D., LL.D. Second Edition. 8vo, 407 pages, illustrated, muslin. W. B. Saunders & Co., Philadelphia. Price $2.50 net.

SURGICAL ASPECTS OF DIGESTIVE DISORDERS. By JAMES G. MUMFORD, M.D., and ARTHUR K. STONE, M.D. 8vo, 395 pages, illustrated, muslin. The Macmillan Company, New York. Price, $2.50.

METHODS OF ORGANIC ANALYSIS. By HENRY C. SHERMAN, Ph.D. 8vo, 245 pages, muslin. The Macmillan Company, New York. Price, $1.75.

A PRACTICAL TREATISE ON SEXUAL DISORDERS OF THE MALE AND FEMALE. By ROBERT W. TAYLOR, A.M., M.D. Third Edition. 8vo, 525 pages, illustrated, muslin. Lea Brothers & Co., New York and Philadelphia.

TRANSACTIONS OF THE WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION. Fourteenth Annual Meeting, held at Milwaukee, Wis., December 28 and 29, 1904. 8vo, 474 pages, illustrated, muslin.

LES INDICATIONS DES INTERVENTIONS CHIRURGICALES DANS LES MALADIES INTERNES. Par le PROFESSEUR DR. HERMANN SCHLESINGER. Part 3. 12mo, 33 pages, paper. Vigot Frères, Paris.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 4, 1905:

| | Cases | Deaths |
|---|---|---|
| Measles | 169 | 5 |
| Diphtheria and Croup | 279 | 22 |
| Scarlet Fever | 79 | 6 |
| Smallpox | .... | .. |
| Chickenpox | 132 | .... |
| Tuberculosis | 363 | 150 |
| Typhoid Fever | 77 | 11 |
| Cerebrospinal Meningitis | 9 | 15 |
| Typhus Fever | ..... | ..... |
| Yellow Fever | ..... | ..... |
| Cholera | ..... | .. .. |
| Totals | 1,108 | 209 |

**The Results of Decapsulation of the Kidneys for Nephritis in Children, with Report of a Case in a Child of Twenty-six Months.**—Edwin E. Graham, on studying the literature of this subject, discovered reports of only eleven cases of children operated upon, while hundreds of adults have been treated. He gives a very brief résumé of these cases. The description of his own case is most interesting. The patient was twenty-six months old. The family history was good, and the child was in excellent health until seven months of age, when she had a mild attack of scarlet fever. Three weeks later dropsy developed, and still later the urine contained a large amount of albumin and many casts. The child continued to grow worse and was admitted to the hospital. Medical care for a week failed to be of benefit, and an operation was performed. Both capsules were easily separated and pushed thoroughly forward anteriorly and posteriorly. The result was most satisfactory, and at last reports the child appeared to be perfectly well. The writer believes that if it is possible to separate earlier the cases suitable for this operation from those in which such treatment is likely to result fatally, a decided decrease in the total mortality might be attained. He believes that chronic interstitial nephritis associated with arterial sclerosis, perhaps with changes in the heart and liver, does not offer much prospect of a cure from a decapsulation. He thinks that if the nephritis is of comparatively recent origin, and if under the best medical care, the case does not improve, but grows progressively worse, and there is more or less renal insufficiency, a rapid improvement may follow decapsulation. A true nephritis is probably rarely, if ever, one sided, and it seems to be a growing practice to operate on both kidneys. Probably renal mobility is a factor of very little importance in relation to the symptoms of the child. Careful bacteriological examination of the urine collected by catheterization of the ureters is important, for the bacteria present may decide the question of a decapsulation or a nephrotomy. As to the ocular symptoms, the eye ground changes are less significant in the child than in the adult. The form of nephritis most benefited by operation is the acute and subacute cases, and those only which are not doing well under appropriate medical treatment.—*Archives of Pediatrics.*

**Subcutaneous Hebotomy.**—Sellheim has performed the operation three times with excellent results. In each case a hematoma of considerable size formed immediately after the operation, but only in one case did this give rise to anxiety; and even in this instance it was absorbed without serious consequences. In carrying the saw around the bone Sellheim considers it very important to guide it with the gloved finger in the wound, in order to be sure of making the cut in the right direction; and he also points out the necessity which exists in many cases of sawing a little more after complete division of the bone, in order to insure division of the anterior ligaments, which are sometimes very heavy, and, if not cut through, prevent the necessary separation of the bone ends.—*Zentralblatt für Gynäkologie.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the period from October 20 to November 4, 1905:

SMALLPOX—UNITED STATES.

| | | Cases. | Deaths. |
|---|---|---|---|
| California, Los Angeles | Oct. 14–21 | 2 | .. |
| San Francisco | Oct. 14–21 | 3 | .. |
| District of Columbia, Washington | Oct. 21–28 | 3 | 1 |
| Illinois, Chicago | Oct. 21–28 | 2 | .. |

### THE TREATMENT AND CARE OF ADVANCED CASES OF PULMONARY TUBERCULOSIS.*

By S. A. KNOPF, M.D.,

NEW YORK.

The subject which the officers of the Committee on Clinical Medicine of our association have assigned to me is indeed an important one, and I approach it with great hesitation. In my humble opinion there is nothing in the whole domain of medicine which is more important, and which demands from the physician more skill, more judgment, more perseverance, more patience, and, may I add, more kindness of heart, than the treatment of advanced cases of pulmonary tuberculosis.

The responsibility which rests upon the family physician treating a consumptive in the advanced stage is as great, if not greater, than that of the surgeon in the presence of a patient on whom he is to perform a difficult capital operation. There are more cases of advanced tuberculosis to be treated than any other disease, and there is no condition more difficult to define than the one designated as advanced pulmonary tuberculosis. There is no disease in which the prognosis as to the time of the final issue is more difficult than in pulmonary tuberculosis after the incipient stage has been passed, for, has it not been the experience of all of us that an apparently light and seemingly favorable case would be fatal within a few months, while a relatively advanced case would linger for years, or even get well? Again, there is no disease where so much can be done to render the patient comfortable and hopeful as in pulmonary tuberculosis in the advanced stage. There is no disease where one case in a family can more readily become the cause of infection of other members, particularly in the stage when the consumptive begins to be confined to the close association of the family members only. Again, in no other condition can the teachings and the guidance of the family physician be productive of so much good, even though the family may be predisposed to the disease under consideration. By the inauguration of timely preventive treatment in such a family the disease can be limited to the one already afflicted, and all other members can be made strong and vigorous. Finally, there is no disease in which the successful management and treatment depends so much on the personal equation of the doctor as in an advanced case of pulmonary tuberculosis.

By advanced pulmonary tuberculosis we generally understand all cases which can no longer be classified as incipient or early. I believe that by incipient we usually mean early cases in relatively young people; and by early I mean, of course, a disease of relatively short duration, with a fairly good physique and nearly normal chest formation, with slight rise of temperature, a normal or only occasionally rapid pulse, the systemic derangement slight, cough and expectoration moderate. The physical examination usually reveals an involvement of only one side, an increased fremitus, a slight dullness on percussion, not extending over the fourth or fifth rib anteriorly, and auscultation reveals the prolonged respiratory sound, rough breathing, sometimes cogwheel breathing, and râles of relatively less magnitude. Even if both apices are slightly involved, and other conditions fairly good, we are justified in calling the case incipient, or at least early.

To do justice to my subject, I must divide the advanced cases into two large classes, namely, ambulant and bed cases. Among the ambulant advanced cases I would place all those who are most of the time without fever, and in whom the systemic disturbances are only a little more aggravated than in the early stage, and who should be treated as incipient with the one exception that if there is a loss of weight instead of gain, or at least retention of their normal weight, they should be put at rest in bed or on the reclining chair, constantly exposed to the open air. I would make this condition *sine qua non*, whether there is fever or not, and to facilitate the metabolism and bring about a gain of weight, I would have them massaged daily during the apyretic hours. Hydrotherapy should be used with all ambulant cases as a tonic and stimulant. The diet should be good and nutritious, of milk, eggs, meat, vegetables, and fruit; in short, they should have the hygienic and dietetic treatment the same as the incipient cases, and their rest cure should alternate with properly gradated breathing exercises. In some the medicinal symptomatic treatment will have to be resorted to where aëro- and hydrotherapy do not suffice to overcome increased cough, digestive disturbances, local pains, etc. It goes without saying that the advanced ambulant tuberculous case needs even more personal supervision, guidance, and direction than an incipient case. Any imprudence on the part of the patient may aggravate his condition beyond repair, and unless the family physician can see his ambulant tuberculous patient daily, or place him in charge of an intelligent nurse or a trained member of the family, such a patient would certainly be better off in a sanatorium. Unfortunately, there are not enough sanatoria for either rich or poor for this class of cases. In a number of cities in this country and in Europe we are treating them in our clinics and dispensaries. While, owing to an insufficient hygiene at home, the result in these cases has been unsatisfactory, a fair amount of good has been accomplished through the work of the dispensaries, particularly when a system of regular visits by trained nurses to the homes of the patients has been connected with the dispensary treatment. The hygiene of the home and the dietetic management of the patients are, as a rule, materially improved by these trained coworkers of the dispensary physician.

One thing, however, which we physicians and our health boards should bear in mind in regard to the

*Read before the first annual meeting of the National Association for the Study and Prevention of Tuberculosis, at Washington, May 19, 1905.

management of these ambulant and advanced tuberculous patients is that they, when careless, really constitute the greatest danger. It is this class of patients who must be considered the most frequent source of infection. The careless, ignorant, or helpless consumptive, when confined to his bed, is not

Fig. 1.—Aluminum spit-cup for bedside.

likely to infect more than the four walls and the floor of his room, but the ambulant advanced case, being up and about, doing odd jobs, or even following his regular occupation, can, if he is careless, disseminate his 7,000,000,000 bacilli daily with the greatest ease. Of all the tuberculous patients he should be the most disciplined and most carefully trained, and in many cases it is wise to tell him that by expectorating anywhere except in a proper receptacle he lessens materially his chances for recovery. The method of disposing of the expectoration, which experience has taught me they are most willing to abide by is not the pocket flask of metal or glass, or the pasteboard purse, but a method which will not attract attention to their infirmity. I advise these patients, if they are men, to have two pockets in their trousers lined with impermeable material, and when they leave in the morning to fill one with either cheap handkerchiefs or muslin cut in squares to look like handkerchiefs, and then use the empty pocket for the reception of the soiled ones. These soiled cloths are to be burned on the patient's return home. I advise the women patients to have a leather bag with two compartments and have them follow the same rule. Such persons must be urged always to wash their hands before touching food.

Another important item is to teach these patients that the moment they become feverish they must return home, and instruct them also what to do in case they should be seized by a hemoptysis. I make it a practice to tell all my patients that a pulmonary hemorrhage may happen, but that it does not necessarily lessen their chances of recovery; and to the ambulant I add that, in case of a slight hemorrhage, they should go home, and if they have a severe hemorrhage, they should seek a place to lie down and send for a carriage to take them home or to a hospital.

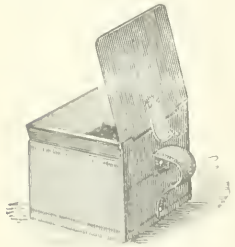

Fig. 2.—Frame for Seabury & Johnson's sputum box.

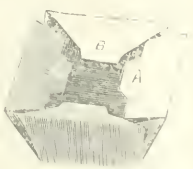

Fig. 3.—Folded pasteboard cup for Seabury & Johnson's frame.

And now we come to the second class of advanced, or bed cases. I will subdivide these into four classes, namely, sanatorium patients, hospital patients, home patients—well-to-do, living either in cities or country, and the consumptive poor, living in villages or in city tenements.

The treatment of advanced cases in a sanatorium has occupied the attention of sanatorium physicians in this country and abroad ever since Brehmer started the sanatorium treatment 50 years ago. There has always been a decided disinclination to receive patients in the advanced stages into sana-

Fig. 4.—Nickel-plated, oval pocket flask, manageable with one hand.

toria, or even to keep cases when they are no longer considered favorable. There is, of course, a justifiable excuse for this policy, as there not being room for all, the advanced cases take up room that might be given to those who still have a good chance for recovery. The managers of pay sanatoria are always anxious to make a good showing, which is not possible when advanced cases are received or previously early cases allowed to remain after their condition no longer assures a favorable issue. It is usually stated also that advanced cases act as depressing factors on the rest of the patients. Whether or not the policy just referred to is a wise or humane one, I do not wish to judge here, but I know from personal experience that there is nothing more difficult in our own country than to find a sanatorium willing to take an advanced tuberculous patient, even where there are slight prospects of recovery. This is a sad condition of affairs, and I sincerely hope that existing sanatoria will either make a division for advanced cases willing to pay,

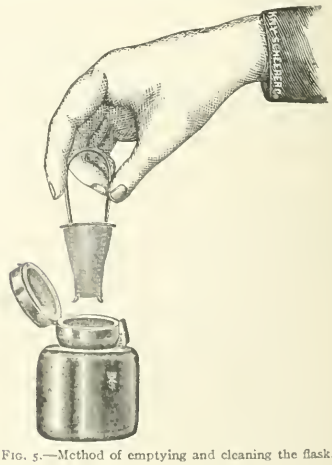

Fig. 5.—Method of emptying and cleaning the flask.

or that special sanatoria for such cases may be established.

How should such patients be treated and taken care of in a special institution? The general hygiene must, of course, be the same as in all well regulated institutions for the treatment of pulmon-

ary tuberculosis. If at all possible, each patient should have his own room and own veranda space, which should be arranged so that it can be separated by sliding doors. The room itself should have painted walls and such furniture as will permit of no accumulation of dust. The walls, floor, and

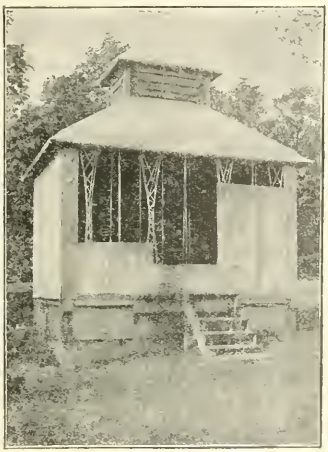

Fig. 6.—Professor Fisher's tent.

furniture should frequently be wiped off with cloths moistened in a sublimate solution of 1 to 3,000. The frequent wiping becomes particularly necessary in the latter stages of the disease, when the patient is weak and becomes less careful to prevent drop infection through the so-called dry-cough. As a receptacle for his sputum he should be provided with a light porcelain or aluminum cup partially filled with scented soap-water. (Fig. 1.) I prefer soap-water because it renders the expectoration less visible and less repulsive to look at than when collected in clear water. Strong smelling antiseptic solutions are not necessary, since the cup is frequently emptied and the sputum destroyed, either by burning or by being poured into the water closet. It is well known that

Fig. 7.—Dr. Millet's sleeping shack.

the saprophytic organisms in cesspools and sewers destroy the tubercle bacilli. The Seabury and Johnson pasteboard sputum boxes, with cover, are also convenient as a receptacle for the sputum if the invalid is willing to use them. (Figs. 2 and 3.) These boxes, removed with their contents from the frame, can easily be destroyed by fire. When the patient is yet strong enough to make use of the sputum pocket-flask (Figs. 4 and 5), he often prefers this to the use of the cup, for he can place the hermetically closed flask under his pillow, and on very cold nights, when he has to expectorate, he can

Fig. 8.—The Tucker tent; a combination of roof and fly ventilator.

do so without much effort and without being obliged to expose his back to the cold.

When the patient has become too feeble even to make use of the light aluminum cup or pocket-flask, moist cloths should be placed where he can reach them easily and into which he may cough and expectorate. In the last days of his sufferings it may become necessary to have a nurse constantly watching the patient to receive the sputum in the moist rags. These should, of course, always be burned before they have a chance to dry.

Every patient should be provided with two handkerchiefs, one for the purpose of wiping his mouth after expectorating and to hold before his mouth during the dry coughing spell, and the other for his nose.

Fresh air must be given to all advanced cases, whether they are bed or ambulant patients. In the

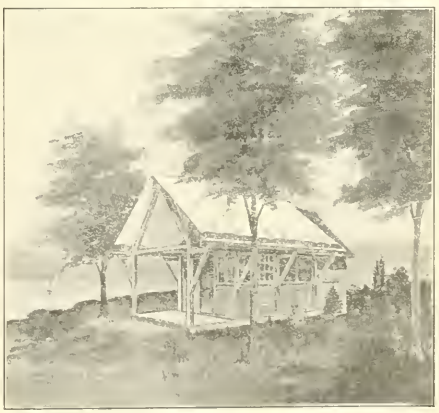

Fig. 9.—The Biggs Adirondack tent house; it can be used with perfect comfort during eight or nine months of the year

well-equipped modern sanatorium this is done during the day by placing the patient in the reclining chair on the rest-cure gallery. At night his bed is moved on to the veranda. In the special hospital for consumptives, with large wards and few special rooms, veranda space and rest-cure galleries are, as

a rule, not of sufficient abundance to supply the demand. We must often content ourselves with well-ventilated wards at night and during the day with a little solarium, often altogether too crowded to be considered sanitary. In the future construction of special hospitals for the treatment of advanced cases

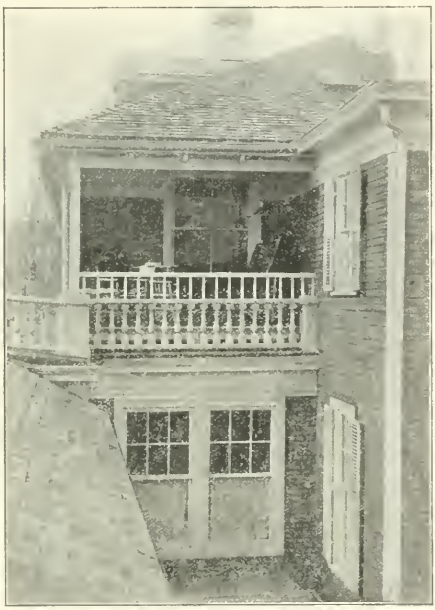

Fig. 10.—Sleeping porch for the open air treatment.

of tuberculosis it should be borne in mind that with more air space and facilities for open-air treatment, by day and by night, such symptoms as chronic fever, night sweats, and persistent cough will be more easily controlled than with most of the antipyretics, anti-sweat, and anti-cough products of our pharmacopeia.

One feature which is so frequently overlooked in the construction of special hospitals for advanced cases of tuberculosis is the necessity of a number of small rooms for dying patients, gangrenous cases, or patients where isolation is desirable or necessary for other reasons. The well-to-do consumptive living in a small town or village may have a Fisher tent (Fig. 6), a millet sleeping-shack (Fig. 7), a Tucker tent (Fig. 8),* or a Biggs tent-house (Fig. 9) near his residence for permanent quarters. All these are practically and easily constructed, and inhabitable throughout the year. These sleeping out-of-doors arrangements are, of course, of equal advantage for the open-air treatment in earlier cases.

Another almost ideal way of making a sanatorium installation in the home of the patient is to utilize the porch or to make an addition to one's house for this purpose. The illustrations (Figs. 10 and 11) were taken from an admirable article on "Sleeping out of Doors" by the pen of our distinguished and beloved president, Dr. E. L. Trudeau, which appeared in the May number of *Outdoor Life*. To show the facility of constructing such a sleeping-out veranda, allow me to quote from Dr. Trudeau's article:

"Ideal sleeping-out places of this kind are built out from a second-story room, and on them the comparatively well patient can sleep at night, or the bed-ridden invalid may spend the entire time out of doors and in close proximity to family and friends. The bed can be moved out at will on this little structure, and the patient can step at once into a room heated when necessary, to bathe or dress at any time, or to get warm if chilled.

"These second-story sleeping-out verandas can be built at comparatively small cost and attached to almost any country house, and the consumptive who, for any reason cannot leave home, can do much to arrest and cure the disease by equipping his house with such an out-of-door sleeping-place, which will enable him to live at rest out of doors the year around, for in winter one step will take him into a warm room where he can bathe and dress in comfort.

"The window of an ordinary second-story room is cut down to the floor and replaced by a door; the floor of the little sleeping-out porch is supported by wooden brackets attached to the sides of the house; the two ends are boarded up with thin boards, with or without glass casings, supplied with dark shades; an overhanging shingle roof completes the structure, and by its overhang prevents the rain from beating in directly on the patient. An awning is a great additional comfort against sun and rain.

"When the invalid has selected an ordinary veranda for a sleeping-out place, his bed should be placed in a corner, if possible, so that he is sheltered from the wind on two sides, at least, and far enough back to prevent the rain from beating on the bed. One end of the veranda can thus, with a bed, a rug, a table and a chair, be turned into a sort of open-air room, where the patient can spend not only the nights, but most of the days, as well. A slender-bowed switch will do to attach the often indispensable mosquito net, or the entire end of the veranda can be screened off for this purpose."

Another permanent arrangement for the open-air

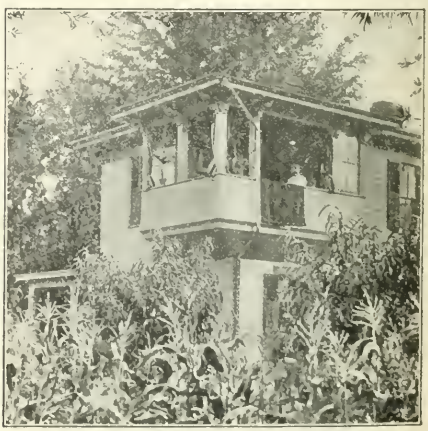

Fig. 11.—A more elaborate sleeping porch than that shown in figure 10.

treatment, easily attached to a home, is the one devised by Dr. Millet, of Brockton, Mass., and shown in the illustration (Fig. 12.)

The open lean-to or "shack" (Fig. 7) is one of the best constructions for applying the open-air method when camping or in the country and at a dis-

*The Tucker tent and Biggs tent house have been reproduced from the pamphlet on County and City Care of Consumptives, issued by the Committee on the Prevention of Tuberculosis of the Charity Organization Society of New York City.

tance from houses. Such a shack is practically like the sleeping-out veranda described above, with the house removed. It is closed on three sides, open in front, can be built of rough boards, and roofed with rubberoid or some of the waterproof roofing papers, or shingled, as desired. Its depth should be sufficient, when combined with a marked projection of the roof, to keep the rain from beating in. If intended for cold weather, as well, it should have a small room at the back, with a stove, where the patient can get warm, wash, and dress.

Fig. 12.—Permanent arrangement for open-air treatment at home; devised by Dr. Millet of Brockton, Mass.

The wealthy advanced tuberculous patient, desiring or being obliged to remain in the city, and so situated as to make the building of a shack or addition to his house an impossibility, must make a sanatorium of his home as best he can. He should choose for his bed and sitting-room the lightest and best-ventilated rooms of the house or his apartment. The half-tent (Fig 13), which protects him against the wind, the hot sun, and the gazes of his neighbors, can be placed either on the roof, the extension, or in the yard. The comfortable reclining chair, with the characteristic knee-bend and adjustable back (Fig. 14), for taking the rest-cure, which should be an indispensable article of furniture for all tuberculous patients, should be placed in the tent, and here the patient will probably spend most of his time during the day. This half-tent and the reclining chair in the home of the well-to-do patient must replace the rest-cure gallery of the sanatorium. For poorer patients the simple steamer chair and a few boards joined together to replace the costly half-tent will have to answer the purpose. A large and stout umbrella, such as is often used at seaside resorts, can be fastened to the back of the steamer chair, and will answer the purpose where the tent cannot be provided. The poor patient will probably be obliged to resort to the roof for his rest-cure, as the small yard of the tenement house, with many children playing in it, will scarcely be suitable. I do not favor the use of the fire-escape for this purpose. A recent conflagration in New York City, where many lives were lost owing to the obstruction of the fire-escape, showed the dangerous results of evading the law in this way.

For all tuberculous patients, and particularly for our consumptives obliged to remain in the city, we must seek to provide as much fresh and pure air as possible. In hot weather no one objects, as a rule, to having all the windows open, but in winter it becomes exceedingly difficult in the houses of the poor. In the hopes of solving this problem in a measure, I devised an arrangement which I call a window tent. Through the kind cooperation of my former house physician at the Riverside Sanatorium, Dr. W. B. McLaughlin, I was able to present the first model of our modest invention at the meeting of the New York County Medical Society last February. I recommended the tent first to a tuberculous physician living in Brooklyn, and he reported such a marked improvement of all his symptoms that I have since suggested its use to a number of my colleagues for their patients. All have reported gratifying results. I recommended the tent in a case of pernicious anemia, and there was a marked improvement after a few days of constant exposure to the fresh air in the tent. The device not being patented, a number of out-of-town physicians have constructed the window-tent themselves, and have written me about their success with it, and suggested some improvements. To Dr. H. F. Stoll, of Harford, Conn., I am particularly indebted for the idea of having an observation glass sewed into the canvas. A number of other modifications and improvements have suggested themselves to me by watching patients use the tent. With the help of Mr. Rich-

Fig. 13.—The half tent.

ard Kny, of the Kny-Scheerer Co., I have incorporated these in a new model which I have the pleasure to present to you herewith.

As you see, this window-tent is an awning which, instead of being placed outside of the window, is attached to the inside of the room. It is so constructed

that air from the room cannot enter nor mix with the air in the tent. The patient lying on the bed, which is placed parallel with the window, has his head and shoulders resting in the tent. (Figs. 15, 16, 17.) By following the description closely, it will be seen that the ventilation is as nearly perfect as can be produced with so cheap a device.

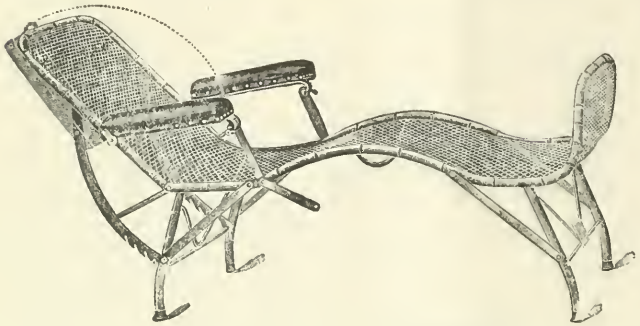

Fig. 14.—Reclining chair with knee-bend and adjustable back.

In the lower half of an American window is placed the frame to which is attached the awning, stretched over a quarter-circle, with a radius of 40 inches.* The frame of the tent does not quite fill the lower half of the window; a space of about three inches is left for the escape of the warm air in the room. By lowering the window, this space can be reduced to one inch or less, according to need. On extremely cold and windy nights there need not be left any open space at all above the window-frame. The patient's breath will rise to the top of the tent, and the form of the tent aids in the ventilation. The awning is made of stout duck and is waterproof.

The patient enters the tent through a flap which can be made either on the right or the left side of the tent. The lower edges of the canvas that come at the head and side of the bed are long enough to be tucked well under the mattress to exclude the air from the room and protect the patient from draught. The flap is so constructed as to admit of easy access to the patient.

The change of hot and cold air in the window-tent takes place in the following manner: In Fig. 18 *ab* represent the roof of the window-tent, it rests on the bed at *b*, and is attached to the window at points *a* and *c*. Now, *d* is the outside air, and *e* is the air in the warm room. If *e* is warmer than *d*, then the roof of the tent will be warm, and will in turn warm that portion of the outside air *d* which is in contact with the roof *ab*. This warmer air will go in the direction of *ba*, and pass out of the tent at its apex *a*. New air from the outside will, of course, take its place, entering in the direction of *df*, insuring a constant change of air. The patient's own expired air rising toward the roof of the tent adds to the circulating current of air, *dfgh*. The vaulted form of the tent facilitates the movement of the air currents and prevents the formation of air-pockets.

The frame of the tent is composed of two lateral pieces, which are attached to the inside portion of the window-frame by four wing screws. The upper transverse portion of the frame of the window-tent is made of telescoping galvanized iron bars, arranged so as to fit any window. The frame is placed in the frame of the window in such a manner as to permit the lowering of the window, which may be essential on unusually stormy days, and is always necessary for a little while in order that the room may become warm for the patient to dress, or to take his cold sponging, massage, etc. While in the tent the patient's body is kept thoroughly warm. In order to protect him from rain beating in his face, a little expansion awning can be fixed in the upper portion of the window. A roller-shade has been placed in the window itself. This shade, running from above downwards, can be lowered at the patient's convenience to protect him from the too strong light or the gaze of the neighbors while taking his medicine, etc. The little expansion awning, or peak, of the tent, is not always essential, particularly if the house has a sufficient projection over the window, or the patient's room is located under the eaves of the upper story.

The cot can be placed in the window to suit the patient's preference for sleeping on his right or left side, so that he has the air most of the time in his face. Another advantage of the window-tent is that it will not attract any attention from the outside. Being placed alongside the window, it will be convenient for a majority of the poor who have small rooms. If, however, the bed must be placed at a right angle to the window, the flap can be made in the middle of the tent.

A piece of transparent celluloid is placed in the middle portion of the tent to serve as an observation window for the nurse or members of the family to watch the patient if this is necessary. It also serves to make the patient feel less outdoors and more in contact with his family. He can, if he desires, see what is going on in the room.

If the window tent must be placed at a right angle to the window, the observation glass can be put in on the side. It goes without saying that, as a rule, patients should not smoke; when, in exceptional cases, this can be allowed, the danger of the celluloid window becoming ignited must be impressed upon them.

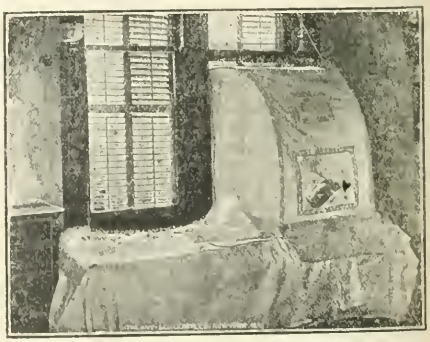

Fig. 15.—Window tent, with patient looking through celluloid window into the room.

and the greatest caution urged. I prefer the celluloid observation-glass to ordinary glass because it can easily assume the vaulted form of the rest of the tent, and thus even the slightest possibility of air-pocket formation, above referred to, is done away with. Placing hinges in the upper part of the frame makes it possible, with the aid of a pulley, to lift the

*When there is a recess, so that the bed placed parallel to the window cannot be moved close to the window sill, the tent has to be made correspondingly longer and the bottom flaps made long enough to reach under the mattress.

whole apparatus from the bed to any desired height. This will facilitate arranging the bed, sponging off the patient, or the application of a compress, massage, or any local remedy.

If it is necessary to raise the bed to the height of the window-sill, it can be done with little ex-

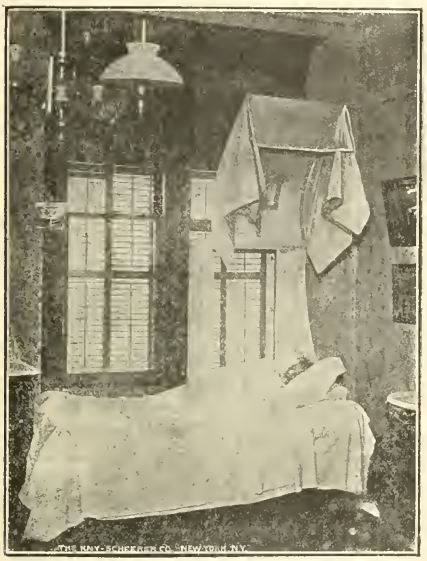

Fig. 16.—Window tent with main portion raised by pulley.

pense. If the bed is of iron, a few additional inches of iron piping can be attached to the legs by any plumber, or one handy with tools; raising a wooden bed can be accomplished with equal facility. If the window-tent is to serve the patient only during the night, the tent can be pulled up and the bed can be moved away from the window during the day and the window closed.

This window-tent will, of course, be of greatest service to the consumptive sufferer in winter. If he is feverish, or his stay in bed is advisable, he can spend his entire time in the window-tent. If the people are poor, and the room where the consumptive sufferer lies serves as living-room for the rest of the family, the fact that the well members need not shiver and yet the patient can take his open-air treatment, is of vital importance in many respects. While the room will not be quite as warm as if the window was entirely closed, it will be much warmer than if there was no tent in front of the open window.

Laying aside the economic advantages to a poor family when not being obliged to heat more than one room, the patient feels that he does not deprive his loved ones of comfort and warmth and that he is less a burden and hindrance to their happiness. The other members of the family, on the other hand, feel that they can give to the patient all the air he needs and that he himself need not suffer for their comfort.

In winter the patient's bed must be covered with a sufficient number of blankets to assure his absolute comfort and warmth throughout the night. Still, this covering should not be so heavy as to press down upon the body and make the patient feel uncomfortable and tire him. The light and tightly woven blanket is a better protection than the loosely woven one. To the poor, whose disposal of blankets is, alas! often very limited, it may be valuable advice to tell them to put several layers of newspapers between the coverings. *Outdoor Life*, of December, recommends to have a dozen layers of newspapers sewed between two layers of flannel. This will certainly make a cheap, light, and warm covering. In extremely cold weather the patient should, while sleeping outdoors, whether in a tent, shack, on the veranda, or in the window-tent, wear a sweater and protect his head and ears with a woolen cap, shawl, or woolen helmet, such as I reproduce here. (Fig. 19.)

Some patients will complain that the bright light awakens them too early in the morning, and that they have difficulty in going to sleep again. In such instances I counsel the patient to have some light-weight, but dark-colored material (such as black lisle-thread hose) to put over his eyes. This usually suffices to obviate the inconvenience caused by the bright light.

The pulmonary invalid should be provided with a bell to communicate with his nurse, relatives, or the friends who take care of him. He should, of course, have a small sputum-cup or pocket-flask handy to receive his expectoration. I prefer the flask for use in the window-tent, for it seems to me that any kind of cuspidor which had to stand on the window-sill would not be as safe, as there is always a danger of its falling. A urinal should also be at the bedside, so that the patient will not have to leave the bed in the night.

There is, lastly, one more advantage to be derived from the use of the window-tent that is not to be underestimated. Patients who can only be persuaded with difficulty to sleep with the window wide open will not hesitate when they have this tent as an inducement.

Besides the fact that the patient feels easier when he knows that the rest of his family are not in discomfort because he must be exposed to the cold, there

Fig. 17.—View of window tent with patient, taken from house opposite

is another advantage in this window-tent arrangement whereby the patient's physical and mental condition will be benefited. His prolonged rest-cure in bed will be more endurable when he is permitted to look out on the street and watch life there than when obliged to gaze at the four walls of his room

When arranging for the rest-cure on the reclining-chair during the day in this half-tent in the garden, on the veranda, in the sleeping-shack, on the roof, or on the balcony, one should always bear in mind that it is much more agreeable and conducive to the well-being of the patient when taking the cure, to

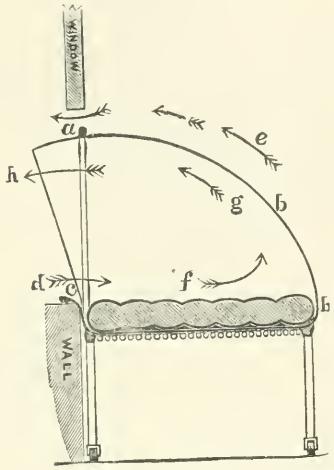

Fig. 18.—Diagram showing ventilation of window tent.

have a pleasant view to look upon. In building sanatoria, the greatest attention is paid to the proper selection of the place for rest-cure gallery or veranda. The more pleasing and entertaining the outlook from these places, the more certain is one to keep the patients quiet and restful.

The aërarium, an invention of Dr. T. M. Bull, of Nagatuck, Conn., is another device for the open-air treatment which is excellent where it can be applied. As the illustrations (Figs. 20, 21) show, the aërarium is an awning covering the whole outside of the

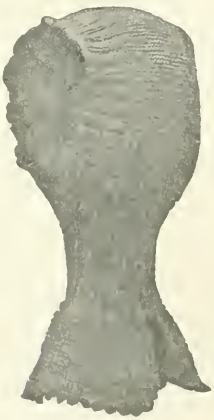

Fig. 19.—Woolen helmet.

window and constructed of wood and canvas, painted the same color as the house. The following is an exact description of Dr. Bull's aërarium as it appeared in *Outdoor Life* of October, 1904:

"The head of a cot-bed is run through the window so that the patient's head and shoulders are outside. From the lower edge of the lower sash (which is raised about 20 inches) is suspended a heavy cloth or curtain, which drops across the patient's body and effectually shuts off the room, and thus permits the room to be warm. In severe weather, the lower edge of the curtain may be drawn out to the sleeper's

Fig. 20.—Dr. Bull's aërarium, view of house, giving outside appearance.

neck, and his body will be practically indoors. In warm weather the curtain may be drawn to the feet and his body will be practically outdoors. Windows may be inserted in the canvas to prevent obstruction of light to the room.

"The sides are all closed. Air enters only through the floor in the slit between the bed and sides. (An extra floor with valve-flaps is provided in cases the rare back draught occurs). The air escapes only through the roof, a vertical current of air being thus

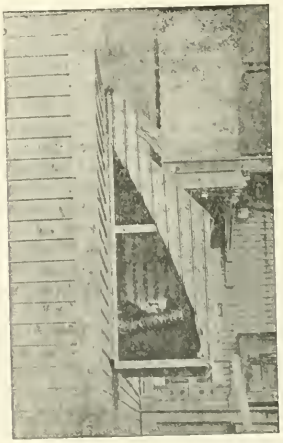

Fig. 21.—Dr. Bull's aërarium, awning cut away, showing inside arrangement.

assured. The top is composed of two superimposed roofs, the upper one foot higher and extending one-third as far as the lower. The sizes of the roof opening can be regulated."

To the best of my knowledge, Dr. Henry B. Dunham, of the Massachusetts State Sanatorium at Rut-

land, was the first to suggest making the patient sleep with his head outside the window.* Dr. Dunham's bed, projecting out of the window, in combination with the aërarium, may be feasible in a one- or two-story house in a village or small town. Those of us familiar with the conditions of the consumptive poor in a large city will, however, agree on the difficulty of making such a device practical and popular among this class of patients. In a New York tenement house, for example, a cot protruding through the window would attract unpleasant attention, and with the phthisiophobia that exists in many minds, the unfortunate sufferer might be obliged to seek other quarters. The cost of the aërarium will also bring it beyond the reach of the poor, and since the device is patented, it would be imprudent to endeavor to copy it with a view of producing a cheaper apparatus.

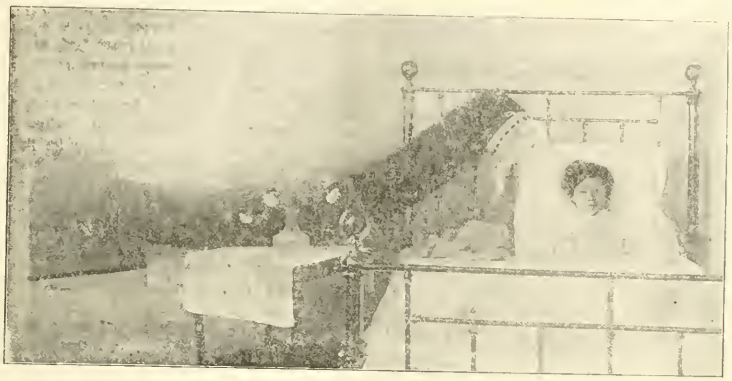

Fig. 22.—Dr. Kellogg's porte d'air.

Lastly, there is another device for bringing open air to the patient, which I saw for the first time at a recent visit to the Battle Creek Sanitarium. It is an invention of Dr. John H. Kellogg, the distinguished director of that institution, and is called "Porte d'Air," or "Air Carrier." The accompanying photographs (Figs. 22, 23) show that Dr. Kellogg's apparatus consists of a large flexible tube, through which the patient can receive fresh air from the window, whether sleeping or waking, resting or at work.

The porte d'air has four parts: *A*, the flexible tube, which is ten inches in diameter, is made of strong cloth (denim or rubber-cloth), supported by steel rings, about six inches apart; *B*, the window-piece, which is about a foot wide, and of length equal to the width of the sash. This may be adjusted to fit different sized windows. It is provided with an opening the size of the tube, which on the inside is surrounded by a metal collar, to which the cloth tube is attached, and on the outside is covered by a door hinged at the top and held open by a light spring. By means of a cord attached to this door, the amount of air entering the Porte d'Air may be instantly and perfectly controlled by the patient from any part of the room. *C*, the outlet or service end of the flexible tube, is furnished with a rigid metal collar, by which it may be supported at the head of the bed, or over a cot, a chair, or a desk. It may be placed in any part of the room, and in any desired relation to the window, as it may be turned around a corner, or twisted in any shape desired, by simply connecting the supporting rings, as shown in one of the accompanying cuts. To the terminal opening or service end is connected a cloth or mackintosh hood (*D*), for the purpose of directing the current of cold as may be desired. This may be used open or closed, or with one side raised, or in many cases it may be dispensed with.

Fig. 23—Porte d'air with hood over patient.

When the slight draught from the incoming cold air is objectionable, this may be obviated by removing the hood and covering the end of the tube with cloth. The air will find exit through the openings in

*American Medicine*, December 28, 1901.

the collar, and will be sufficiently diffused to prevent draught.

The service which such an apparatus renders is, to my mind, of especial advantage when there is a severe rain or snow storm, when windows cannot be opened and the window tent or aërium cannot be used. The air is brought from outdoors through the tube right over the patient's bed or his reclining chair. Dr. Kellogg suggests the use of his porte d'air in summer; I can understand how it may render valuable service then. He supplements it by a small electric fan, which is placed near an open window, and joined to the porte d'air by a funnel-shaped connection. This secures a constant current of air at any desired point. The air may be cooled while coming in by sprinkling the tube or by laying wet towels on it.

I now desire to make a few additional hygienic and medicinal suggestions concerning the treatment and care of the more advanced tuberculous cases which are applicable to all, rich and poor, sanatorium and private patients alike. I have nothing new to offer in the way of symptomatic medicinal treatment, still less in the line of specific treatment. I will speak of what may be done to render our patients comfortable, in addition to the hygiene and aërotherapy already referred to. Every room occupied by the pulmonary invalid should have a comfortable bed, a commode, and a comfortable reclining chair (Fig. 14), preferably one which will hold a mattress, and an easy chair with back arranged so as to facilitate deep breathing. (Fig. 24.) If the patient is obliged

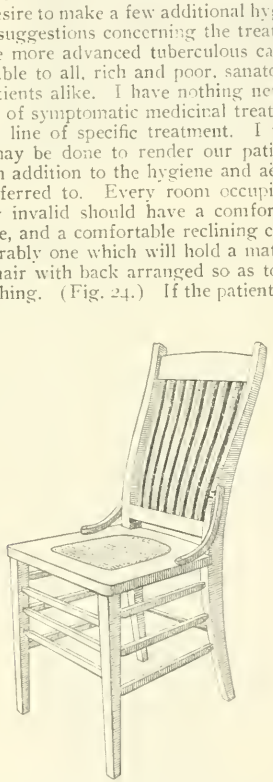

Fig. 24.—Comfortable chair with back arranged to facilitate deep breathing

to remain in bed all the time, or for a number of days in succession, it is best that he should have two beds —one for the day and one for the night. Of course these should be single beds, and with light metal frames. By thus changing beds, the patient will be much refreshed and bedsores will be largely prevented. A small down pillow, which may be placed under the small of the back, adds much to the patient's comfort. Patients have assured me that nothing rested them so much as this little support, which brings about a most grateful change of position. When tired of this position, the pillow can easily be removed.

In ordinary weather, the patient in bed should wear a muslin nightshirt; in colder weather he may wear linen mesh underwear underneath, and an additional outer garment, if necessary. I prefer the linen underwear because it produces a pleasant friction on the skin, and dries quickly when the patient has perspired. The patient should be exposed as much as possible to the rays of the sun, in bed or on the reclining-chair, but with the head always in the shade. Fever is, of course, a contraindication to solar therapy.

Judicious massage during the non-febrile state is a valuable remedy to counteract lack of appetite, lack of assimilation, and a progressive atrophy. The diet of the advanced tuberculous case should be appropriate to his condition. I do not believe in overfeeding the patient distressingly; it makes him uncomfortable and unhappy, and while he may thus add fat to his flabby muscles, the improvement in the pulmonary regions will never be concomitant. The patient should eat as much as he can without causing him distress. The food should consist of a mixed diet and be varied and appetizingly served. If there is a persistent anorexia and weakness, some tonic bitters, the arsenic and strychnine preparations, are often helpful.

The patient's digestive tract must be kept in good condition. Washing out the mouth with some aromatic and refreshing solution is particularly indicated for the consumptive, who often complains of a bad taste in the mouth. He should use a toothpick and toothbrush often. The latter should, however, have soft bristles or be made of rubber. A coarse toothbrush is apt to lacerate the delicate gums, and can do a great deal of mischief in the mouth of a consumptive where there are any number of pathogenic microorganisms. Another excellent way to clean the teeth without injuring the gums is to rub them with a bit of antiseptic cotton. With a little care this can be made very thorough and effective, and as a fresh piece can be used each time, it is preferable to a toothbrush, which cannot be easily sterilized.

The bowels should be kept open by an appropriate diet, and, except in diarrhea, plenty of good, pure water internally is always indicated. A diarrhea caused by injudicious overfeeding must be treated by cleansing of the internal canal, by fractional doses of calomel, and a subsequent absolute rest and light diet. When the diarrhea is due to tuberculous invasion of the intestinal tract, an anti-diarrheic diet, consisting of rice, hard-boiled eggs, chocolate, mucilaginous soups, etc., is strongly indicated. As additional measures, I recommend hot claret with cinnamon, tannin, bismuth, and opium. If night-sweats cannot be controlled by outdoor sleeping, sponging with aromatic vinegar and water at bedtime, and a light meal just before retiring, they may have to be combated by the addition of some atropin or agaricin. But before resorting to active medication in hyperhydrosis, I resort to two hydrotherapeutic means which have often rendered me most valuable service, and which, to my mind, should always be preferred to medicinal treatment. The first is the wet compress. Several thicknesses of rather coarse linen, folded in the form of a shawl, or, better yet, three different cloths,—one narrow one for each apex like a broad shoulder strap, and another wider one to wrap around the chest,—are soaked in water at a temperature of about 55° F., wrung out, and then closely applied over the apices and around the thorax. A thick flannel band, somewhat wider than the compress, is wrapped over this, and the whole is fastened in place, where it remains all night. The patient usually feels no discomfort, sleeps well, and sweats but slightly, if at all. In the morning the compress is removed, and the chest and shoulders are rubbed thoroughly dry. The second procedure is the sweat bath. It can safely be applied when the patient

is relatively strong, and experience has demonstrated to the attending physician that it does not exhaust the patient to any severe degree. It will then almost invariably not only combat hyperhydrosis, but will lower the patient's temperature and improve his general condition. Through the sweat-bath the excretory action of the skin is considerably increased, and a larger quantity of toxin is thus more rapidly eliminated. Frequency, time, and duration of the bath must, of course, be always carefully controlled. A portable sweat-bath apparatus, which can be placed in the bedroom of the patient, is the most convenient manner to apply this hydrotherapeutic measure. In a publication by Dr. De Lancey Rochester, of Buffalo, on the "Treatment of Pulmonay Tuberculosis," * I find that he, as well as my friend, Dr. Charles G. Stockton, of the same city, have employed this method for a number of years, and with satisfactory results. Against severe hemoptysis an icebag over the heart, a little ice internally, quiet, and morphine, and the ligation of the extremities are still our only resources.

Carefully graduated breathing exercises, directed by the physician, will help to overcome a dyspneic condition, facilitate hemoptysis, and indirectly facilitate expectoration. I have repeatedly published my exercises, and I do not think it necessary to again describe them here in detail.† I only wish to mention the necessary precaution, particularly when recommending them in the more advanced tuberculous patients. These exercises should never be taken when there is an active febrile process, never when the patient is tired, nor to the extent of getting tired; never after a hearty meal, never when uncomfortably or tightly dressed, never in an overheated room or dusty or otherwise vitiated atmosphere.

To control the cough we must use the well-known remedies, viz.: proper breathing, discipline, codeine, and heroin. Fever should, as far as practicable, be controlled by frequent partial sponging, and the heart-depressing coal-tar products should be utilized only as a last resort. The various other serious symptoms arising from the secretions of the tubercle bacilli and their associates in the mixed infection can often be successfully combated by rectal injections of a physiological saline solution for the purpose of absorption or by hypodermoclysis or antistreptococcic serum. Subnormal temperature is an indication for hot-water bags, hot lemonades, milk, weak teas, or hot mildly alcoholic drinks. Sleeplessness may usually be combated by gentle sponging with tepid water, a lukewarm bath before retiring, or the wet pack, but at times such substances as trional or even opiates may become indispensable. The wet pack will often suffice to combat pleuritic and intercostal pains, but in some cases morphine alone will help to ease the sufferings, and I believe that in the last stages of consumption, when all hope of improvement must be abandoned, we should not be too sparing in the administration of morphine to render the patient comfortable and let him suffer as little as possible.

The psychic treatment of the consumptive invalid in the latter stages of the disease is important. While many are sanguine, not a few are morose and need encouragement, and kind and hopeful words. Should we tell the absolutely hopeless bluntly that there is no hope for him? I do not believe that this is necessary as a rule. He can be told to arrange his affairs, and still we need not deprive him of all hope. Many of this kind of patients hardly ever realize their true condition, and would not believe us would we tell them the truth, for it is an undoubtable fact, borne out by the experience of many, that, owing perhaps to the extreme toxicity of the blood, there seems to be a sort of general anesthesia without involvement of the mental faculties.

As in the hygienic, dietetic, and medicinal treatment of the consumptive, the individual must be considered, and no routine treatment can ever be successful, so must every consumptive's mind be treated as a distinct entity. No two are alike. We can do a world of good to our consumptive fellowmen who are no longer in the earlier stages by prolonging their lives and making them comfortable and even happy and useful. History is full of instances where the most beautiful work has been accomplished by men in the declining stages of consumption. It lies thus with us, when in the presence of an advanced case of pulmonary tuberculosis, to do good, not only to the individual, his family, and his friends, but even to the world at large. But, as stated at the beginning of my paper, we must bring to this work a careful study, a keen intelligence, much patience, forbearance sometimes, and firmness at others, but always our whole heart.

16 West Ninety-fifth Street.

## PRIMARY CRYPTOGENIC PNEUMOCOCCUS CEREBROSPINAL MENINGITIS, WITH A REPORT OF THREE CASES.*

By R. C. CUPLER, Ph.G., M.D.
CHICAGO.

During March, 1902, I attended a most interesting case of pneumococcus meningitis. Six months later another, and during February, 1904, a third case.

Fränkel, in discussing the diplococcus intracellularis meningitidis says that in its morphological peculiarities it has much in common with the pneumococcus, so that the most refined methods of differentiation should always precede a positive diagnosis. Its resemblance to the gonococcus should also be kept in mind. McFarland points out that the primary form of meningitis seems to be caused by the intracellular diplococcus. Osler says the pneumococcus is the most common cause of sporadic meningitis. As early as 1887, Weichselbaum carefully described a diplococcus found in six cases of cerebrospinal meningitis. This microorganism is briefly described as a biscuit-shaped diplococcus, usually found in the protoplasm of the leucocyte. The organism stains with the aqueous solution of the anilin dyes, and not by Gram's method.

The diplococcus pneumoniæ is variable in morphology; when grown in bouillon it has a disposition to occur in pairs, and frequently in chains resembling the streptococcus. In the exudate of pneumonia it occurs in pairs, lanceolate in shape, the pointed ends being approximated, and usually surrounded by a distinct capsule. It stains with the ordinary anilin dyes and by Gram's method. Leube says that the nature of epidemic cerebrospinal meningitis has been determined by recent bacteriological investigations. We know that apart from the secondary forms of meningitis in septicopyemia, pneumonia, tuberculosis, and enteric fever, cerebrospinal meningitis may occur primarily, due to the action of various pathogenic microorganisms. Should the affection

*Read at a meeting of the Douglas Park branch of the Chicago Medical Society, September 11, 1905.

be due to pneumococci, or intracellular meningococci the affection shows a tendency to become epidemic. It is to be assumed that the invasion of the pathogenic microorganism in these cases occurs from the nose and surrounding cavities. In favor of this is the frequency of the localization of the pneumococcus in the middle ear, and the frequent occurrence of the diplococcus intracellularis in the nose and surrounding cavities.

The character of the meningitis may be serous, epidemic meningitis, tuberculous, suppurative, or metastatic, as during the course of septicopyemia, usually complicating puerperal fever, endocarditis, articular rheumatism, miliary abscesses of the lungs, septic nephritis, cutaneous suppurations, otitis, rhinitis, and certain infectious diseases.

The clinical differential diagnosis from delirium tremens, hysteria, enteric fever, septicopyemia and uremia—that form of uremia which may have the irregular stertorous respirations, delirium, convulsions, and coma—is, I think, first to be considered. The finding of albumin is of limited value, for it may be found in meningitis. The most important findings are casts, albuminuric retinitis, which is scarcely ever absent in chronic nephritis, and hypertrophy of the heart. In cases of acute uremia, in which retinitis is absent, the presence of blood and epithelial casts in the urine, and cutaneous edema aid in the diagnosis of nephritis. Meningitis may complicate nephritis. Cabot says meningitis is the only intracranial disease, except abscess and apoplexy, which shows leucocytosis, and this fact may be of great help in excluding other causes of coma.

Enteric fever (meningo-typhoid) resembles meningitis, for painful rigidity of the neck, insensibility, and convulsions may dominate in this form of typhoid. The blood findings show a slight relative increase in the lymphocytes, in contrast to the polynuclear leucocytosis of meningitis; absence of enlargement of the spleen, irregular course of the pyrexia, the retraction of the abdomen, intense headache, general cutaneous hyperesthesia, herpes, multiple joint affections, and constipation are in favor of cerebrospinal meningitis. These points are also conclusive in cases in which, inversely, after a longer duration of cerebrospinal meningitis, the affection assumes the typhoid state.

In delirium tremens, if the psychical symptoms are prominent, the diagnosis from meningitis is quite difficult. Epileptic convulsions occur in both affections, as also partial convulsions in the region of the facial nerve and in the extremities. The fever is uncertain, as it may be absent in meningitis on the one hand, which is the usual occurrence in delirium tremens, and, on the other hand, elevation of temperature to 104° and above may occur, especially in the fatal cases of delirium tremens. The differential diagnosis in such cases must be based primarily on the presence or absence of focal symptoms; their presence points decidedly to meningitis. The prominence of the clinical picture of rigidity of the neck of intense headache, and the ophthalmoscopical picture may guide the diagnosis toward meningitis.

Hysteria is much less frequently mistaken for meningitis. There may be rigidity of the neck, vomiting, convulsions, retinal hyperesthesia (the patients prefer a darkened room), sighing respirations, hyperesthesia of the skin, pain in the head, usually over the sagittal suture, pain in the back and joints, paralysis, monoplegic, hemiplegic, or paraplegic, or any form of organic paresis; spurious ankle, clonus, phantom tumor, clonic spasms, anesthesia, tremor, hysterical hemoptysis, tachycardia, bradycardia, hemorrhages of the skin, hyperpyrexia, apparently severe stupor. A close observation will show some special traits in the picture which may assist the diagnosis in the right direction. The effect upon the convulsions of pressure upon certain parts of the body, the stupor due to pronounced sensory irritation, the occasional cataleptic character of the spasmodic condition, the restriction of hyperesthesia to circumscribed areas of the skin are points in favor of hysteria, and could not be symptomatic of anatomical lesion of the brain. To complete the diagnosis, the blood findings in meningitis, the optic neuritis, paralysis of the facial nerve and of the muscles of the eye, and the results of lumbar puncture, will suffice.

Septicopyemia, with severe cerebral symptoms, does not represent a meningitis, but a septic intoxication of the entire nervous system. The clinical observation may be the same as in meningitis, coma, delirium, contractions of the arms and hands, opisthotonos, general hyperesthesia, herpes, inequality, and, later, contraction of the pupils, divergence of the bulbi, Kernig's sign, the Cheyne-Stokes phenomena and even rigidity of the neck. Ophthalmoscopical examination may show retinal hemorrhage; lumbar puncture may be negative, but, as it is so occasionally in meningitis, it is obvious that a diagnosis cannot always be made.

Meningitis represents itself as a diffused affection of the surface of the meninges. It manifests itself primarily in general symptoms. To these are added focal symptoms. Some of the prominent general symptoms are headache, caused by a compressive action upon the dura with its abundance of nerves, by the meningitic exudate itself or the inflammatory edema of the brain substance, and the accumulation of fluid in the ventricles; restlessness, caused primarily by the direct irritation of the cortex, or a manifestation of the severe pain. The pulse is usually retarded at first, due to the intracranial pressure, and possibly the later rapidity is due to paresis of the pneumogastric. Respiration loses its regular type early; it is sighing, accelerated, and later intermittent. Contracted pupils may be considered as a spastic myosis, due to the irritation of the cortical origin of the third nerve. Rigidity of the cervical muscles, trismus and grinding of the teeth, and hyperesthesia of the muscles and skin, are, I believe, dependent upon cerebral pressure. The retraction of the abdominal muscles may be due to a spasmodic contraction of the intestinal coils. The reflexes of the extremities are exaggerated at first; later they are absent, or partially so. Involuntary micturition and defecation may be present, albumin may appear in the urine, and sugar may be present. Focal symptoms that may be present are paralysis of any of the cerebral nerves, paralysis of the extremities, in whole or in part, some form of aphasia, and optic neuritis.

Case I.—Italian, age 26; came to this country ten years ago. The following history was obtained from his brother and constant companion: The patient is unmarried, never had otitis, rhinitis, or gonorrhea, no evidence of syphilis, no previous injury, diseases of childhood negative. I saw the patient twelve hours after the beginning of his headache. During this time he had taken a package of headache powders, with the druggist's assurance that it would cure his headache. I found the patient madly delirious, neck not rigid, pupils of unequal size, tongue furred, jaws quite rigid, chest well developed, findings negative, abdomen slightly contracted, hands constantly at his head, skin moist, no swollen glands, pulse 50, temperature 98.6°. Six hours later the con-

dition was slightly changed, the respirations showed an intermittent type of slow character, pulse 70, temperature 100°; the patient was groaning, his hands being constantly applied to his temples, and if removed they would, without hesitation, return at once to his head. The abdomen was retracted. Lumbar puncture was followed by cessation of the groaning and less insistence in keeping the hands to the head. The cerebrospinal fluid first exuded in spurts; 30 c.c. of seropurulent fluid were removed. Examination showed the presence of pneumococci; no other microorganism was found. Blood findings: Red cells, 4,000,000; white cells, 38,000; hemoglobin, 90 per cent. The urine did not show albumin or sugar. Coma developed and the patient died thirty-six hours after the beginning of the headache.

Case II.—Male, age 20; Italian, in this country one year. I saw the patient two hours after the beginning of his headache. He was restless, his manner of speaking was one of excitement and confusion, pupils contracted, cervical muscles not rigid, skin of the extremities hypersensitive, reflexes exaggerated, abdomen not flat, no history or evidence of otitis or accessory sinusitis, gonorrhea and syphilis denied. He received no recent injury; the throat, chest, abdomen, skin, and glandular findings were negative. He had never been sick, except with typhoid fever, five years ago. I immediately did a lumbar puncture and removed 30 c.c. of floculent fluid. Pneumococci were present. The puncture was followed by relief from headache and the nervous excitement. The patient was taken to Wesley Hospital. During his illness several lumbar punctures were made. Following each puncture after the first, the symptoms, which were rapidly increasing in severity, showed a temporary improvement. The cerebrospinal fluid, while at first only floculent, became more clouded. The fourth and last puncture showed only a slight turbidity, and few pneumococci. Blood examination on the third day: Red, 5,600,000; whites, 30,000; hemoglobin, 80 per cent. The patient left the hospital at the end of the fifth week apparently well.

Case III.—Male, 30 years old; fairly well developed; examination of the head, throat, neck, chest abdomen, extremities, skin, glands, and genitals gave negative results. A peridental abscess was incised externally ten years ago. Several years ago he had repeated tonsilitis, but the tonsils were removed and no attack has occurred since. He never had otitis or rhinitis. Temperature 98.6°, pulse 70. His only complaint was that of a severe throbbing headache, which came on suddenly three hours previously. I was summoned twelve hours later, the patient was raving with delirum, and presented a similar picture of an unconscious man groaning with hands to head. He was removed to Wesley Hospital. He there had retracted abdomen, not noticeably rigid cervical muscles, slight convulsions, vomiting, slow pulse, intermittent respiration, with a tendency toward paresis, involuntary urination and defecation, and contracted pupils, which before death became unequal. Coma supervened and death occurred forty-eight hours after the onset of the headache. Red cells, 6,000,000; whites, 56,000; hemoglobin, 70 per cent. Lumbar puncture showed a purulent fluid under high tension and the presence of pneumococci.

Autopsy.—The general surface of the body showed no signs of injury or foci of suppuration. Chest: lungs float in water, no signs of pneumonia, bronchial and mediastinal glands not enlarged, heart and pericardium negative, spleen slightly swollen, capsule not tense, gastrointestinal tract negative. Kidneys, liver, and pancreas apparently normal. Genitals normal. Brain and meninges showed no sign of localized abscess. There seemed to be a uniform distribution of purulent fluid in the ventricles, under the cerebellum, around the pons, anteriorly to the longitudinal sinus, and laterally into the Sylvian fissures. The hemispheres were flooded with this thick greenish pus, the bones of the skull were quite normal, no evidence of accessory sinus inflammation or disease of the auditory canal, orbit, or nose.

One cardinal point in treatment is drainage. The thicker the pus, usually the more serious the prognosis. Lysol injections have been reported with favor. Carl Franca was the first to report a series of cases. He removed 30 c.c. of cerebrospinal fluid and injected 9 to 12 c.c. of one per cent. lysol solution into the subarachnoid space. The temperature and rigors subsided at once, but sometimes rose again after from one to three days. The lysol solution may be repeated until the fluid is clear. During the Lisbon epidemic of cerebrospinal meningitis, repeated lysol injections were used. Of thirty-one cases, thirteen died, four only from the disease. C. E. Nammack reports twenty-seven cases of cerebrospinal meningitis treated at Roosevelt Hospital during the 1904 epidemic, with lysol injections, with a mortality of 90 per cent. The withdrawal of fluid should not be sufficient to cause symptoms of collapse and the injections should not be carried to a degree of over distention. Wolf used diphtheria antitoxin serum with apparently good results. Waitzfelder treated seventeen cases of epidemic cerebrospinal meningitis in this manner, five of the patients recovered completely, three died, and nine were still under observation at the time of the report. The procedure is based on the supposition that an antagonism exists between the diplococcus intracellularis and the Klebs-Loeffler baccillus. Paralysis of respiration requires careful attention; caffeine citrate served admirably in my cases; if stupor is great and cessation of breathing is imminent, lingual traction may be used. Morphine in large, frequently repeated doses, is used for restlessness, jactitation, and severe pains. Leeches to the neck and mastoid region may be used and cold may be applied to the head and spine.

Headache, with no other noticeable symptom, may be the beginning of meningitis. Quincke's lumbar puncture relieves the intracranial pressure, lessens the severity of symptoms, assists in diagnosis, and meets the requirements of a rational principle in treatment. Primary pneumococcus meningitis is not common, and recoveries from it are few.

---

## A PENETRATING GUNSHOT WOUND OF THE ABDOMEN.

By J. H. IDEN, M.D.,

PAST ASSISTANT SURGEON U. S. NAVY.

Nobutara Miyamota, cabin cook, U. S. N., age twenty-eight years four months, a native of Japan, serving on board the U. S. S. *West Virginia*, was accidentally shot with a 32-caliber revolver at 7:45 P. M., July 31, 1905. The ship was at anchor off Newport, R. I., and after an examination, the surgeon of the ship deemed it advisable to transfer the patient to the U. S. Naval Hospital at Newport. First aid dressing was promptly applied on board ship.

At 10:25 P. M. the patient was admitted to the hospital. At the time of his admission I was not present, but the medical officer on duty informed me upon my arrival, about half an hour later, that the

patient's pulse was sixty-two and compressible upon admission.

Examination revealed a wound in the abdomen, slightly above McBurney's point. The abdomen was distended, and physical signs of fluid were present. Pallor was present, but not marked. When questioned, the patient stated that he had a little pain. The pulse was 110 and of fair quality. The patient was vomiting every few minutes. From the symptoms, there seemed to be no doubt but that the bullet had penetrated the abdominal cavity. There was little or no hemorrhage from the external wound. Strychnine sulphate, gr. 1-30, had been administered some time previous to the examination, and orders were given to prepare for operation in case it was deemed advisable.

The patient rapidly became worse; the pulse was small and feeble, the face pale, and the body bathed in cold perspiration; the pupils were dilated; the temperature was subnormal. Vomiting continued. The typical abdominal facies was present. Morphine sulphat, 1-4 gr., and strychnine sulphate, 1-30 gr., were given hypodermatically, and the patient was sent to operating room at 12:10 A. M. Ether was administered by Asst. Surgeon J. L. Belknap, U. S. N., assisted by Hosp. Steward C. P. Hines, U. S. N.

The abdomen was prepared with the usual antiseptic precautions. Assisted by Asst. Surgeon L. H. Wheeler, U. S. N., I made a long median incision. The abdomen was found to be full of blood, though hemorrhage had apparently ceased. The omentum was congested, and the bullet wound was plainly visible. Blood was removed from abdominal cavity with sterile gauze sponges. Beginning at the duodenum, the small intestines were rapidly examined, and nineteen perforations were found, besides a number of wounds of the mesentery. At one place there were five perforations in about four inches of the gut, necessitating resection. End-to-end anastomosis was done, using Cushing sutures. Other perforations were closed by purse-string sutures, first employed by Dawbarn of New York. The wound in the omentum was ligated with silk, and the injured part removed. The borders of the wound in the mesentery were inverted and closed with silk sutures. In the examination of the intestines it was impossible to avoid eventration, so they were covered with sterile gauze wet with hot salt solution. The intestines were only moderately full. The intestines and abdominal cavity were hastily wiped with sterile gauze, wet with hot saline solution, and the intestines were replaced and the abdominal wound closed with three rows of buried catgut sutures and a superficial row of silkworm gut.

From the location of the intestinal and mesenteric wounds, the bullet must have passed transversely through the abdomen, with an upward and backward direction, and buried itself in the deep muscles of the back on the opposite side. On account of the grave condition of the patient, no attempt was made to locate it.

Anesthesia was begun at 12:15 A. M. The patient took it well, and was fully under at 12:35 A. M. The pulse was then 118, of fair volume, and low tension; respiration, twenty-four per minute, and regular. During the operation the pulse increased steadily in rapidity, and became small and thready, finally irregular, and at last imperceptible in the radial, facial, and temporal arteries. The heart sounds at the end of the operation, which was of two and one-half hours' duration, counted from 170 to 180 per minute with the stethoscope. Respiration was shallow, somewhat irregular, and varying in rapidity. The extremities were cold, the forehead bathed with cold perspiration, and there was marked venous stasis of the hands and forearms. During the operation four doses of strychnine, gr. 1-30, and three of atropine, gr. 1-150, were given subcutaneously. Before the patient was removed from the operating table one quart of hot saline solution was given in the left median basilic vein, to which he reacted well, and at 6:00 A. M. the pulse was 128, and of good volume.

Nothing was given by the mouth for forty-eight hours, except a little cracked ice and brandy. Morphine sulphate, gr. 1-4, was given every four hours, and the patient was kept as quiet as possible. Strychnine sulphate was given as necessary. The patient rested well all day and night. The highest temperature, per rectum, was 101° F. Catheterized and 200 c.c urine drawn off.

The following day, August 2, his highest temperature was 100° F., and pulse 124; he vomited frequently, the vomitus having a distinctly fecal odor. Morphine sulphate was discontinued, and strychnine sulphate, gr. 1-30, given hypodermatically every four hours. The urine was voided twice. Peptonized milk was given, per rectum, every six hours, which was retained fairly well.

August 3, vomiting stopped; temperature, per rectum, 100° F.; pulse, 92, and strong. Had large soft stool and voided urine three times. Rested well all day, and stated that he felt well and had no pain. Milk and liquor calcis was given by mouth, and retained.

August 4, temperature and pulse normal. Bowels moved twice. From this on the patient improved rapidly; the wound practically healed by first intention, though there were one or two stitch abscesses. The superficial sutures were removed on the seventh day. The wound of entrance of the bullet healed very quickly.

On September 5, the patient had gained flesh and strength and was permitted to walk around, after an abdominal support had been applied. On September 20, fifty-one days after the operation, he was sent to duty perfectly well.

The imbedded bullet had not given him the slightest inconvenience.

This case is thought to be worthy of report on account of the unusual number of perforations of the small intestine, and the great rapidity with which the patient recovered from shock incident to loss of blood and prolonged manipulation of the intestines. I believe his quick recovery was due in a great measure to his sanguine disposition, for at no time did he seem to have the least doubt as to his ultimate recovery.

## A CASE OF TYPHOID FEVER WITH TRIPLE INTUSSUSCEPTIONS.

By BERTRAM L. BRYANT, A.M., M.D.,
VISITING PHYSICIAN EASTERN MAINE GENERAL HOSPITAL; AND
JESSE S. BRAGG, A.B., M.D.,
BANGOR, MAINE.

John W., age 23, fireman, was admitted to the hospital September 2. For ten days he had been having the usual prodromal symptoms of typhoid fever. On admission the abdomen was found to be swollen and somewhat tender, tongue coated, temperature 101°, pulse 104; leucocytes 7,400, hemoglobin 90; Widal positive. Urine, sp. grav. 1,030, albumin a trace, few pus and red blood cells. Treatment: milk eight ounces every four hours and

all the water the patient could drink; daily cleansing bath, soapsuds enemata, and cold sponge bath when the temperature reached 102°.

The patient was somewhat restless and at times delirious, but otherwise the fever ran an uneventful course, and no additional treatment was given until September 27, when the pulse began to weaken and whiskey, one-half ounce, and strychnine, 1-30 grain, were added.

On September 30 at eight o'clock in the morning the pulse was 100, temperature 101.2, respirations 23; the patient was resting comfortably and took milk as usual. At 9.45 he was suddenly seized with pain in the right iliac region; he cried out and seemed in great distress; he perspired freely and had a small movement of the bowels. Temperature 102.3°, pulse 120 and very weak, respirations 24. Morphine, gr. ¼ hypodermically, and nitroglycerin, gr. 1-100, were given. At 10 o'clock the pain was less severe, temperature 102.8°, pulse 130; leucocyte count 7,300. The abdomen was extremely sensitive, the tenderness being most marked one inch above McBurney's point. At 10.30, the temperature was 103.8°, pulse 140. The patient was free from pain; leucocytes 7,800. At 11 A. M. the patient was quiet, pulse 145 and very weak, abdomen not distended. He was transferred to the surgical side for operation, the diagnosis being perforation of the bowel.

Operation was performed by Dr. W. C. Mason, visiting surgeon. The incision was made one inch to the right of the median line. The abdomen was found filled with clear serum. The small intestine near the cecum was deeply congested. On drawing out the small intestine a short distance from the ileocecal juncture an intussusception was found about eight inches long, invaginated both ways; this was easily reduced. A short distance further on a second was found about five inches in length, also invaginated both ways; and drawing out more gut there was a third intussusception about three inches long, invaginated from the right. Beyond this the gut appeared normal in color excepting the infiltrated patches and lymph nodes due to the typhoid infection. The incision was closed by through-and-through silk worm sutures. The pulse was then 150 and almost lost at the wrist. Hypodermoclysis of salt solution and stimulating enamata and other stimulants were given, but the patient did not rally from the shock and died five hours later.

We have been unable to find a published case of typhoid complicated by intussusception, and as this patient seemed to have been so plentifully supplied with intestinal knots, we considered the case worth reporting.

## ANTITOXIN OF UNUSUAL DOSAGE, IN A CASE OF SCARLET FEVER COMPLICATED BY DIPHTHERIA.

By ST. CLAIR STREETT, M.D.,
KANSAS CITY, MO.

The following case is of interest on account of the severity of the infection by the organisms of scarlet fever and diphtheria, and especially because of the success which followed the employment of heroic doses of antidiptheritic serum.

In the diagnosis and treatment of this case I had the advantage of the opinions of Dr. J. D. Griffith and Dr. J. Block as consultants. It is tempting, in cases of mixed scarlet fever and diphtheria infection, to employ not only the antidiphtheretic serum but antistreptococcic serum as well. In scarlet fever I have on numerous occasions made use of the latter remedy but never have been able to see any good result, which could reasonably be attributed to it. The exhibition of antistreptococcic serum itself of doubtful value, might conceivably have interfered with the action of the proved agent—antidiphtheritic serum, hence it was not used. In the case reported it is interesting to note that only after 67,000 units of antitoxin were administered did the patient show response to treatment. Of course when ordinary large doses were ineffective, suspicion was aroused as to the reliability of the antitoxin used. The fresh product of two well-known and reliable firms was used and gave like results.

The great lesson taught me by this case is the propriety and necessity of continuing the use of antitoxin even when the patient does not seem to respond to it, and the further necessity of increasing the dose administered until such time as results are obtained.

The grave sequelæ, otorrhoa, meningitis, adenitis, acute nephritis, and partial paralysis of the muscles of deglutition and of the larynx with complete recovery, raise some interesting questions. Of course the paralyses noted were due to the diphtheria, but the other inflammatory sequelæ might be due to either infection or to some secondary infection with ordinary pyogenic organisms. In fact this is more probable than that they were diphtheritic. If due to scarlet fever or to septic infection, did the specific antitoxin exert any influence on them? I cannot but believe it did.

Paton considers diphtherial antitoxin almost specific for septic conditions generally, but his conclusions are not generally accepted. Bosanquet suggests that the antitoxin may act in sepsis by the production of leucocytosis. There is no evidence to show that the sequelæ discussed here could be due to the exhibitions of the antitoxin. If the antitoxin had been impure, one would suppose that the various lymphnodes involved would have been those corresponding to the tissues into which the injections were made. This was not the case.

Another feature of importance is that although the corneæ as well as the conjunctivæ were covered with membrane and a most acrid discharge was given off, sufficiently acrid to cause widespread scalding and blistering of the skin, yet as soon as there was evidence of response to the antitoxin the structures underwent complete restoration. The same complete restoration of the kidneys and other organs involved holds true.

Twelfth and Wyandotte Streets.

## A CASE OF ANTHRAX—PROBABLY DUE TO INOCULATION—WITHOUT A VISIBLE INITIAL LESION.

By J. D. JONES M.D.,
UTICA, N. Y.

John T. W., a farmer in the town of Prospect, N. Y., forty years of age, of good family and personal history, entered the hospital at 10 o'clock in the evening of September 30. He gave the following history: He had lost several cows out of a certain swampy pasture on his farm in previous years. On September 21 one died after one day's illness. A veterinary surgeon said she had not died of anthrax, so he skinned the carcass. One week later, September 28, having remained perfectly well and continued at his work in the meantime, he noticed a little swelling without any pimple or redness of the skin on the palmar surface of the left forearm. Having lifted a hayrack the day before, he attributed the swelling to a strain. It was not painful, and he continued at his work that day and the following. On the morning of September 30, as the swelling in

the arm was increasing, on his way home from the milk factory he consulted Dr. Cline of Prospect. The doctor bandaged the arm. During the day the swelling increased rapidly, and blisters formed on the palmar aspect of the forearm. In the evening of the same day Drs. Cline and Sparks of Remsen saw him together, and, suspecting anthrax from the history, the latter brought the case to the hospital in this city.

On his arrival here the arm was greatly swollen and the forearm was covered with large dark, dark bullæ on the palmar surface just above the wrist. Between there and the elbow the skinw as dusky. From the elbow to the anterior axillary border there was a great edematous swelling, terminating abruptly at that point as if a constricting band had been applied there. In the vicinity of the elbow the arm felt hot, but down toward the hand it was cold to the touch. The axillary glands and spleen were not appreciably enlarged. The man did not seem to feel very ill. His temperature on admission was 101.2°; pulse 72, full and regular; respirations normal.

The patient was chloroformed and free linear incisions were made in the arm to relieve the tension. The swelling was so great that gangrene was feared. At this time Dr. W. S. Nelson, of this city, made some cultures from the serum of the bullæ, as well as from the blood. The arm was encased in a moist bichloride dressing and placed in an elevated position.

At 9:30 A. M. the following morning—October 1—his temperature was 102°, pulse 94, respiration 22. He complained of pain in the thumb and hand as if the bandage was too tight, and of difficulty in passing his water, which subsequently disappeared. During the forenoon of this day Dr. Nelson reported the cultures to be positive of anthrax. At 3 P. M., the same day, his temperature was 101.4°, pulse 98, but weaker than in the morning; respiration 20. The arm was redressed. It was found that in that part of the forearm where no incisions had been made the skin and fascia seemed to be constricting the underlying muscles, which fairly bulged out of the incisions already made. Two of these were joined, virtually laying the skin and fascia open from the elbow to the wrist, and the arm was wrapped in a moist bichloride dressing and elevated as before. At 6:30 P. M. his temperature was 100°, pulse 84, respiration 30, and he vomited for the first time since admission. During the evening he rejected all nourishment, perspired freely, and complained of feeling very weak. Salines with whiskey by the rectum were also expelled. At 10 P. M. the temperature was 100°, pulse 90, respiration 28. October 2, at 7 A. M. the temperature was 97.8°, pulse 96, and hardly to be felt at the wrist, respiration 28. He complained of pain in the abdomen and was restless. At 2 P. M. the same day his temperature was 97.8°, pulse 100, and very weak, respiration 24. Retained but very little nourishment by the stomach or bowel. His mind was quite clear and his spleen was not enlarged on percussion.

October 3, at 5 A. M., the temperature was 95.6°, pulse imperceptible at the wrist, and the patient was delirious and urinated involuntarily. He died at 8:15 A. M. the same morning.

I have deemed this case worthy of record, both on account of the scarcity of recorded cases in medical literature in this country, as well as on account of the unusual manner of invasion. There is no question in my mind that the inoculation took place in the left forearm, and yet the patient was very positive that there was no pimple, or vesicle, or redness of the skin to indicate the point of entrance of the virus. As the first swelling did not appear until over a week after the date of exposure, it does not seem probable that the bacilli could have entered his lymphatics or blood vessels at that time, but probably were on the skin and gained entrance to the circulation later, through scratching the arm possibly. The progress of the local and general infection was so rapid and virulent after the first appearance of the swelling in the forearm that it does not seem credible to me that the infection could have lain dormant for so long a time.

With regard to the treatment, anything like excision of the infected area was out of the question when the case came under our care, so nothing was attempted beyond relieving the severity of the local inflammation, rendering the discharges innocuous, and supporting the patient's rapidly ebbing strength. I hope the recital of this case will make others alive to the possibility of the presence of this dread infection even in the absence of the typical "malignant pustule."

---

**Questions Relative to Rabies.**—Claudio Fermi has sought for an animal that is susceptible to hypodermic injections of fixed rabic virus, and found that the rat and the mouse answer to these requirements. He then used these animals for experiments to determine various actions of the virus. The virus produced a paralytic form of rabies in these animals, no furious cases being noted. He attempted to give these animals rabies by feeding them materials containing rabid matter, and believes that he demonstrated that they became rabid as a result. He tried to demonstrate whether the cerebrospinal fluid of rabid animals is virulent. Only two out of sixty-two animals died, with uncertain symptoms of rabies. As to whether the saliva is virulent, he was not able to demonstrate its virulence. As to the virulence of urine of rabies, he found of 170 animals treated by injection of urine none died of undoubted rabies. Many chemical agents destroy the activity of the virus. The action of cocaine and holocaine, used to relieve pain of injections, was found to have no effect in counteracting the virulence of rabic virus. The author also sought to obtain a vaccine that would immunize against rabies and take the place of Pasteur treatment with its inconveniences. His results were unsatisfactory. —*La Riforma Medica.*

**Disadvantages of the Dry-Gauze Dressing After the Operation for Septic Thrombosis of the Lateral Sinus.**—H. Gifford characterizes a dry-gauze dressing under the conditions named as a "bad use of a good thing." An operation for the lesion named generally leaves one or two openings discharging a fetid pus laden with virulent germs from the portions of the sinus not fully exposed; and as the inner wall of this tube is the only barrier between the germs and the intradural cavity, and as a large proportion of the deaths from the sinus thrombosis are the results of meningitis caused by the germs passing through this barrier, it would seem as if nothing could be more obvious than the necessity for giving the freest possible vent to the pus which continues, for a time, to be formed within the unexposed portions of the sinus. But instead of doing this, the great majority of operators seem to think that they are neglecting their duty unless they close these openings as thoroughly as possible with dry gauze, a material which, if the liquid in question were simply water, would certainly afford drainage by capillary attraction, but which, in the case of a thick albumin-laden liquid like pus, acts chiefly as a plug to keep it from escaping. The author prefers the free use of boric acid powder or the wet packing, his impression being that the former is preferable if the cavity can be cleaned more than once a day; but if the dressing is to be left for twenty-four hours, he prefers the wet (bichloride) gauze. He has treated five cases with the wet dressing, three of which recovered.—*Archives of Otology.*

New York, November 18, 1905.

## THE TREATMENT OF INACCESSIBLE BRAIN TUMORS.

THE surgery of the brain constitutes one of the most fascinating as well as one of the most difficult and dangerous branches of operative medicine. Tumors of this organ have received a great deal of study and attention, and although neurological methods have been sufficiently perfected to admit of a diagnosis, the recognition of the exact location of an intracranial growth is often a matter of conjecture. The cases which can be benefited by surgical interference are still greatly limited in number; of those in which the tumor is accessible, only a small proportion permit of such complete removal as to leave the patient free from paralyses and with unimpaired mental powers. In another class of cases the site of the neoplasm can be approximately determined, but it may be surgically inaccessible. There remain an unfortunately large number of patients, therefore, in whom radical procedures are impossible and where a mere relief from symptoms would prove a therapeutic desideratum of considerable moment. To meet the indications demanded by this group, it has been suggested that a portion of the enveloping bony cranium be removed in order to allow a part of the brain to protrude and thus provide a means of relief for the constantly increasing intracranial pressure. Few surgeons have given any attention to this subject and a great deal of misunderstanding exists with respect to the limitations of such a procedure.

The suggestion of alleviating, in this manner, the distressing symptoms which are associated with brain tumors, is based on the experience gained in cases where operative interference has brought about more or less relief, though the efforts to remove or even to locate the offending growth were ineffectual. One of the most recent contributions to this subject is an article by Harvey Cushing in *Surgery, Gynecology, and Obstetrics* for October, 1905. On whatever physiological grounds, he says, we may wish to account for the individual phenomena which attend these brain tumors, it is quite certain that they are due to the pressure effects from a slowly enlarging foreign body, and it should therefore be possible to relieve them by allowing the compressed brain to protrude through an opening made for the purpose in the skull. During infancy and early life, the purposes of a palliative operation would be fulfilled by the distention permitted by the partially membranous character of the cranial covering, and this has actually been observed. But when the elements of the vault have become fused, this is no longer possible except by some means such as that under discussion, unless an opening in the skull has resulted by a process of slow pressure absorption from the contact of a growing tumor with the bone immediately over the latter.

It would be a mechanically ideal treatment for inaccessible cases of brain tumor, if during adult life it were possible to bring about a dislocation of the cranial sutures, similar to that which has been observed to take place in small children. The attendant difficulties are obvious and under the circumstances we must content ourselves, for the present at least, with some such method as that here referred to, imperfect by reason of the fact that the "decompression" is very unevenly distributed. The dangers of such an operation are many, and instead of being palliative, it may only serve to aggravate the condition, a circumstance which has deterred many from undertaking it. But even in the comparatively small number of cases on record, an improvement in the results is evident between the earlier and later ones. Aside from the immediate mechanical disturbances due to a cerebral hernia, the almost inevitable result of the protrusion is an interruption in the functions of that portion of the cortex which is included in the bulging mass, and a preexisting paralysis may be greatly aggravated. In doing the operation it is therefore desirable to establish the hernia over some "silent" or unimportant part of the cortex and to avoid making it unnecessarily large. In two of the author's fifteen cases osteoplastic resections of the posterior aspects of the cranium were made, and although the results must be considered satisfactory as far as they went, the growth of the resulting hernia could not be suitably controlled. It was from a desire to obviate this formidable complication that Cushing determined to make the bone defect under the temporal muscle, which not only afforded a certain degree of protection, but exposed an area of the cortex which involved but few, and these not very important, motor centers. In six cases thus operated upon, the results are stated to have been very gratifying, without the undesirable sequelæ of the other method.

It seems quite reasonable to assume that in the case of subtentorial growths, it would be better to "decompress" through an opening in the suboccipital region. If the skull had already been opened in this portion with the expectation of finding there a removable tumor, this would remain the location of preference. Cushing doubts, however, whether the final result is any more effectual than would be the case were the defect placed elsewhere and the muscular incapacity which results may be very disturbing. Though limited in its application, the suggestion contained in Cushing's paper will generate a renewed interest in this branch of surgery. The tendency here as well as in other fields of surgical endeavor has unfortunately been towards the abandonment of the more conservative operative measures primarily intended for palliative effect only, for here the surgeon was not as likely to be rewarded and flattered with a brilliant success as regards a cure. At any rate an opportunity is here afforded for relieving distressing symptoms even when a cure is impossible, and it is to be hoped that others who may undertake to follow Cushing's suggestions will meet with equal success.

## PERFUME IN THERAPEUTICS.

It has long been known that certain odoriferous exhalations can exert a powerful influence on particularly susceptible individuals, even producing marked nervous disturbances. It has been shown that perfumes or odors produce nervous and respiratory reflexes, as well as urticaria and vertigo. These manifestations are rarely single, but combined or alternate. Odors will also produce a decided impression at times upon the digestive apparatus. Among the symptoms arising in the latter condition are nausea, vomiting, diarrhea, and excessive salivation. Nausea is more common, this symptom being excited by stenches, as well as odors from certain flowers or plants.

Odors, whether agreeable or disagreeable, are not causes of disease in the sense generally taken. They may disorder certain healthy functions by impairing nervous energy, by diminishing wholesome respiration, and thus creating a predisposition to attack by disease. And yet, strange as it may seem, scavengers, collectors of night soil or garbage, and laborers in slaughter houses or tanneries, do not seem to be particularly affected in consequence of inhaling the odors so prevalent in the vicinity of their labors. We are familiar with the assertion that emanations arising from manure act as a specific in rheumatism. Severe faintness is sometimes observed to overcome persons upon their entrance into a room in which tuberoses are kept. Headache is often produced by the odors emanating from the honeysuckle, lily, rose of Sharon, or carnation. The odor of betony, in flower, is said to have caused intoxication in those who gather it. The making of linseed decoctions, and the triturating of roses, pinks, walnuts, or colocynth, are often accompanied by attacks of syncope. Snakeroot, or black cohosh, has a faint, disagreeable odor, which sometimes causes headache and nausea. The odor from freshly ground coffee produces in some individuals a sickening sensation followed by nausea and in rare instances vomiting, but usually it is agreeable and appetizing. These few illustrations will suffice to show the marked influence that may sometimes be exerted over the nervous system by certain odors.

Attempts have been made to utilize odors in therapeutics. For instance, musk is said to exert a powerful impression on the sexual appetite. Persons given to lasciviousness are noted for their particular preference for this odor, and hence it has been suggested to employ this drug on these lines in the treatment of diminished sexual appetite. The odors of vanilla and heliotrope are credited with possessing a soothing influence over persons subjected to attacks of nervousness. The use of toilet water in the form of a spray will often restore those exhausted with the cares of business, social, or domestic duties. In the East the use of perfume is considered a purifier, though we look upon it merely as a luxury. It is asserted that those who are employed in laboratories where perfumes are made, or among growing flowers, are healthy to an extent exceeding those not so employed. As a result of further study and careful observation, it may be that we shall yet be able to utilize perfume in the treatment of certain complaints.

## Railway Sanitation.

At a recent meeting of the surgeons of the Erie Railroad, W. B. Landon, the chemist of this road, read a paper setting forth the methods of cleansing the cars, shops, etc., of that road, and suggesting ways and means for improving railroad sanitation which are well worth while considering. We may gain some idea of the extent of this problem when we note the fact that the Erie Railroad has a mileage of 2,314, with over 600 stations, through which passed in 1904, 20,395,440 passengers; the coaches in service numbered 750. These figures apply to but one system, but they give us some conception of the enormous number of persons traveling over the various railroads of this country. There are about twenty-eight varieties of pathogenic bacilli of wide distribution, and the chances are that many of these must lurk in the buildings and cars frequented by such a vast number of individuals. During and at the end of a run the condition of the cars as the result of expectoration, presence of food refuse, etc., offers an ideal culture bed for bacilli. The passenger cars in through service are thoroughly dusted, swept, and mopped, the side walls from ceiling to floor are washed with warm water and oil soap after every trip; cushions and carpets are cleansed by compressed air as their condition seems to require; toilet rooms are washed with warm water and soap and sprinkled with a disinfectant solution, and all porcelain work is cleaned with the same. In addition to this, each water-closet is provided with a disinfecting machine. In the case of transportation of persons known to have some contagious disease, the cars are taken off, kept out of service for one trip, and disinfected with formaldehyde gas. Cars used in local and commutation service, for some unknown reason, do not have the ceilings and walls washed so frequently as the coaches on through trains. It is quite evident that while these measures may secure that degree of cleanliness demanded by the traveling public, so far as outward appearances go, many dangerous microbes may easily escape destruction by such an inadequate process as that described. Cars should be sterilized with some suitable disinfectant at short stated intervals, and when the time comes that this is done, we may believe that the number of cases of the more common forms of contagious disease, such as grip, measles, diphtheria, etc., will be materially lessened. The reader of the paper referred to above, concludes that every railroad system of any size should have a sanitary force with a proper head and standard methods of caring for stations, cars, shops, etc. It is questionable whether entirely satisfactory results could be obtained by entrusting this matter to individual systems to carry out according to their own ideas. We should have some recognized standard as to what is effectual in disinfecting cars, stations, and public waiting places, and after having ascertained what is requisite to reduce the danger of contagious diseases to a minimum, an efficient corps of inspectors should be appointed to see that measures adopted are put into practice. This might perhaps be done by the health authorities of the cities in which terminals are located, the railroad recompensing the municipality for the service. When the necessity for more careful sanitation has been more thoroughly agitated, practical methods for carrying these measures into effect will no doubt suggest themselves. If more care is necessary on our great railway systems it is equally imperative on street cars, in our large cities, for there can be no question that these public conveyances serve as disseminators of disease.

### The Cuban Department of Health on Trial.

For the first time since the sanitary control of the city passed out of American hands, Havana is now seriously threatened with an epidemic of yellow fever. Cases have been imported from time to time, but there has been no spread of the disease, and no infection of mosquitos, the patients having been in every instance carefully and effectively screened. This time, however, the disease slipped in unannounced, and was not discovered until several persons had been attacked. Various theories regarding the importation have been current in Havana. One is that the fever was introduced by infected mosquitos imprisoned in a box of electrical apparatus brought from New Orleans; another, and most improbable, theory is that some infected mosquitos escaped from Las Animas Hospital, where yellow fever patients are cared for; a third is that the disease came from Mexico, as the first case was that of a passenger who had just arrived from that country. Since the first case was discovered several others have developed, one in the person of an American tourist, who had landed in Havana from New York five days before. This case is regarded as proof that there is now an infection of mosquitos, and we may, therefore, expect to hear of new cases from time to time until the infected stegomyias have been destroyed or have died a natural death from old age. Whether or not Havana is to suffer from an epidemic of yellow fever and a return to the ante-bellum condition of endemicity rests with the health authorities of the city. Doubts have been expressed, though without apparent justification, of the efficiency of the Cuban Department of Health, and the prediction has been ventured more than once that it would not stand the test of an actual invasion of yellow fever such as now threatens. We hope and fully believe that Dr. Finlay and the sanitary officials under his able direction will prove equal to the task, but, if they fail, the duty of this country is clear. We cannot allow Cuba to become again a menace to the health of our Gulf and South Atlantic ports, and, under the provisions of the Platt Amendment, American intervention will become imperative if the present little outbreak of yellow fever should unfortunately assume the proportions of an epidemic.

---

### Home Treatment for Consumptives.

The fact that efficient work may be done in the home treatment of tuberculous patients in the tenement districts of large cities has been shown by the results recently made public by the Medical Department of Columbia University. The experiment of attempting vigorous home treatment of the consumptive poor was begun early in 1903, and the work has been carried on and gradually extended since that time. The chief feature of the plan, in addition to the keeping of careful records of each patient's progress on special charts, is the putting forth of every possible effort to educate the patient and his friends in regard to the prophylaxis of the disease and the measures necessary to be followed in order to lead a sanitary life and secure fresh air, rest, and good food. A feature to which special importance is attached is the fact that each patient is constantly under the supervision of a visiting nurse, and the needy are provided milk, eggs, clothing, etc., if required. There have usually been about one hundred cases under treatment at one time. In the year ending September 30, 408 cases were treated, and the nurse made 2,746 visits. The results are said to have been extremely favorable.

## News of the Week.

**For Federal Quarantine Control.**—At the Southern conference on Quarantine and Immigration held at Chattanooga, Tenn., on November 9 and 10, nearly 300 delegates, representing sixteen Southern States were present. After considerable opposition from Governor Vardaman of Mississippi, a resolution presented by Congressman John Sharp Williams as chairman of the Quarantine Committee was adopted with but one dissenting vote, that of Senator Mallory of Florida. This requests Congress to enact a law whereby coast, maritime, and National frontier quarantine shall be placed exclusively under the control and jurisdiction of the United States Government, and matters of interstate quarantine shall be placed under the jurisdiction of the United States Government, acting in cooperation with the several State Boards of Health. Congress is asked to make adequate appropriation to enable the sanitary workers to stamp out as nearly as practicable the yellow fever carrying mosquito in its habitat in the United States. It further urges upon the Legislatures of the several Southern States the enactment of quarantine regulations as nearly as possible in accordance with each other. Resolutions were also introduced which indorse and approve the recommendations of President Roosevelt for changes in the immigration laws with a view to making it more difficult for the pauper and criminal classes to enter the United States.

**Diphtheria in Chicago.**—Four hundred and thirty-eight cases of diphtheria and fifty deaths were reported during the month of October to the division of contagious diseases of the Chicago Department of Health. During October, 1904, 294 cases of diphtheria were reported to the department, with recorded deaths of 38 for the same period. For the week ended November 3, 1905, 120 cases of diphtheria were reported, and 16 deaths from the same disease. Last week 113 cases were reported, with 16 deaths. This is a slight increase in the number of cases reported, but no increase in deaths. The disease is pretty well distributed. There has been no relaxation on the part of the health department in regard to inspection, disinfection, and the free use of antitoxin, but it is believed that if antitoxin were as freely used in private practice as it is by the department of medical inspectors, the death-rate from diphtheria would be reduced at least one-half. This is the month of highest diphtheria mortality. The school spread of the disease always culminates in November; but the eight thousand children now in school in excess of last year do not account for the nearly one-third excess of diphtheria deaths. That is due, it is claimed, almost solely to the neglect to use antitoxin, and such neglect is surely inexcusable in view of the fact that the Department furnishes the remedy gratuitously. The Commissioner asserts, with all the emphasis at his command, that no child will die of diphtheria to whom 3,000 units of a pure, tested diphtheria antitoxin is administered in the early stage of the disease.

**National Association for the Study of Epilepsy.**—The fifth annual meeting of the National Association for the study of Epilepsy and the Care and Treatment of Epileptics is to be held in the main hall of the New York Academy of Medicine, on November 29, 1905. The first session will begin promptly at half after 2 o'clock in the afternoon; the second at 8 o'clock the same evening, and the Association extends to all persons interested in

philanthropic work a hearty invitation to attend these meetings. The objects of the association are: (1) To promote the general welfare of sufferers from epilepsy; (2) to stimulate the study of the causes and the methods of cure of this disease; (3) to advocate the care of epileptics in institutions where they may (a) receive a common school education; (b) acquire trades; (c) be treated by the best medical skill for their malady; (4) to assist the various States in America in making proper provisions for epileptics. Arrangements have been made for a program of much interest, and the president of the association, Dr. W. P. Spratling of Sonyea, N. Y., will, in conjunction with Dr. W. G. Chase of Boston, present a set of biographs of various types of epileptic seizures and other pathological conditions affecting movements. The secretary is Dr. Everett Flood of Palmer, Mass.

**Obtaining a License by Process of Law.**—A physician has filed a petition for mandamus against the board of medical supervisors of the District of Columbia. The allegation is that when he took the examination for license to practice before the board he was unfairly treated. The examination which he took, and others precedent and subsequent thereto, were conducted, the petitioner charges, without any regard whatever for the law which prescribes the manner of conducting them, and he declares that the oral examination as conducted was arbitrary, capricious, and void, and that he should be granted a license upon the written examination alone. He further alleges that the board of medical supervisors have admitted that it is impracticable to comply literally with the law in the oral examinations, and that, therefore, these oral tests should be eliminated altogether.

**St. Luke's Hospital of Utica, N. Y. Dedicated.**—Announcement of the early completion of this hospital was made in the MEDICAL RECORD of August 26, and on October 18, St. Luke's day, the building was dedicated by the Bishop of Central New York. The hospital, which has a capacity of seventy-five beds, was constructed by Mr. and Mrs. Frederick I. Proctor, and was turned over to the Board of Trustees of St. Luke's hospital, fully paid for and completely furnished and equipped, the gift representing an outlay of about one quarter of a million dollars.

**New York Orthopedic Dispensary and Hospital.**—The Trustees of the New York Orthopedic Dispensary and Hospital announce that the Surgeon-in-Chief, Dr. Russel A. Hibbs, will give a course of clinical lectures on Orthopedic Surgery at the Institution, on Tuesday and Thursday afternoons, at four o'clock, from November 14 to December 19 (both inclusive). The course will be free to the medical profession and students.

**Rhode Island State Tuberculosis Sanatorium Opened.**—On November 1, the State Sanatorium for Consumptives at Wollum Pond was turned over to the State of Rhode Island by the commission having in charge the erection of the buildings. Addresses were made by C. Alvin Potter, chairman of the building commission; by J. Fred Gibson, in behalf of the trustees, and by Governor Utter, Dr. V. B. Bowditch of Boston, and others.

**Information Wanted as to the Practical Lives of the Blind.**—Dr. George M. Gould, 1722 Walnut street, Philadelphia, would be grateful for any trustworthy information as to the methods which have been devised by the blind in overcoming their disability or in gaining a livelihood. Accounts of such lives, anecdotes, references to literature, etc., are also desired.

**New York and New England Association of Railway Surgeons.**—The Fifteenth Annual Meeting of this Association will be held at the New York Academy of Medicine on Friday and Saturday, November 17 and 18, 1905, under the presidency of Dr. G. P. Conn of Concord, N. H. The secretary is Dr. Geo. Chaffee, 338, Forty-seventh street, Brooklyn, N. Y.

**Cincinnati, Hamilton & Dayton Railway Surgeons' Association.**—The annual meeting of this association will be held at the Commercial Club, Dayton, Ohio, on November 14, 1905. The *President* is Dr. M. F. Hussey of Sidney, Ohio, and the *Secretary*, Dr. Mark Millikin of Hamilton, Ohio.

**Diphtheria Closes Schools.**—Four schools in the Borough of Queens were closed recently because of a diphtheria epidemic in Woodhaven and Union Course. The Assistant Sanitary Superintendent is quoted as saying that some of the local doctors have been very lax in their duties, and as a result hundreds of children attending these four schools have been exposed to the infection.

**The Plague in Brazil.**—It is reported that several cases of bubonic plague have occurred in Rio Janeiro, and the Board of Health has called a meeting to consider what measures are necessary to prevent an epidemic.

**Open-Air Treatment of Smallpox.**—The open-air treatment has recently been successfully applied to smallpox at Nottingham, England. All patients so treated in the sanatorium made a rapid recovery. The patients are nursed singly in bell tents, with open sides, *i. e.* practically in the open air.

**A Telephone Without a Mouthpiece.** — From Nottingham, England, comes the description of a telephone apparatus designed to obviate the possibility of disease transmission by the usual mouthpiece. The construction is such that the mouthpiece is omitted altogether, and the receiving and transmitting apparatus is combined in a small metal case, shaped like a watch. This is held continuously to the ear, both in speaking and in listening, the transmitting microphone being made so sensitive that it becomes unnecessary to concentrate the sound waves on it by the aid of any mouthpiece such as is ordinarily used.

**A Physician Punished for Falsifying a Death Certificate.**—For the first time in the history of the Department of Health a physician has been imprisoned for making a false report on a death certificate. On November 8, 1905, in the Court of Special Sessions, a physician was found guilty of making a false report as to the cause of death in the case of a young woman who died last July. Upon the certificate of death the cause of death was given as "Sloughing fibroid tumor and paralysis of the heart." An autopsy revealed the fact that a criminal operation had been performed, and the cause of death as stated by the coroner's physician was "Sepsis following uterine infection."

**For a Tuberculosis Hospital in Yonkers.**—At the meeting of the Practitioners' Club of Yonkers, held on November 15, the subject for discussion was Tuberculosis, Its Prevention and Cure. The object of the meeting was to create a public sentiment in favor of establishing a Dispensary and Hospital in Yonkers for the treatment of tuberculous patients. Papers were read by Dr. Herbert M. King of Liberty, Dr. S. E. Getty of Yonkers, Health Commissioner Darlington of New York, Dr. Alfred Meyer of the Montefiore Home at Bedford, and Drs. George F. Laidlaw and Barstow of New York.

**Consolidation of Journals.**—Announcement is made that, with the beginning of the new year, the *Medical News* will cease to exist, being incorporated with the *New York Medical Journal* and the *Philadelphia Medical Journal*. We are sorry to have to record this fact, for the *Medical News*, established over sixty years ago, has always held a high position among the medical journals of the country—never higher than under its present editorial management—and its demise is a distinct loss to medicine.

**In Aid of the Russian Sufferers.**—A sub-committee of the Medical and Allied Professions has been organized under the auspices of the National Committee for Relief of Sufferers by the Russian Massacres. The officers of the committee are Dr. A. E. Isaacs, chairman; J. Weinstein, pharmacist, and D. N. Booth, dentist, vice-chairmen; Dr. J. Barsky, treasurer, and M. Dlugasch, secretary, and included among its honorary members are Drs. I. Adler, M. Einhorn, W. Freudenthal, M. Manges, Alfred Meyer, Willy Meyer, and J. Rudisch. The committee issues an appeal to the members of the Medical, Pharmaceutical, and Dental Professions of Greater New York for subscriptions to the Relief Fund. Checks should be drawn to the order of Jacob H. Schiff, Treasurer, and forwarded to Dr. J. Barsky, 203 East Broadway.

**Dr. Senn Honored.**—A testimonial banquet was given to Dr. Nicholas Senn at the Auditorium Hotel, Chicago, last Saturday evening. There was an attendance of 686, comprising representatives from twenty States. Letters and messages of congratulations were read from several prominent physicians in different parts of the United States, who regretted their inability to attend. Dr. Wm. A. Evans acted as toastmaster. Dr. Joseph D. Bryant of New York presented a gold medallion to Dr. Senn, miniature replicas of which were distributed among those in attendance. On one side of the medallion was a likeness of Dr. Senn; on the other the inscription: "To Nicholas Senn, the Master Surgeon, from his Fellows, November 11, 1905." Dr. L. G. Nolte of Milwaukee presented Dr. Senn with a silver loving cup, which was given by his former private pupils. Addresses were made by Drs. Wm. F. Mayo, Lewis S. McMurtry, John A. Witherspoon, Charles Adams, Daniel R. Brower, Charles A. L. Reed, Wm. E. Quine, and Col. Harvey. The speeches were interspersed with music by a Swiss quartette and by the banqueters. Dr. Norval H. Pierce led the singing. The occasion was a memorable one and Dr. Senn received a great ovation.

**Leper Colony for Massachusetts.**—It is expected that the camp now in process of construction on Penikese Island, fourteen miles from New Bedford, will shortly be ready to receive Massachusetts' leper population of five patients Dr. Louis Edmonds of Harwich, who has had charge of the lepers at that place, will become superintendent of the colony.

**Hospital Bequests.**—By the will of Rebecca M. St. John the Associated Charities of Newburgh inherits $5,000 and the Northern Dispensary of New York $3,000.

**Cold Air Not Good for Monkeys.**—The keeper of the Lincoln Park Zoo, who had a theory that the open-air treatment might be successful in averting tuberculosis from monkeys, has had occasion to learn that in this respect at least the bond between man and his simian ancestor is a slight one. Just three monkeys remain of the colony of ten that three weeks ago began to take the fresh-air cure.

**Boston Tuberculosis Exhibition.**—An exhibition for the instruction of the people in regard to the nature and treatment of tuberculosis, and especially concerning prophylaxis will be opened in Faneuil Hall in Boston on December 28. It is expected that much of the material collected for the New York exhibition will be utilized.

**Fair for the Hospital for Crippled Children.**—At a "bazaar of all nations" held at the Waldorf Astoria Hotel on the afternoon and evening of November 9, for the benefit of the Hospital for Crippled Children, it was estimated that over $6,000 was realized between noon and eight o'clock.

**Obituary Notes.**—Dr. Geo. W. Hudspeth of Little Rock, Ark., died on October 29, in Memphis, at the age of fifty-four years. He was graduated from the Memphis Hospital Medical College in 1885. He practised dentistry for some time and then took up the study of medicine.

Dr. G. W. Kemp of Marseilles, O., died on October 24 at the age of eighty-three years. He was graduated from the Cleveland College of Physicians and Surgeons in 1870, and was one of the oldest practitioners in central Ohio.

Dr. Frederick Templeton Zabriskie of New York City died suddenly on November 5, at the age of thirty-four years. His death was due to heart failure, following pneumonia, from which he had been ill a week. Dr. Zabriskie was graduated from the College of Physicians and Surgeons, New York, in 1895. In recent years he devoted much of his time to work in Lenox and Pittsfield, and was on the staff of the House of Mercy of Pittsfield.

Dr. G. N. Munsell of Harwich, Mass., died on November 1, at the age of sixty-nine years. He was graduated from the Harvard University Medical School in 1860, and served as surgeon in the 35th Massachussetts Volunteers in the Civil War. He held many public offices, and in 1890 represented his district in the Massachusetts House of Representatives, being clerk of the committee on charitable institutions.

Dr. J. B. Bouchard of Montreal died on November 5, at the age of forty-nine years. He was graduated from the University of the Victoria College, Cobourg, Ont., in 1877, and was for over twenty-five years the police surgeon.

Dr. Joseph Watson of Detroit, Mich., died on November 2, of heart failure, at the age of eighty-one years. He was graduated from the Cleveland University of Medicine and Surgery in 1853. He practised in Ohio for almost fifty years, and then retired to Detroit.

Dr. A. M. Pierce of New Bedford, Mass., died on November 6, at the age of fifty-three years. He was graduated from the College of Physicians and Surgeons of New York in 1889, and had held every office in the South Bristol Medical Society.

Dr. Clarence B. McClure of Jeffersonville, Ind., died on October 29 at the age of fifty-one years. He was a son of Dr. David McClure, who was a pioneer physician of Clark County, and was graduated from the Kentucky School of Medicine, at Louisville, in 1871. Later he was made assistant physician at the Central Hospital for the Insane, at Indianapolis, and for a time lived at Shoals, Ind.

Dr. W. M. Woodworth of Grayling, Mich., died on November 2, at the age of seventy-six years. He was graduated from the Medical School of the University of Michigan, in 1853, was county physician for several years, and was coroner at the time of his death.

## OUR LONDON LETTER.

(From our Special Correspondent.)

MEDICAL OFFICERS OF HEALTH ON NOTIFICATION—PRIMARY TUBERCULOSIS OF THE FALLOPIAN TUBES — FOUR YEARS OF HOSPITAL ABDOMINAL SURGERY — SIR W. CHURCH ON SCHOOLS AND HEALTH—DR. THOMPSON ON MILK DEPOTS —NEW ELECTRIC THERAPEUTICS — FINGER-PRINTS — SIR H. CROOM—OBITUARY NOTES.

LONDON, October 27, 1905.

At the annual meeting of the Society of Medical Officers of Health Sir Shirley Murphy was inducted as president for the ensuing year, and after acknowledging the compliment observed that in a few months the society will be celebrating its jubilee. He hoped the purposes for which it was constituted fifty years ago would still be pursued—viz., mutual assistance and information, and the advancement of sanitary science. The past records, showed it enjoyed the confidence of the public, and the increasing work put on medical officers of health should be an additional incentive to rise to their responsibilities as useful servants of the public.

Dr. Charles Sanders then opened a discussion on the relation of the officers to practitioners in respect to the Notification Act. As one who devoted his whole time to the office and had no control over a hospital he referred to the cases sent to the hospitals of the Asylums' Board with erroneous diagnosis—about 10 per cent. last year. He considered the mistakes were mostly due to a desire to make a speedy diagnosis rather than wait for full evidence. The statutory duties devolving on the officer of health precluded his undertaking consultative work in infectious diseases, and the Local Government Board held that it would be contrary to public and professional interest to alter this relationship. He suggested that it was expedient for hospital authorities to arrange for isolation of infectious cases, but this suggestion met with hardly any support, and will certainly not commend itself to the ratepayers, who are already much dissatisfied with the extravagance of the Asylums' Board.

Dr. Howard Jones thought the administration was most efficient when the health officer personally knew all the practitioners. The larger the town the greater the official distance between them. Where isolation was not carried out doubtful cases would be sent to the hospital. He advocated the supply of antitoxins to the practitioners, as it brought them and the health officer together, and enabled the latter to urge the use of the antitoxin as a preventive in the case of contacts.

Dr. J. G. Glover, speaking from the practitioners' point of view, said error often arose from hurrying off the patient when he should be kept at home for the development of evidence. It would be desirable for removal within a certain time to be optional—not compulsory. It should also be optional to consult with the health officer, and with tact on both sides there would be no difficulty in reducing the number of errors of diagnosis. He strongly opposed the increase of hospitals with a view of admitting suspicious cases.

Dr. Goodall said most errors were connected with diphtheria. It was impossible in many cases to be sure about this without waiting too long, and he held that the practitioner was right to certify them; otherwise much mischief might result. The public press had reported that a patient certified for scarlet fever was taken into a ward where, if he had not got it, he would contract it. This was false, so far as the Asylums' Board was concerned, for they had plenty of accommodation for doubtful cases.

Several other members joined in the discussion and it seemed to be thought the officer of health might very well render assistance to any practitioner who desired his opinion.

At the opening meeting of the Gynecological Society Dr. Macnaughton-Jones read notes of a case of primary tuberculosis of the Fallopian tubes. At one operation the condition was found and the tubes resected. Sections were shown. There was no evidence of tubercle elsewhere and the patient was otherwise healthy. Recent statistics indicate that tubercle is more frequent in the female genitalia than usually believed, and of these parts the tubes seem the most liable to be attacked. Secondary cases are, of course, more frequent. In this case the ovaries were not infected.

Dr. Parsons referred to Behring's view, that miliary tubercle was the expression of immunization, and his proposed serum would produce this and immunize against the bacillus. In opening the abdomen, if one found tubercle of a miliary character the prognosis was good; the process of immunization was, in fact, going on, whereas the presence of caseating masses was of bad import. He instanced a case in point the patient having made a rapid recovery.

A member remarked that in most cases of tuberculous peritonitis ascites was present, but in this there was none. Another said ascites was not common when tuberculosis was limited to the uterus and adnexa, but was common in malignant disease. One had found tubercle more common in single women, but another in married.

Dr. Bedford Fenwick then read a paper, detailing four years of hospital abdominal surgery. He pointed out the different conditions of the patients in hospital and private cases, which gave the latter better chances, and his private cases had been even more successful than hospital ones. The records he now submitted were his operations in the Soho Square Hospital, from March, 1901, to February last, in which period he had performed 185 sections, with 6 deaths. The cases included 121 for removal of appendages, 55 of hysterectomy, others of ventral hernia, ectopic gestation, hysteropexy, and prolapsus. Of the operations for adnexal disease 3 cases died, the other 3 fatalities being cases of hysterectomy. Dr. Fenwick said he thought general physicians were not usually aware that after 50 years of age fibroid fixed in the pelvis, by losing the full blood supply they obtained during menstrual life almost invariably degenerated, and that if such patients were left to nature septic infection occurred sooner or later. He considered the following principles might be enunciated with all the authority of the society to the immense service of the profession:

1. A fibroid in a patient over 40, which fills the pelvis in the great majority of cases, exercises dangerous pressure on the rectum, bladder, or ureter, and should therefore be removed.

2. In such a case a fibroid which extends centrally half way to the umbilicus and is nodular on the surface and hard should be removed as soon as possible, or will degenerate and endanger life.

3. Where the patient suffers from frequent and prolonged losses, unchecked by rest or medicine, where the uterus is enlarged and nodular to the level of the pelvic brim, hysterectomy should be done as the safest and best course.

Further Dr. Fenwick held that tubal cases can be operated on with infinitely greater safety than is involved in the risk of less radical treatment. As to after treatment he made some practical statements that were generally approved by the audience. He has given up both washing out and drainage. He has watched others washing up pus and blood and thought they could not afterwards get rid of it, and he does not attempt to drain against gravitation. The moment the pulse begins to quicken after the second day he gives calomel and salts—if necessary an enema. If there is dullness of first sound at apex, stimulants and strychnia at once. If there has been much loss of blood or collapse he puts a pint or two of hot water into the peritoneal cavity before closing the wound. Not a mouthful of anything for twenty-four hours, and only tea, milk, and bread and butter until the bowels have acted. "The best way to dry the pelvis and peritoneum, and so secure rapid healing, is to make the vascular system and the patient deadly thirsty."

Dr. Lewis Jones, in the first Hunterian Society's lecture (T. F. J. Smith presiding), pointed out some new lines of work in electrotherapeutics. Having remarked on the advantage of public supplies of current, and the value of the surgical exploring lamp, he emphasized the value of Röntgen rays. As more serious diseases became referred to the medical electrician, there was less danger of the work falling into the hands of unqualified persons, especially as the methods become more exact. High frequency currents and light baths, Dr. Jones thinks, will lose the prominence lately given to them. Electrolysis has lately extended its applications. The writings of Leduc on the "Ions in Medicine" induced Dr. Jones to treat some cases of lupus and rodent ulcer by the electrolytic introduction of zinc ions, using a 1 per cent. solution of zinc chloride. Two cases of rodent ulcer were perfectly healed by a single application, continuing well to the present time, six and nine months respectively. The results in lupus were not so decisive, but they encouraged him to persevere. Electrolytic introduction differs from subcutaneous injection, as the latter conveys the drug into lymphatic spaces, but electrolysis forces the ions into intimate union with the protoplasm of the cells.

Sir Wm. Church has spoken out on the evils of infant schools in a way that disturbs the self-styled "educationists," whose obsession is assuming a threatening aspect for the community. The ex-president of the College of Physicians is as great an authority, in public estimation, on the health of children as the professional crammers of their young minds with useless facts. He says the infant class, as hitherto conducted, has a benumbing influence on the mental activity of the children, and those who have watched the listlessness of the lower forms in any of the schools

will heartily indorse the statement. He said, further, that free breakfasts are no remedy for the improvidence and ignorance that prevails; and even State employment will not raise the standard of the lowest classes or teach them the essentials of decent and healthy life. Thus Sir William evidently approves the rising revolt against driving babies to schoolrooms to be nursed by teachers. The changes forced on the domestic life of the people are decidedly prejudicial to health. Formerly mothers instructed their elder daughters on the care of the younger ones; now all are driven to schools, and even the elders suffer, as they marry in total ignorance of the management of a home, the care of food, and the responsibilities of a family.

Dr. W. J. Thompson devoted an address at the Jervis Street Hospital, Dublin, to the value of infant milk depots as established first in France, in 1890, and then in New York, in 1893. The plan was not taken up here until 1898, since which it has gradually spread, and a number of towns have institutions under municipal management, while private depots have been established in London and York Commenting on the good results on the Continent, in the United States, England, and Scotland, Dr. Thompson urged the establishment of depots in Dublin, where the infant mortality is enormous.

Dr. J. G. Garson lectured at the Medico-Legal Society on finger-prints, showing the various forms by lantern slides. The arch, the loop, and the whorl, as well as the composite, or mingling of the two latter, were shown and their relative frequency stated. Between the two hands of the same person there is some correlation, most marked on the middle fingers; the same pattern on all ten digits is rare. Dr. Garson emphasized the necessity of extreme exactitude and the great importance of discrepancies; if these are neglected erroneous conclusions may be drawn from resemblances. This is specially likely to occur in examining accidental prints. The Prison Service finger-print staff is carefully trained in taking, reading, and classifying prints. At present no two sets of prints of even a single digit have been found to be identical unless they were made by the same person, and the prints are not materially changed after years have elapsed.

Sir Halliday Croom succeeds Professor Simpson in the Chair of Midwifery at the University of Edinburgh. He was for several years assistant to Professor Simpson, but left that post for one in the extramural school. He is a past president of the Edinburgh College of Surgeons, and was many years physician to the R. Maternity Hospital. Three years ago he received the honor of knighthood.

Mr. Henry Morris, surgeon to the Middlesex Hospital, has presented £1,000 towards the endowment of the Medical School.

Dr. Robert Somerville, J.P., died on the 15th inst., aged 69. He was M.D., Edinburgh, 1859, L.R.C.S., Edinburgh, 1858. He had an extensive practice in Galashiels, where he resided many years. He was highly esteemed throughout the Border counties, and took an active interest in public matters. One of his sons was associated with him in practice.

Mr. Jones Morris died on the 15th inst., aged 57. He was M.R.C.S., England, 1870, and L.R.C.P., Edinburgh, 1872. He was one of the most active practitioners in North Wales, and took great interest in public affairs, and in the welfare of the profession. He was a governor of the University College of North Wales and an ardent worker in educational matters.

## SEVENTY-SEVENTH CONGRESS OF GERMAN NATURALISTS AND PHYSICIANS.

(From Our Special Correspondent.)

NEUROLOGICAL SUBJECTS — DEATH BY ELECTRICITY — PULMONARY TUBERCULOSIS—ARTERIOSCLEROSIS—SERUM TREATMENT OF SCARLATINA—DEFECTIVE CHILDREN—GYNECOLOGICAL SUBJECTS.

MERAN, October 30, 1905.

NUMEROUS interesting topics were discussed in the Section in Neurology of which Professor Heinrich Obersteiner of Vienna was president. Dr. Edinger of Frankfort spoke on the evolution of the cerebral cortex from the lower orders, and described a new method of subdividing the brain which is based in studies in comparative anatomy. By using this it is possible to devise a nomenclature applicable to all the vertebrates, from the lowest up to man. In the discussion that followed, Dr. Edinger's proposal was warmly seconded by Dr. Ziehen of Berlin. Dr. Egmont Müner of Prague discussed the question of autogenous regeneration of nerve fibers. His experiments in rabbits gave results that were somewhat at variance with those of Bethe. He excised large portions of the sciatic nerve, and in four instances obtained visible growth of the peripheral and central stumps through the scar. Three times the growth could be demonstrated only by means of the microscope, while the physiological test was negative. In four cases no union of the severed ends had taken place, and no trace of regeneration could be detected in the peripheral stump. Dr. Marburg of Vienna spoke of the so-called acute or subacute form of multiple sclerosis. This he said was characterized by a pronounced stage of several months which was followed by a rapid onset of grave symptoms. The causes of such affections were blood poisons, which were able to attack the nervous system only after the vessels had been injured through cold or trauma. Foci formed in which the nerve fibers degenerated without any functional lesion of the axis cylinders, after which multiple sclerosis followed. Dr. Hermann of Gratz presented the results of his own clinical and pathological observations relative to the origin of tumors of the base of the skull. The conclusion reached was that the fibromatosis and fibrasarcomatosis forms are to be regarded as neurofibromata of the basal nerves, and microphotographs were demonstrated to show this.

Dr. S. Jellinek of Vienna delivered an address on the subject of the nature of death by electricity. His studies, which had been uninterruptedly carried on for a period of six years, were founded on cases of accidental electrocution, animal experiments, and histological observations in the central and peripheral nervous systems. The manifestations presented by those dying as the result of electrical discharges were discussed from the standpoint of phenomena due to disturbances of consciousness, of the motor centers, of the respiratory apparatus, of the heart, and also regarding the time of death. Both clinical and experimental observations lead to the conclusion that there is no typical scheme of death by electricity. The technical character of the current on the one hand, and the individual circumstances on the other cause the picture to be a variable one and determine whether disturbances of consciousness, of respiration, or of the heart's action shall be most prominent. The mechanics of death by electricity depend on a double action, first, the physical component working as an overstimulation closely allied to shock, and second the purely electrical action of the current on the cells and cell groups of the various organs. Two experiments described by Dr. Jellinek illustrate these two phases. An anesthetized rabbit can stand without injury contact with a current that would otherwise be fatal, that is, the physical component is eliminated. The heart of a rabbit killed by electricity may be brought into action again after a half hour of arrest, by the application of the same current, that is, the dynamogenic action of the current produces inhibitions or disturbances of vital functions, which may, however, be susceptible of relief. For this reason it appears that death by electricity may for a time in many instances be only apparent.

In the Section on Internal Medicine, Dr. Maxim Wassermann spoke of his method of producing passive hyperemia of the lungs in pulmonary tuberculosis. In addition to his 32 old cases he had tried it on 28 new ones. In nearly all cases the procedure was easily applicable, and undesirable or weakening effects were not observed. It was especially noteworthy that in spite of the marked passive hyperemia hemorrhages were never caused. This, he said, was strong evidence against the existence of the congestive hemorrhage, which was denied by many authors. The therapeutic results were favorable in all stages of the disease, and the patients treated in this way progressed more favorably than the control cases. Only when there was marked involvement of the bronchi did the method fail to give good results. Dr. Auffrecht of Magdeburg spoke of the use of tuberculin in pyretic consumptives. He considered the tuberculin treatment suitable for cases in which the process might be supposed to be restricted to a more or less limited number of foci, in which the temperature was not too high and in which the pulse rate did not greatly exceed 100 per minute. Dr. Barth of Leipzig, said that he had found that in tuberculous guinea-pigs the hypersensitiveness to tuberculin went hand in hand with the severity of the lesions. This susceptibility was not altogether due to a general disturbance of the entire organism through the disease, but was in relationship with the local foci. In the discussion that followed several speakers argued against the tuberculin treatment.

Drs. E. Ponfick of Breslau and Friedrich Müller of Munich discussed nephritis. According to the former the subdivision of Bright's disease into parenchymatous and interstitial forms of nephritis is, in view of modern knowledge, neither necessary nor feasible. A rational classification, while founded on a histological basis, should also take into consideration both the variety of the clinical manifestations and the wide range of etiological factors. Müller said that as the term nephritis could be translated only as meaning inflammation of the kidney, it was applicable only to a restricted and poorly defined group of renal affections, and not to the mainly degenerative forms. The term morbus Brightii had lost its old significance as a disease characterized by albuminuria and edema, and had not received a new

one, so that he suggested the appellation "nephrosis" for the degenerative types. The closer classification of renal affections would preferably follow etiological principles.

Dr. Lustig's topic was arteriosclerosis and its treatment. He pointed out the great increase in the frequency of this disease, which, formerly associated almost exclusively with old age, had now become common in the years of most active life. Two chief factors required attention in order to make treatment effective; diet, and elimination of the causative factors. The dietary regulations had as their object the restriction of the albumin metabolism to its lowest terms, the avoidance of foods rich in lime such as milk, cheese, eggs, and certain vegetables, and prohibition of alcohol or much tobacco. General metabolism was to be encouraged by exercise and by mild drinking cures, which were of great importance, as they tended toward decalcification. The speaker at first employed distilled water for this purpose, but abandoned it, as it damaged the kidney. Since then he had recommended certain natural mineral waters, which were valuable on account of their freedom from lime salts.

In the Section on Pediatrics, Dr. Schick of Vienna again recommended the same treatment of scarlet fever with Moser's serum, in view of the favorable results obtained in the Vienna Pediatric Clinic. Fifty-seven cases were treated with the serum; of these 8 were of moderate severity, 39 had a doubtful prognosis, and in 10 cases the outlook was unfavorable. When the injection was given on the first or second day (18 cases) no deaths followed, and when on the third day (12 cases) one death was reported. Of 13 children that did not receive the serum till the fourth day 5 died, and the 3 cases taken still later all died. So it appeared that even up to the third day the serum might be expected to save life. Only the very grave and extremely grave cases of scarlatina formed the field for Moser's serum, but in these cases other modes of treatment offered little hope, so that there was nothing to lose and much to gain by making the injections.

Dr. Theodore Heller, Director of the Institution for Defective Children in Vienna, presented a paper on the effect of occupation therapy on abnormal children. Among other things he said that by a proper selection of bodily exercises it was possible to effect improvement and even cure in various phases of mental abnormality in children. In the case of slightly weak-minded children, who not infrequently showed great proficiency in their studies without being able to make practical use of them, the treatment was intended to train the powers of coordination and to assist the faculty of adaptability under practical conditions. Physical treatment was especially valuable for hysterical children, whose minds were often filled with morbid vagaries. Corporal exercise brought these children back to the domain of reality, and gradually caused their phantasies to disappear. In conclusion Heller spoke of the so-called psychosthenic children, who, while endowed with normal intellectual faculties, manifest defects of emotion and volition. He warned against confusing such a condition with insanity, and stated that it could often be entirely cured by a plan of treatment in which occupation therapy played a large part.

In the Section on Gynecology, Dr. Polano of Würzburg presented observations on the prophylaxis of streptococcus infections in the puerperium and after operations, by active immunization. Starting with the view that the virulence of the streptococci is largely due to the nature of the soil in which they grow, Polano sought to alter the nature of the organism serving as culture medium by injecting dead cultures of pathogenic streptococci. After experiments on himself, he injected such material into 60 obstetrical and gynecological patients as a prophylactic. No undesirable effects were produced, but the practical value of the procedure was still in doubt. In experiments on animals it was found possible in this way to prevent infection, and the speaker hoped that other clinicians would test the method.

Dr. Engel of Dresden said that the Freund-Virchow theory regarding milk formation had been abandoned, and that the fat of the milk was formed by the cells of the mammary glands either from the body fat or from that of the food. By determining the iodine number of the milk fat before and after increased amounts of food fat were given to nursing women he was able to show that the food fat took direct part in milk formation. If fatty food was withheld the milk fat approached the type of body fat. He concluded that the dietary of nursing women should be subjected to further study. Engel also discussed the variations in the functional efficiency of the mammary glands of different individuals. A study of the anatomical structure of well-developed puerperal breasts showed that two main types existed. In the one the parenchyma was in excess and the connective tissue scanty, while in the other the reverse was the case. The former variety was the more efficient, but it was impossible from surface conformation or by palpation to distinguish the two. In considering disorders of the breast the question of whether the disturbance was a functional or an organic one required investigation, for it could not be denied that psychical factors were of importance during lactation.

## OUR BERLIN LETTER.

(From Our Special Correspondent.)

### THE TUBERCLE BACILLI OF MAN AND THE LOWER ANIMALS.

BERLIN, October 26, 1905.

ALTHOUGH the medical societies of Berlin are not yet in active session, nevertheless the report of a most important piece of work is at hand. These investigations which have been made during the last three years by members of the Reichsgesundheitsamt have been concluded this summer. They relate to the tubercle bacilli of different origin and to the relations between tuberculosis of men and the lower animals. The work comprises two main divisions, the theoretical and the practical.

Tuberculosis of the warm-blooded animal is caused by two kinds of tubercle bacilli, the one kind found in chickens, the other in mammalia; the latter can be divided into two well characterized kinds of bacilli, viz., the bovine type and the human type. Although the bacilli of tuberculosis which infect chickens have been cultivated for a period of two years in guinea-pigs, mice, rabbits, and cattle, a transition into the bacilli common to the mammalia has never been observed. Furthermore, the tubercle bacilli common to man have never been observed to change into the bovine type, although the former were cultivated for a long time in rabbits, goats, and cattle. It must be noted, however, that the bacilli of the typus humanus have been found in two tuberculous parrots.

In the tuberculosis of cattle only the bacilli of the bovine type have been cultivated in eleven cases. The bacilli of the human type have never caused a progressive tuberculosis in cattle, although attempts at infection were made by the implantation of pure cultures, by the feeding of pure cultures and of materials from tuberculous catarrh, and by inhalation of pure cultures. In pigs there were found in seven cases of tuberculosis the bacilli of the bovine type, and little pigs could be infected without exception by being few with pure cultures of this type. By feeding pigs with an abundance of the pure cultures of the human type, a general tuberculosis of slow progress has been caused.

Sixty-seven different cases of tuberculosis in human beings were carefully examined. As a result of these investigations it is stated that infection of man with bacilli of the bovine type may occur. In fifty-six cases the human type was found, in nine the bovine type, and in two both types mixed. In the majority of cases the bacilli of the bovine type were found at the portal of entry or in the glands adjacent to the intestines and mesentery or in the glands of the neck. In twelve cases of tuberculosis in children under ten years of age the intestines were found to be the portal of entry. The bacilli of the bovine type cultivated from the human body could never be distinguished from the same bacilli cultivated from cattle, either by the morphology or by the methods of cultivation.

The practical results should be considered in two groups, those relating to domestic animals and those relating to the human being. The tuberculosis of cattle is caused by bacilli of the bovine type which have their source in other infected cattle suffering from tuberculosis of various parts of the body. But it is possible that cattle can become infected by the bacilli of the bovine type which have infected sheep, goats, pigs, and human beings. The prevention of the propagation of the tuberculosis of cattle may be accomplished by the destruction of the bacilli which infect these animals. It is possible that the bacilli common to all other domestic animals, to poultry, and to the human being, are capable of infecting the pig, but since we have noted that in these diseased animals the bovine type has been found nearly without exception, we can assume that the tuberculosis of pigs is due to the bacilli common to cattle. In the same way it may be assumed that the tuberculosis of other domestic animals is caused by the bacilli infecting tuberculous cattle. Thus it may be assumed that by diminishing the disease in cattle, tuberculosis of the other domestic animals will also be lessened. The tuberculosis of domestic poultry such as chickens, pigeons, and geese, is caused and propagated by the tubercle bacilli of chickens.

In tuberculous organs of human beings the bacilli of the human type have been found for the most part. Consequently human beings as a rule infect one another, and the fight against tuberculosis is this respect should be directed principally against the bacilli of infected human beings. However, researches have shown that human beings may also become infected by the bacillus of the bovine type by means of the milk and meat of tuberculous domestic mammalia. The bacilli of the bovine type as a rule, infect the orifices and the neighboring glands or the latter alone. But because these bacilli have in isolated cases infected the vital organs, it must be considered dangerous for human beings, especially in childhood, to take

as food any part from tuberculous animals which contains living bacilli of the bovine type. A conscientious oversight of all meat offers great protection against the dissemination of tubercle bacilli. Another means of protection is found in the proper preparation of such food. The possibility of transmitting tubercle bacilli to human beings by means of milk and milk products becomes greatly diminished by protective measures in relation to tuberculous cattle.

The importance of these researches, both on account of the long period devoted to the observations and on account of the men who have conducted them, is very great. Since Koch in the Congress of Tuberculosis at London, called attention to the great difference between bacilli of the human type and those of the bovine type it has not been definitely accepted in Germany that human beings could be infected by milk from tuberculous cows. Now, however, it is positive that the fight against tuberculous cattle must be continued. Behring's new vaccine was looked upon coldly in Germany because it was considered that this investigator should not have spoken of the possibility of the cure of tuberculosis in human beings before he could show practical results. However, these researches which have just been described at least prove as true Behring's statement which was published at Cassel in 1903, that the milk of tuberculous cattle is very dangerous for infants.

## Progress of Medical Science.

*Boston Medical and Surgical Journal, November 9, 1905.*

**Treatment of Chronic Prostatic Enlargement.**—J. P. Lewis offers the following conclusions: (1) The use of sounds is generally to be condemned. (2) The sphere of usefulness of the catheter is growing smaller and smaller, as the advantages of an early operation make themselves manifest. (3) The Bottini operation may be applicable in selected cases, but should seldom, if ever, be adopted. (4) Orchidectomy, vasectomy, ligation of the internal iliacs, injection of carbolic acid, application of electricity, and allied methods are to be condemned. (5) Prostatectomy is the procedure of choice, best performed when the symptoms first make themselves manifest and the patient's condition is presumably at its best. (6) The preferable route is through the perineum, the preferable method that of Young or one of its modifications, but much depends upon the skill of the operator as regards the method employed. (7) In patients with foul bladders and diseased kidneys who, we have reason to expect, would not stand an extensive operation, thorough drainage should be first instituted either by a suprapubic or perineal incision under local anesthesia, to be followed later by enucleation, if deemed advisable. (8) The use of local anesthesia, especially spinal cocainization, is of great value, and should be more extensively employed.

**Amblyopia from the Fumes of Wood Alcohol.**—A. T. Hawes reports the case, his patient being a painter fifty-three years of age, who was employed in the application of shellac and removing old paint from furniture. In these labors wood alcohol was freely used. While the man was not a total abstainer he fully understood the dangers of drinking wood alcohol, and his symptoms could not be referred to the ingestion of this agent. After one day's work in a closed room he had headache, nausea, faintness, and smarting of the eyes, but recovered on going out into the open air. After working the second day under the same conditions, he felt a blur coming on over the visual field. The next morning all his symptoms were more pronounced and the condition serious. He was semiconscious, but his speech was unintelligible. There was slight fever, and pulse was somewhat rapid. The blur continued, pupils were widely dilated and not responsive. The man was extremely restless, but in a few hours became conscious; the visual interference remained. Ophthalmic examination showed blurring of the disc in one eye and contraction of the arteries in the other. In a few days he was all right. Treatment was directed toward elimination by the kidneys and liver with strychnine in full dosage.

*New York Medical Journal, November 11, 1905.*

**Talma's Operation.**—G. C. Stemen reports one case with recovery. His patient was a man suffering from hepatic cirrhosis, and the usual methods of Talma were followed. The abdomen was opened between the umbilicus and the ensiform cartilage, evacuating the accumulated fluid. The liver was rubbed with a nail brush, until there was a slight hemorrhage; the diaphragm, or, rather, the peritoneum covering the diaphragm, was also treated in a like manner, and five sutures of forty-day catgut were used in stitching the abraded surface of the liver to the abraded surface of the diaphragm. Five or six loops of omentum were then made and stitched to the parietal peritoneum, and also included in the sutures, which closed the abdominal incision, thus gaining a broad surface for adhesions to establish a collateral circulation, which constitutes the only feature of the operation. The man made an uninterrupted recovery from the surgical interference, and left the hospital in a little over three weeks. Three subsequent tappings were necessary before the collateral circulation was sufficiently established to prevent the reaccumulation of fluid. Subsequent progress was uneventful, and the man has been able to resume his occupation as cook. He now enjoys perfect health. The author admits that while the cure cannot, as yet, be looked upon as permanent (ten months and a half), yet all the conditions at the present time warrant him in saying that recovery is complete. As only six patients, prior to the report of this one, have been cured by surgical interference, it makes a surgeon loath to report a recovery until at least one year has elapsed, but taking into consideration the patient's condition, now ten months and a half after operation, he feels warranted in claiming a recovery and would advocate the operation in all well-attested cases of cirrhosis presenting ascites, believing that under favorable conditions eighty per cent. of all patients thus operated upon will recover.

**Ocular Symptoms of Gout.**—A series of clinical cases is narrated by K. K. Wheelock. Case 1 presented a reddened eye, like "pink eye," the inflammation being confined to the globe and corneal margin. Atropine revealed the iris slightly adherent to the capsule of the lens. Sclerotomy was finally done. Two days later a typical gouty condition was present and the eye had become normal. Case 2 presented a diffuse redness of the globe. Joint symptoms appeared three days later. In Case 3 the patient had had several gouty attacks and developed pain and pulsation in the eyes. Iridectomy was done, and, under antigout remedies, recovery was uneventful. Later there were attacks of iridocyclitis, and finally glaucoma developed, with necrotic ulcer at center of cornea. Sclerotomy was done, followed by partial excision of the ciliary body. Case 4 presented glaucoma simplex. The author enumerates as forms of eye inflammation caused by the gouty diathesis, iritis (plastic and serous), cyclitis (plastic and serous), retro-bulbarneuritis, retinitis, scleritis, and episcleritis, cataract, hemorrhagic retinitis, and glaucoma. He also recognizes gout as the causative factor in several forms of keratitis.

**The Relation of Milk to Typhoid Fever in New York City.**—J. S. Billings describes the plans of the Health Department in investigating this question. The researches of the Department make it probable that the majority of cases of typhoid fever in New York City are due to infected water, and that milk plays relatively a very small part in the spread of the disease. This conclusion is borne out by the recent epidemic of typhoid fever in Brooklyn, which was very soon checked by the adoption on the part of the residents of that section, of the widespread advice of the department: boiling of water before using for drinking purposes. It is true that in one or two instances family and neighborhood epidemics due to cases of typhoid fever in the family of the milkman in the city have been recognized, and the contamination of the milk put a stop to. In one instance, a number of cases having occurred among the customers of a certain wholesale dairy, and an investigation showing a number of suspicious fever cases on the farms in New York State where the milk was obtained, the issuance of milk by the dairy was stopped. Further investigation showed that the cases of fever in the country were not typhoid, and more cases developed in the city in the same locality, although none of that particular milk was being used.

*Medical News, November 11, 1905.*

**Report of the Committee on the Influence of Climate in Pulmonary Tuberculosis.**—The committee consisting of Drs. Minor, Baldwin, Solly, McGahan, Sewell, and Bridges, note a certain tendency in the minds of the profession to doubt the value of climate in this malady. The causes of this tendency, they find, first, in the unskilful use in the past of climate as a therapeutic measure; secondly, in the formerly widely spread belief in a mysterious specific influence of climate which led to a superstitious faith in its unaided powers, and therefore to a neglect of those even more important matters, hygiene, diet, instruction, and detailed supervision; third, in the effect on the general profession of their recent and all too-limited experience with outdoor treatment at home, which has caused them to go from the extreme of an undue hopelessness in the past to that of an equally unwise hopefulness that any case can be cured in any atmosphere by sleeping out on a porch and eating heartily and freely. The climatic elements of

value are, in the Committee's opinion, to be classified in the following order of relative importance: (1) abundance and bacteriological and chemical purity of the air; (2) sunshine; (3) coolness, or, in a certain number of cases, warmth; (4) dryness, or in a few cases, a moderate degree of humidity; (5) altitude; (6) wind; (7) equability; (8) soil. In regard to the ultimate condition of patients discharged from sanatoria, the Committee declare that the patient should not be told that he is cured, but only that the progress of his disease is arrested, and that if, when he returns home, he can show for two years, by faithful living, a continuation of the condition obtaining on his discharge, then he may justifiably consider himself cured. A climatic resort should be regarded as a university, teaching discipline and instruction, which the patient can bring back home, and continue to apply to his own daily living.

**A Case of Spinal Apoplexy, with Findings.**—W. Browning and F. Tilney report the case of a man of sixty years with a sudden onset of impaired sensation and motion below a line midway between the pubes and umbilicus. A diagnosis of probable hemorrhagic process about the spinal meninges was made and a laminectomy was done the laminæ of the eighth and ninth dorsal vertebræ being removed. No hemorrhage was discovered, but on pressing aside the cord, bloody serum oozed up from below. The tenth and eleventh vertebræ were then denuded and their laminæ removed. More oozing occurred from in front of the cord. Total amount was estimated at two drams. The wound was closed. Patient died inside of twenty-four hours. Detailed autopsy findings are given, the following being the most important features: (1) The central hemorrhagic areas; (2) circumscribed and diffuse disintegration of the white substance characterized by much swollen axons with swollen sheaths, also by large lacunæ caused by the total disappearance of many axons with their sheaths; (3) Chromatolysis and degeneration of many cells; (4) injected and dilated condition of the blood vessels; (5) increase of neuroglia in size and number. The authors note that all of these changes, except the hemorrhagic areas, would appear in a true myelitis (exclusive of the very rare form, myelitis hemorrhagica acutessimus) but the presence of the central hemorrhage determined the diagnosis of hemorrhagic myelitis.

**Thrombosis of the Receptaculum Chyli and Chylous Ascites as a Complication of Cirrhosis of the Liver.**—H. J. Nichols reports this interesting case, which occurred in a man of seventy-five years, who presented the usual symptoms of hepatic cirrhosis and was tapped several times. Each time the fluid removed was milky-white, with a tinge of pink, which became more pronounced on each tapping. On standing, this pink color disappeared and a film appeared at the bottom of the vessel. The specific gravity varied from 1010 to 1013. The patient finally died without any positive diagnosis as to the cause of the chylous nature of the fluid having been ascertained. Abdominal cancer, tuberculosis, heart disease, and hepatic cirrhosis were considered as among the possibilities. Autopsy revealed among other lesions, not accounting for the chylous fluid, the receptaculum chyli formed by two large lymph vessels entering from below, one at each corner. Lying in the body they looked very much like veins, as they were thin and of a dark color. On opening they were found to be completely occluded by a firm fibrous clot which extended upward into the receptaculum and duct for about six inches, growing gradually smaller. The valves were easily demonstrated in the upper part of the duct, but no blood was found in this region.

*American Medicine, November 11, 1905.*

**Scopolamine-Morphine Anesthesia.**—Alfred C. Wood epitomizes his personal experience with scopolamine-morphine anesthesia and a brief study of the subject as follows: It is capable, in many cases, of producing a satisfactory surgical narcosis lasting several hours. When successful, the patient avoids the anxiety or even alarm often felt before taking ether, and the nausea, vomiting, and depression following its administration. If it should partly or wholly fail to anesthetize the patient, the surgeon may use ether or chloroform, with the assurance that the effect will be more prompt and satisfactory than when either is administered alone. When used in conjunction with ether or chloroform, it has been especially satisfactory. The time required to induce anesthesia was lessened, relaxation promoted, the secretion of mucus in the respiratory tract prevented, and the quantity of anesthetic required greatly reduced. To induce full anesthesia in the average healthy adult, 0.0006 gm. (1-100 gr.) scopolamine and 0.01 gm. (1-6 gr.) morphine should be given hypodermically two or two and one-half hours before operation, and a second similar dose an hour later. The doses should be considerably reduced in children, feeble patients, and the aged. Its use is contraindicated in acute affections of the pharynx and larynx; operations involving the mouth or air passages, edema of the lungs, and in cases in which capillary hemorrhage may be a troublesome factor. A few deaths have been ascribed to this anesthetic. Both scopolamine and morphine are powerful drugs, and prudence demands that they be used with caution. The safety and success of this method depend upon having pure and reliable drugs, accurate dosage, and perfectly fresh solutions.

**Distinctive Features of Animal and Vegetable Dietaries.**—Lafayette B. Mendel says the possibility of nourishing man on an exclusively vegetarian régime is admitted, and the relative physiological and chemical merits of the two types of dietaries are contrasted. As a rule, the proteids are utilized better from animal products than from ordinary vegetable foods. This is owing to the physical texture of the latter. The isolated vegetable proteids are readily digested and absorbed. The chemical composition of a food is no adequate index to its utilization in the alimentary tract—a fact illustrated by studies on the availability of different kinds of bread in nutrition. The chief characteristics of the modern ready-to-eat cereal preparations are discussed, as well as the newer vegetarian products, especially nuts, rich in proteids. The greatest danger of a rich meat diet lies in the tendency toward excessive eating and drinking. Proteids should be differentiated into various groups, *e. g.* nucleoproteids, simple proteids, etc., which have different fates in intermediary metabolism. No exclusive system deserves defence on scientific grounds. The great principle in regulating diet is to regard quantity rather than kind.

**Pathology and Etiology of Human Vaccina.**—W. T. Howard reports the results of his experiments. He concludes that in human vaccina, vesiculation is well-established by the end of the second day. The changes in the epidermis correspond closely to those of variola, but are more severe and rapidly destructive of epithelium. The changes in the corium are much more intense and persistent in vaccina than in variola. The primary cytoplasmic stage of cytoryctes variolæ occurs in human vaccina. This, and the intensity of lesion (owing probably to the greater number of organisms introduced in vaccination) mark the main differences between variola and vaccina. Granted that the groups of cytoplasmic and intranuclear bodies described by Councilman and his coworkers, by Calkins, and by Howard and Perkins in the skin lesions of variola and vaccina are parasites causing these diseases, it seems that certain lower animals have the poperty of inhibiting the development of the sexual cycle, but permit that of the asexual cycle, which is pathogenic for both man and these animals, and gives rise to an immunity in man which protects against both cycles.

*Journal of the American Medical Association, November 11, 1905.*

**Repair of the Perineum.**—G. B. Somers criticises some of the methods recommended for the repair of the perineum as failing to restore the function of the part, which depends on the action of its muscles rather than on its bulk or the strength of its fascia. Its function, he says, depends mainly on the action of the levator ani, and the importance of this fact, he thinks, has apparently had very little influence on the technic of perineorrhaphy. If the levator is uninjured a laceration of the superficial muscles hardly needs repair. It is the levator that is at fault when the perineum fails to do its duty, when there is rectocele or cystocele, and it is what we should seek to repair. The Reed method, he considers, is based on correct principles, and satisfactory when only a small amount of mucosa is to be removed. In most cases, however, it is desirable to remove more or less tissue on account of cicatrices, irregular sulci, etc., and he describes the following method which he calls the "fishing" operation as an easy method for exposing and uniting the levator fibers in such cases. In the first place, the edges of the levator are located by the finger in the vagina and exposed by a simple triangular denudation The muscle is then fished out on both sides with a vulsellum or tenaculum forceps and kept under observation and control. This, Somers believes, should be the basis of every perineal repair operation, at least when there is rectocele or cystocele. The main thing is to expose and directly to unite the severed parts. The use of interrupted sutures, he thinks, is the cause of much trouble in perineal operations, and he offers the following as avoiding the chief objections to the interrupted and the buried sutures, at the same time allowing for swelling. "Silkworm gut is used. Passing through the apex of the triangular denudation the suture is inserted with a mattress stitch, from side to side, in the deepest portion of the wound. In passing by the exposed levator ani fibers (still held by vulsella) it passes through the edges of each two or three times. It then continues in the

deep portion of the wound, taking up next the tissue over the denuded ends of the superficial perineal muscles. Finally, it emerges through the skin, on the perineal surface, just above the lower angle of the wound. It is then drawn taut, approximating the tissues. A second and third are passed in similar fashion, each taking in a portion of the levator ani, one above the other. As each suture is drawn taut, the tissues come together, bringing the denuded surfaces in contact. The fourth suture may be submucous or a whip stitch, and serves for final closure of the wound. The most important part of the suturing is the fastening of the ends; with all drawn taut, the vaginal ends are drawn into a single shot and clamped from half an inch to an inch from the surface. The perineal ends are similarly clamped at the same distance. This allows for swelling. In removing the sutures, usually on the tenth day, the shot in the vagina is seized and cut off close to the surface. The perineal ends are then grasped and the sutures pulled out. By this method of suturing, Somers, claims, the perineum is built up layer by layer and the surfaces approximately evenly, without tension and without constriction of the circulation. The parts are therefore in the best possible condition for repair."

**Bone Transplantation for the Relief of Saddle-Nose.**—C. F. Welty discusses the comparative merits of paraffin injections and plastic operations for the relief of nasal deformities, giving the history of a case in which he operated by transplanting a piece of bone from the crest of the tibia. Perfect bony union was not obtained, but the piece remains in place, and it is hoped permanently. He reviews the literature of paraffin prothesis and concludes that the risk of embolism is such that plastic surgery should be preferred when possible, and that, if paraffin is employed, it should not have a melting point below 115° F., and a screw piston syringe, allowing definite measurement of the amount injected, should be used. He is satisfied that only a small part of the accidents from paraffin have been reported. The production of new tissue by paraffin injections is, he says, almost ideal, but there is the uncertainty of possible loss of vision or life or of other complications, while with plastic surgery the surgeon works on better established principles.

**Intracranial Complications of Ear Disease.**—J. F. Barnhill discusses the conditions of sinus thrombosis and brain abscess complicating acute or chronic ear disease. In view of the fact that without treatment these conditions are almost invariably fatal, their early diagnosis is most important, and the history of earlier ear disease should be looked for. Sinus phlebitis or thrombosis may come from other causes, such as deep infections of the neck or infections of the nasal sinuses, etc., but it is most frequently the result of ear disease. In its latter stages, it is easily recognized by its attending general pyemic condition, but its early diagnosis may be difficult. When, however, with persistent ear discharge and simple mastoid inflammation, the patient's symptoms seem to be more serious than the local conditions alone would warrant, Barnhill thinks that exploration of the mastoid is entirely justified, and that even if it fails to reveal sinus disease, it is still a prophylactic measure of the greatest importance. Without the drainage thus afforded, the possibility of sinus involvement is vastly increased. Outside the skull the occurence of edema behind the mastoid swelling along the course of the internal jugular and edema of the eyelid have valuable diagnostic bearings, but the most characteristic symptoms are the high temperature with remissions and septic chills. Any of these symptoms occurring with persistent ear discharge, or with a violently acute otitis, should suggest the possibility of sinus involvement. Brain abscess may follow long-continued chronic ear disease or an acute attack. Vomiting is a prominent symptom, occurring in nearly all cases, and the eye fundus may give important evidence as changes are noticed in about one-half of the cases. A brain abscess, however, may be latent as to symptoms and exist for a long time unsuspected. Barnhill believes that with more careful ear examinations and observation of general symptoms this would not often be the case, and the needed surgery could be done in time.

**Peculiar Symptoms Following a Mastoid Operation.**—George F. Cott reports a case of long standing in which after a mastoid operation the patient complained of almost constant pain, and the temperature varied from 104° to about 99° F. for two weeks. The patient had a regurgitant murmur and there was at times pain in the region of the heart. As the patient was markedly neurotic, the sinus was not explored, though sinus phlebitis was suspected. The patient was able to leave the hospital on the thirty-fourth day after operation. During the following year there was frequently pain in the ear, but not so severe as to require opiates. The temperature has never been quite normal, though the patient has improved in general health, and the ear is practically well.

*The Lancet, November* 4, 1905.

**Third Eyelid in a Human Subject.**—W. Robertson found in an adult male of India a supernumerary eyelid which was situated under the right upper eyelid and protruded when the eye was in natural function two millimeters beyond the margin of the natural lid. This exposed part which led to the discovery was darker than the rest of the structure, the latter approximating to the color of the conjunctiva. It was normally sensitive and cartilaginous to the touch. Of the thickness of a sixpence, it evenly and completely followed the contour and movement of the upper lid, lying closely over the globe without fold or corrugation on either surface and with a clean-cut margin at its periphery. The author notes that the condition was an example of the plica semilunaris or membrana nictitans of birds and reptiles. It will be remembered that the conjunctiva is developed from the surface epiblast and that the membrana nictitans divides the conjunctival sac into two portions in birds and reptiles.

**Impaction of a Gallstone in the Large Intestine.**—The patient of F. V. Milward was a woman of sixty-seven years with intestinal obstruction calling for surgical intervention; operation and subsequent recovery. The stone was 1⅝ x 1½ inches, with a circumference of 3¼ inches, with a weight of 465 grains, was ovoid shape without facets, and located in the segmoid flexure. It possessed the usual chemical composition of gallstones except that the percentage of magnesium carbonate was abnormally large, and this fact pointed, in the author's estimation, to the possibility of the calculus having been supplemented in the bowels by the addition of this particular salt which had been taken freely as a medicine. There was no history of previous gallstone trouble, but the author did not doubt that the calculus originated in the gall bladder and reached the bowel by direct ulceration into the large intestine. Had it passed in the first place into the small intestine, it seems improbable that it should stick in the segmoid flexure after having traversed the ileocecal valve.

**Malignant (?) Tumor of the Hypochondrium; Lumbar Incision, Followed by Laparotomy; Recovery with Cure.**—F. W. Forbes-Ross reports the case of a woman, aged thirty-five years, with an irregularly ovoid, hard, movable mass in the right hypochondrium, as large as a small cocoanut It did not seem to be connected with either bowel or gall-bladder. A provisional diagnosis was made of a tumor of the right adrenal Incision showed the mass to be a diseased outgrowth from the lines occupying the normal position of the right kidney, which lay on the pelvic brim. The anterior surface of the right hepatic lobe and a portion of the left were adherent to the abdominal wall. The hepatic flexure of the colon was long, sigmoid, and adherent to the edge and anterior surface of the right lobe of the liver and to the anterior abdominal wall, thus interposing its resonance between the tumor and the liver proper and apparently determining its non-connection with the liver. The adhesions were carefully separated, and the tumor being reached, it was found to be an adventitious outgrowth of the posterior border and under surface of the right lobe of the liver, attached thereto by a broad, soft, pliable stalk of hepatic tissue. The whole liver was soft and jelly-like, and gave the sensation of handling omentum. The right lobe and tumor were gently dragged out of the abdomen as far as possible, with a view to remove the tumor by the galvano-cautery, but as the disease involved the whole of the posterior border of the liver and its connection with the vena cava it was deemed inadvisable to interfere with it further. Careful examination of the condition, and the absence of any signs of a primary malignant growth anywhere else in the abdomen after careful search, it was decided that appearances tended to support a specific causation, mainly affecting the movable part of the right lobe of the liver. Rectal injections of the iodide in saline solutions were given and one of the organic iron preparations. Under this treatment the mass began to disappear rapidly, and on her discharge from the hospital was palpable only as a growth the size of a hen's egg.

*British Medical Journal, November* 4, 1905.

**Treatment of Uterine Hemorrhage.**—H. L. Donovan was recently called to a case of severe hemorrhage after complete abortion in a multipara who always lost large quantities of blood after her labors. The writer plugged the vagina and gave ergot, but bleeding recurred about seven hours after the removal of the plug. The patient was then placed on her back with the pelvis raised on two pillows. The bed was firm and flat The hem-

orrhage ceased immediately. The patient suffered no discomfort from this position and was kept in it for twenty-four hours.

**A Plea for Evacuation of the Uterus in Unrelieved Cases of Puerperal Eclampsia.**—Ernest Brice speaks of six cases of his own in each of which relief followed the birth of the child. The convulsions were always relieved after the evacuation of the uterus. The writer gives the following suggestions for these cases: An attempt should first be made to control the convulsions by the administration of morphine or chloroform. If the convulsions do not pass off and labor does not soon begin, then delivery should be induced. The writer advocates the use of the finger for this process, as he considers it the safest and most effectual form of dilator. If it is impossible to begin the dilation with the finger, the sound may be used to start the process.

**Treatment of Puerperal Eclampsia.**—Arthur C. J. Wilson has been very successful in treating these cases by the immediate administration of chloroform, which he gives slowly till the patient is fully under its influence. He states from his own experience that when chloroform was given fully, in cases of eclampsia occurring in pregnancy, soon after the first convulsion, and when its effect was kept up some time after the termination of labor, no more convulsions occurred. Termination of labor by dilatation of the os can, as a rule, be easily carried out, provided the patient is kept fully under chloroform, and seems to have no effect in causing a return of the convulsions. In nearly all cases in which some time had elapsed before the administration of chloroform, convulsions recurred after labor, and the patient did not make so good a recovery. The danger to the child is increased by delay. Forced delivery is quite a different thing when a patient is fully under chloroform from what it is when there is not complete muscular relaxation. The writer presents notes of a number of cases which he has treated by this method

**Notes of an Epidemic of Influenza.**—J. P. Sturrock reports this outbreak, which occurred in an asylum. The disease spread from ward to ward in series in spite of the fact that all of the patients were coming into daily contact, and that on the female side patients from different wards slept side by side in the same dormitory. Although the bacillus was undoubtedly carried from ward to ward, it appeared to attack those who were working outside the wards or were in "open-door" wards, and who could go out and in to cold corridors as they pleased. The temperature in the wards is often far too high on account of the system of heating by hot-water pipes. This probably made the patients who go about from ward to ward in working costume more susceptible to cold. The disease first affected the staff, and a day later the patients. The disease did not seem to spread from a patient once put to bed. The spread of the infection on the female side seemed to indicate that it was carried along in the currents of air caused by the overheated wards and colder corridors, and that the patients became infected only when it reached their ward. Women were affected in a large proportion, and the strong and working patients were attacked almost exclusively. In marked contrast to the cases not so treated, in those to whom carbolic acid was given, the sudden fall of temperature in twenty-four hours was striking. Comparative comfort was soon enjoyed by patients receiving this treatment. The method of administration consisted of 1-minim doses of liquid carbolic acid, in not less than two ounces of water, given at once on the onset of the symptoms, and repeated every two hours till the temperature fell to normal. There were no bad effects from the use of the carbolic, which was in no case given longer than for twenty-four hours A purge was given afterwards. It is highly probable that the infectivity of the cases was lessened by this treatment. The nature of most of the complications was septic. The deaths amounted to less than four per cent. of the total number of cases. The average age of those affected was well over fifty years, so that this mortality rate is markedly small.

*Munchener medizinishe Wochenschrift, October* 17, 1905.

**The Prevention of Laryngeal Stenosis after Intubation and Secondary Tracheotomy.**—V. Ranke recommends secondary tracheotomy in cases of diphtheria, in which the previous introduction of laryngeal tubes has resulted in decubitus. The resulting stenosis that sometimes occurs, he believes to be due not to cicatrization of the ulcer, but to the exclusion from the larynx of the inspired air that normally acts as a dilator. To avoid this complication v. Ranke allows the tracheal cannula to remain *in situ* two to three days only, after which he again resorts to intubation if dyspnea recurs. Gradual dilatation of a laryngeal stenosis with curved sounds he believes to be utterly inadequate, this condition being relieved by the permanent wearing of a tracheotomy tube alone.

**A Case of Sepsis Due to Staphylococcus Citreus.**—Jacobowitz records a case of sepsis ending fatally in which the portal of entry for the organism was an abrasion of the skin of the chin. Clinically the infection was characterized by a universal erythema with vesicle formation, irregular temperatures, the formation of abscesses on the right foot, and necrosis at the site of the abrasion, gradually extending to both cheeks. From the cutaneous vesicles the ulcers of the chin, the abscesses of the foot, and from the sputum cultures of staphylococcus citreus were isolated. No blood culture could be made, but in confirmation of the writer's belief that this organism was the cause of the sepsis it was found that a potent staphylococcus serum agglutinated the cultures of staphylococcus citreus in a dilution of 1-3000. Weak alkaline bouillon cultures of the organism as well as their filtrates, exerted a hemolytic action upon the erythrocytes of rabbits. No agglutination was obtained with cultures of staphylococcus aureus that were also isolated from the cutaneous vesicles, nor did these cultures exert a hemolytic action upon red blood cells.

*Deutsche medizinische Wochenschrift, October* 19, 1905.

**The Pseudoinfluenza Bacillus.**—Korentschewsky records a case of a bullet wound of the neck resulting in empyema of the pleural cavity. From the sanguineopurulent exudate a Gram-negative organism, growing, only in the presence of blood in minute transparent colonies, was isolated. Transplantations to ordinary media were unsuccessful unless blood were added, when growth was luxuriant both on solid and fluid media. Morphologically the bacilli varied considerably in size, but even after many generations the organism was found growing in chains. This feature serves to distinguish the true from the false influenza bacillus. In the patient's sputum true influenza bacilli were demonstrated. The writer believes that the pleura was secondarily infected from the lung, and that the bacillus isolated from the former and corresponding in all details with Pfeiffer's pseudoinfluenza bacillus was in reality a true influenza bacillus that had grown for some time under changed conditions. A mixed infection cannot, however, be excluded.

**Intention Tremors in Children.**—Urbach calls attention to the existence of intention tremors in children as the sole manifestation of chronic lead poisoning, reporting a case in a child five years of age, in whose urine lead was chemically determined. The writer inclines to the belief that even in the absence of lead from the urine this etiological factor in cases of mild ataxia and tremor may not be disregarded if all other pathological conditions of the nervous system can be excluded.

*French and Italian Journals.*

**Severe Chronic Radiodermatitis Cured by the Galvanocautery.**—A patient of Springer had suffered for three years with badly ulcerated fingers—the index and the middle finger—caused by frequent and long exposures of the right hand to the *x*-ray. The fingers were cracked and bloody, the phalanges thickened and stiff, and the nails atrophied and striated. On the large joint of the middle finger was a fungous growth. The injured members were extremely sensitive to contact. Various methods of treatment had failed to ameliorate the condition. Springer, before having recourse to amputation, for which the patient begged, attempted to destroy the mushroom-like growth and its base by means of the galvanocautery. Cauterization was practised and was carried deep. A deep eschar, dry and hard, formed and fell off on the sixth day, when the dry dressing was removed leaving bare a healthy wound, covered with small red granulations. The raw spots were bathed with a solution of permanganate of potash, followed by the application of hydrogen peroxide. Simple dry dressings with salol were employed. At the end of three weeks the operative wound was entirely covered with healthy skin, which was supple, and solid, and which remained so. The tissues of the middle finger at the same time became normal and regained their normal functions.—*Revue Française de Médecine et de Chirurgie* October 16, 1905.

**A Case of Exophthalmic Goiter.**—E. Doumer and D. Maes report the case of a man fifty-one years old who was conscious of only one uncomfortable symptom — very painful and frequent cramps, which affected particularly the calves of his legs, though sometimes he had them in his arms. At night they came on in paroxysms, and repeated themselves four or five times almost always attacking the lower extremities. In the daytime the crises were a little less frequent and generally affected

the upper extremities. The length of these attacks was variable, but averaged from five to eight minutes. This symptom had troubled the patient several years when he came to the writers for treatment. On examination a distinct tachycardia was noted. A slight trembling was also noticed, although it had escaped the attention of the patient himself. Moisture of the hands was another sign to which he had attached no importance. The patient was irritable and suffered at times from insomnia and inaptitude for work. He was given systematic treatment by faradization according to the classic method of Vigouroux. The cramps disappeared with great rapidity, the skin became normal, and the other symptoms disappeared or became attenuated. The patient considered himself cured at the end of three treatments, and ceased to apply for them.—*Le Nord Médical*, September 1, 1905.

**Training in Relation to Alimentation.**—Maurice Champeaux declares that it is a fact well established by physiology that the amount of food ingested outght to be in relation to the work done by the body. When the work increases, food ought to increase in proportion. Training brings about an overworked condition, and the organism becomes a prey to intoxication. Discord then exists between the necessities and conditions of life. On the other hand the term adaptation represents the physiological state exactly opposed to that of training. The bodily functions are at a maximum. There is an absolute accord between the necessities and conditions of life. In the army the aim should be toward adaptation and not toward training. It is necessary to work with moderation and with reason. An overworked condition should be avoided, and each organism should be adapted to the exigencies of its particular physiological condition.—*La Presse Médicole*, Sept. 20, 1905.

**Discontinued Anesthesia in Gastric and Intestinal Surgery.**—C. Arnaud states that it is not without danger to keep a patient already enfeebled by disease under the influence of prolonged anesthesia while a resection of the stomach or intestine is being accomplished. The writer suggests the suspension of anesthesia during visceral intervention, since the stomach and intestine are not at all or at least only slightly sensitive to operative measures, whether it be contact, section, or suturing. The parietal peritoneum alone is sensitive to pain during a surgical operation. The writer advises discontinued anesthesia, by which he means suspension of anesthesia during the section and suturing of the viscera, while it is to be resumed during the peritoneal toilet as well as at the time of incision and suturing of the abdominal wall. This method, so the writer believes, would diminish the dangers of anesthesia in the case of a feeble patient. —*La Presse Médicale*, September 20, 1905.

**Musical Heart Murmurs.**—Michele Landelfi has observed one case of musical heart murmur which came to autopsy, and has listened to five others that have not yet come to autopsy. He analyzes these murmurs as to site, time of heart cycle, etc. They are usually heard over the valvular areas, are prolonged and musical, like small ronchi that are heard in the small bronchioles of the lungs. Capozzi observed them in five cases, two of mitral insufficiency, and three of aortic insufficiency, and at the autopsy found constantly perforations of the valves, small and oval, with thickened margins. He believes that the perforation is in etiological relation to the character of the murmur. In the author's case there was tuberculosis of the lungs, anemia, and galop-rhythm of the heart, with a musical murmur localized at the apex and not radiating. The murmur was not constant. The patient died with uremic symptoms. The autopsy revealed no perforation of the valves, but a concentric hypertrophy of the left ventricle and chronic pericarditis. The left auriculoventricular orifice was normal, and the whole valvular mechanism was sufficient. The author believes that there was, nevertheless, relative insufficiency, and that this was of prognostic value, indicating that the heart was unable to carry on its work any longer. He concludes that these murmurs are generally due to valvular insufficiency, but are not usually of diagnostic value.—*La Reforma Medica*, September 30, 1905.

**Hematological Researches in Pleurisy.**—Ettore Tedeschi has made examinations to ascertain the changes in the red and white corpuscles in number and quality, in different forms of pleurisy, in order to find out the hematological formula of the different forms of the disease. Also the agglutinating power of the blood serum in tuberculosis, and in other forms of pleurisy. He has examined twenty cases of different types of pleurisy. He concludes that sero-fibrinous tubercular pleurisy differs from sero-fibrinous pleurisy from other causes, in that it is accompanied by a moderate hyperleucocytosis; there is also a lymphocytosis, relative or absolute, and frequently an increase of the large mononuclear leucocytes. These conditions vary with the severity and course of the tuberculosis. These alterations are of diagnostic and prognostic value. The sero-reaction is more evident in the exudate than in the blood serum, especially at the beginning of the process, and this should be used, instead of the blood, for an aid in diagnosis.—*Il Policlinico* October, 1905.

**Ammonuria in the Puerperal State.**—A. Mariani has examined the urinary conditions in normal women during pregnancy and the puerperium as to the elimination of ammonia and the relation to the hepatic functions. Normally, in the unimpregnated condition, there are only traces of ammonia eliminated as salts. It is increased by a meat diet and decreased by a vegetable diet, by the febrile state, and by severe poisoning by phosphorus and other inorganic poisons. The author concludes that during the last months of pregnancy a larger amount of ammoniacal salts are eliminated than normal. It is increased during labor, and continues large through the first week of the puerperal state. This increase of ammonia in the urine may be attributed to a slight acidosis of the organism, as well as to an insufficiency of the liver to produce urea.—*Archivio di Ostetricia e Ginecologia*, September, 1905.

**The Vibratory Winking of the Eyelids and Renal Affections.**—M. G. Ullmann believes that vibratory winking constitutes a true pathognomonic symptom of renal affections. This sign shows itself especially when the affection is in its infancy. On this account this observation is of great importance, since at this stage the affection amounts to only a simple irritation and has not yet become serious. Vibratory winking is most often seen in the upper eyelids, generally in only one. The duration of this movement varies from a few minutes to half an hour or more. The writer thinks that this phenomenon is due to an autointoxication, the consequences of which manifest themselves in the visual apparatus and particularly in the nervous filaments coming from the fifth nerve and from the facial. In support of this hypothesis, vibratory winking is most often accompanied by myosis. —*La Presse Médicale*, September 23, 1905.

**Albuminuria in Tuberculosis of Infants.**—Rodolfo Benati says that albumin in infantile tuberculosis may be slight and transitory, or serious and permanent. The first is the result of acute or subacute disease; the second of the chronic form. The renal lesions may pass from congestion to glomerulo-nephritis, large white and amyloid kidneys. According to some authors it is infrequent, to others it occurs in eighty per cent. of cases. The etiology is various. In some cases it arises from a mixed infection with other bacteria; in others it is toxic, arising from the gastrointestinal tract; again it is due to mechanical factors, disturbances of circulation, or it may be due to the tubercular cachexia. The author collected all the cases seen at the Hospital for Children in Florence, from 1892 to 1898 in which the diagnosis was confirmed by bacteriological examination, three in number. These statistics show that tuberculosis is rare in the early years, and becomes most frequent from the age of five to seven years. Renal disease occurs most frequently in combination with tubercular meningitis, next in pulmonary tuberculosis, then in tubercular peritonitis. He concludes that albuminuria is more frequent than has been supposed; that it is most frequent from five to seven years old. When tuberculosis is generalized albuminuria is most frequent; it occurs in sixty per cent. of cases of tubercular meningitis; it comes on when the tubercular symptoms become severe; it is more frequent when the tuberculosis has attacked several organs; it occurs especially near the fatal issue of the disease.—*Rivista di Clinica Pediatrica*, September, 1905.

**Anatomopathological Researches in Experimental Poisoning with Formalin.**—Corrado Tommasi-Crudeli has made a series of experiments as to the anatomical and pathological effects of small doses of formaldehyde long continued, such as would be taken in the use of the substance to preserve foods and milk, and of large doses. The formaldehyde was used both by way of the stomach and of the respiratory tract, in dogs and other animals. The author's conclusions are as follows: 1. In actue poisoning by the stomach the anatomical alterations are limited to the stomach and consist of necrosis and desquamation of the epithelial lining, intense hyperemia, and hemorrhagic infiltration of the mucosa. 2. In acute poisoning by inhalation the larynx trachea, and large bronchi presented diffuse necrosis, with exudative inflammation, forming a diphtheroid membrane, and with rich small-celled infiltration of the surrounding tissues. The small bronchioles showed purulent inflammation, with acute emphysema of the pulmonary tissue, and hemorrhagic and purulent bronchopulmonitis. 3. In chronic poisoning by the stomach the alterations were confined to the organs of digestion. The stomach showed gastritis, simple, catarrhal or hemorrhagic, and ulcerative. There was the same condition in the intestines. In the other organs there was diffuse hypermia, with hemorrhages and slight parenchymatous alterations.—*Il Policlinico*, September, 1905.

# Book Reviews.

A Manual of Diseases of the Nose and Throat. By Cornelius Godfrey Coakley, M.D. Professor of Laryngology in University and Bellevue Hospital Medical College, New York City, etc. Third Edition revised and enlarged. Illustrated with 118 engravings and five colored plates. New York and Philadelphia: Lea Brothers & Co., 1905.

This manual has already received favorable mention in these columns. The present edition contains 28 more pages than its predecessor. Each article has been brought up to date, while the chapter on diseases of the nasal accessory sinuses has been entirely rewritten. The manual is a good one for both student and practitioner. Under the heading of treatment in each section the author elaborates those medical and surgical measures which have given, in his experience, the most satisfactory results. We renew emphatically our former endorsement of Dr. Coakley's work.

Sewerage and Sewage Purification. By M. N. Baker, Ph.B., C.E. Associate Editor, "Engineering News;" Joint author, "Sewage Disposal in the United States;" Author, "Sewage Purification in America;" "British Sewage Works." Second Edition, revised and enlarged. New York: D. Van Nostrand Company, 1905.

The matter of sewerage and sewage disposal is one that the practitioner, especially in smaller places, is often called upon to discuss, and it may at times be his duty to speak with authority regarding it. It is incumbent upon all medical men to have at least some idea of what at present are considered the fundamental principles of sewerage and drainage systems, and of the methods by means of which sewage may safely be disposed of. The present volume is written in simple fashion for the instruction of the non-engineer and contains the essentials of modern practice in concise form. The author regards the subject thoroughly from the standpoint of the sanitarian, and the little book may confidently be commended to all who are interested in the subject.

The Microtomists' Vade-Mecum. A Handbook of the Methods of Microscopic Anatomy. By Arthur Bolles Lee. Sixth Edition. Philadelphia: P. Blakiston's Son & Co., 1905.

The laboratory worker has long regarded this book as an indispensable adjunct to his desk outfit, and it is therefore agreeable to find that it has been subjected to another revision. The volume has not been increased in size, though the author tells us that the index contains some 300 new entries, the added space having been gained by condensation and rearrangement of the old text so as to avoid repetitions. In spite of the mass of new methods by which laboratory technique has been enriched of late years, the only notable omission that strikes the reader is the absence of any mention of Wright's useful stain for blood films. The five chapters dealing with the nervous system are an especially notable feature of the book and contain much that is new regarding the recent methods for neuroglia and the chromophilic bodies.

A Manual of the Practice of Medicine. By A. A. Stevens, A.M., M.D., Professor of Pathology in the Woman's Medical College of Pennsylvania, and Lecturer on Physical Diagnosis at the University of Pennsylvania. Seventh edition, revised. Philadelphia and London: W. B. Saunders & Company, 1905.

Stevens' Manual of Practice is by this time too well known to require either description or commendation. The seventh edition differs but little, if at all, from its predecessor; indeed, the only alteration we have discovered is the increase in price. For student or practitioner this is one of the best compends on Practice in the market.

A Manual of Clinical Chemistry, Microscopy and Bacteriology. By Dr. M. Klopstock and Dr. A. Kowarsky, of Berlin. Translated by Thew Wright, M.D., London: Rebman Limited; New York: Rebman Company, 1905.

In response to the stimulus which the methods of laboratory diagnosis have received in the last few years it is only natural that a large number of books on the subject should be produced. It is equally natural that there should be a great disparity between these, and accordingly we have them good, bad, and indifferent, large and small, elementary and advanced. The present volume is short but distinctly of the latter class for, as the authors state in their preface, it is assumed that the reader has had an elementary chemical and bacteriological education. This is certainly no disadvantage, for it renders it possible to compress descriptions of the ordinary diagnostic laboratory aids into a volume that is not too bulky to have at hand about the working table. The book is rendered still more attractive from a mechanical standpoint by unusually good paper and clear type. In regard to matter but little can be said in criticism, though there are some decidedly weak points, such as the absence of an index, which is a serious defect in a book of this sort, and particularly the plates of blood spreads whose only virtue is that there are so few of them. The section on the examination of the blood is probably the least satisfactory in the book. For example, Hammerschlag's method of obtaining the specific gravity of the blood is given, but not the table by which one is enabled to estimate the hemoglobin from the specific gravity, the only purpose for which this method is ordinarily used in clinical work. The characteristics of the blood picture in the various anemias are not discussed at all. Iodophilia is not mentioned and the technique described for performing the Widal reaction is not at all modern. The Jenner stain is given, but as usual in continental publications is credited to Way and Grünwald. Defects are also to be noted in other parts of the book such for example as the omission of all reference to the Sahli test meal in the section on gastric analysis. The book contains much that is of value, however, and should prove a useful adjunct to other works on the subject.

Lectures on the Principles of Surgery. By Chas. B. Nancrede, A.M., M.D., LL.D., Professor of Surgery in the University of Michigan; Professor of Surgery in Dartmouth Medical College, etc. Second Edition, Thoroughly Revised. Philadelphia and London: W. B. Saunders & Co., 1905.

In the book at hand, now in its second edition, the author has attempted to overcome the objections usually associated with works of this kind, namely, that they are too comprehensive or that undue prominence is given to special methods of applying surgical principles to practice. He also wisely omits extended references to bacteriological and pathological details, for these subjects are now fully taught as special branches in our medical schools. The book is in the form of lectures addressed to undergraduates, and includes the usual array of "principles" and their application to therapeutics. The author takes a decided stand on the subject of inflammation, claiming that it is never anything but an ineffective process. He does not recognize any aseptic variety the only true inflammatory processes being those in which the microorganisms, their products, or both are concerned. The other aspects of the question are discussed, however, in a supplementary chapter by Dr. W. A. Spitzley, in which the history of the subject and the other theories are taken up. This appendix, moreover, is in pleasing contrast as regards its style and diction to what goes before. The construction of the sentences in the body of the work is involved, irregular, and unsatisfactory, so that considerable mental effort with consequent loss of time and interest, is required to digest the meaning of most of them. A decided improvement would have resulted from a less frequent use of the dash and an increased employment of the period. Books addressed to medical students, such as this purports to be, should certainly be written in good, easily read English.

A Practical Treatise on Sexual Disorders of the Male and Female. By Robert W. Taylor, A.M., M.D., Formerly Clinical Professor of Genitourinary Diseases at the College of Physicians and Surgeons (Columbia University), New York; Consulting Genitourinary Surgeon to Bellevue and to the City (Charity) Hospitals, New York. Third Edition thoroughly revised, with 130 illustrations and 16 plates in colors and monochrome. New York and Philadelphia: Lea Brothers & Co., 1905.

The subject of sexual disorders is not so well represented in American medical literature as in that of Europe, perhaps because such affections are less frequently seen in this country. Dr. Taylor's book has come to be recognized as a standard American work on this branch of genitourinary practice, and though it is not so important in many ways as his larger treatise on venereal diseases, it forms a fitting supplement to that volume. The present third edition has been considerably amplified, the principal additions being concerned with sexual disorders in the female and comprising four entire chapters. One of the most important of these is that devoted to the neglected subject of injuries to the female genitals in coitus, which is founded on Neugebauer's exhaustive study of the subject. Other new material concerns the anatomy and physiology of the genital organs, deformities of the genitals, the *x*-rays in relation to the cure of tuberculous or malignant disease of the genitals, and as a cause of sterility, etc. The book is thoroughly practical and helpful in its suggestions as to treatment, and though it lacks the thoroughness of the German works, particularly as regards the nervous and mental conditions underlying sexual abnormalities and perversions, it is well designed to assist the practitioner in dealing with the cases that may come under his observation.

# Society Reports.

## MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, Held October 23, 1905.*

THE PRESIDENT, DR. HENRY S. STEARNS, IN THE CHAIR.

THE one hundredth anniversary meeting of the society was opened by the president, with the announcement that polls were opened for balloting and would remain open for one hour.

**Annual Reports.**—The treasurer announced that there remained on hand on October 23 a balance of $373.37. The Comitia Minora reported the addition of 106 new members during the past year, and an average attendance at meetings of 203. The list of deaths occurring during the past year was the largest in the history of the society, numbering 55. At this time there were 2,200 active members. It was a matter for congratulation upon this one-hundredth anniversary that they were soon to witness the amalgamation of the medical men in the State of New York in one great body. The Milk Commission reported satisfactory larger than in previous years. They sought as counsel of the society made his annual report, and said that the amount of fines imposed and convictions obtained had been larger than in previous years. They sought as counsels for the society, not only to punish, but to have a deterrent effect upon possible offenders. He narrated a number of cases in which action had been brought against men who professed to cure drug habits, cancer, etc., and then spoke of the continued criminal alliance that existed between quacks and charlatans, and the newspapers, and he spoke in laudatory terms of the work that was being done by the *Ladies' Home Journal* and *Collier's Weekly* in exposing certain frauds, and in their efforts to make the newspapers realize the crime in opening up their columns to these quacks for advertising purposes. He hoped that eventually there would result a Public Health Society. Such a movement would be the beginning of the end of this criminal alliance.

**Resolution Against the Criminal Alliance Between Quacks and Newspapers.**—Dr. WENDELL C. PHILLIPS offered the following, which was unanimously carried:

*Whereas*, The Medical Society, for over one hundred years, with the sanction of the State of New York, has been engaged in an effort to "regulate the practice of physic and surgery," and

*Whereas*, The Legislature of said State has expressly authorized the enforcement by this and other county medical societies in the State of the public health law regulating said practice, and

*Whereas*, Hundreds of prosecutions and convictions have resulted as a direct outcome of the work of this society in enforcing the law, and

*Whereas*, A large percentage of the quacks and charlatans convicted as a result of the work of this society have been already admitted to the advertising columns of various papers in the city and county of New York, and the protection of the public health been made much more difficult as a result of said advertisements.

*Now, therefore, be it Resolved*, That the Medical Society of the County of New York, at its hundredth annual meeting, emphatically protests against the criminal alliance between quacks and certain newspapers in the city of New York and elsewhere; that in the courts of honor and conscience and morals, if not in the courts of law, the newspapers that profit by the publication of the alluringly false advertisements of notorious quacks and charlatans are in no wise less guilty than these charlatans themselves.

*Be it further Resolved*, That the thanks of this society are due to the *Ladies Home Journal* and *Collier's Weekly* for their telling exposures of the criminal alliance existing not only between quacks and some newspapers, but between the latter and powerful companies controlling well-known patent medicines long since proven to be dangerous to the health and comfort of the people.

**Origin and Early History of the Medical Society of the County of New York.**—Dr. JOHN VAN DOREN YOUNG read this paper, which was of a historical nature, dealing in particular with important events and actions during the past one hundred years, since the foundation of the society.

**Some of Our Predecessors.**—Dr. A. JACOBI read this paper. He said that the combination of men and of circumstances made history, and this was what made the writing of history so difficult and the esteem in which recital of human endeavor was held so precious. He said he intended giving the sketches of a few men only whose names might have been, but never should be, forgotten in the profession they had adorned and benefited. He held in his hand the sketches of many men, and some he only mentioned. Austin Flint he had already extolled shortly after his death; A. L. Loomis had too great a personality to be extinguished from the memory of his generation; Cornelius Agnew, public spirited, unselfish, warm-hearted, and generous; Alonzo Clark, most elegant, best informed, eloquent, who awoke a sensation of melancholy whenever the thoughts were turned to a consideration of human inconsistency—and gratitude. After having been the most admired and sought-for consultant he fell sick and was out of sight for a few years, when the grave was ready for him. The number of medical men attending his funeral was exactly 29. He then read the names of a large number of the absent, the dead, reviving the memory of but a few of them.

John Putnam Batchelder, 1784-1868; he took his degree at Harvard, in 1815. The last twenty-five years of his life he practised in New York, where he was the president of the Academy of Medicine in 1858. In 1817 he took the Chair of Anatomy in Carleton, Vt., and afterwards that of Surgical Anatomy, in Pittsfield, Mass. He became widely known as an operator on tumors, on stone in the bladder in 1818, ligature of the corotid in 1825, for sarcoma of the maxilla, in 1832 removal of the upper jaw. He was one of the first, if not the first, to remove the head of the femur. He contributed to medical literature and never ceased to work and keep his eyes open.

Horace Green, 1802-1867; he taught medicine in Carleton, Vt., several years, and was one of the founders of the New York Medical College in East Thirteenth street. There he taught until 1860; a reorganization took place and he remained in the faculty as emeritus. He settled in New York in 1835, and as early as 1846 began medical writing, the first being a treatise on diseases of the air passages; in 1849 he published his "Pathology and Treatment of Croup," in 1852 "The Surgical Treatment of Polypi of the Larynx," and these books were soon followed by many others, and articles in journals. His skill was such in laryngeal work that he could make laryngeal and sublaryngeal applications with silver nitrate and other substances for croup and tuberculosis of the lungs. He was bitterly attacked in the New York Academy of Medicine; the greatest men of those times proved, to their full satisfaction, that the thing could not be done. He exhibited his instruments and did it. But the overwhelming vote was that it could not be done

Mortimer G. Porter, 1826-1863, aided Dr. Jacobi in establishing a section for the diseases of children in the New York Academy of Medicine, although it was twenty-five years before that end was attained.

James Stewart, 1799-1864, who was very much interested in sick children and who translated and published much about them. In his obituary he was called "retiring and thoughtful, yet humorous."

James Livingston Brown, born in 1831, was an example of a typical American career, cut short by death. He attended public school, was a pupil in a private school in Canal street, and paid for his tuition by serving as a janitor. He began early to teach Latin, Greek, and the rudiments of music. He had a scholarship in Columbia College, received his A.B. in 1852 and A.M. in 1868. During vacations he

peddled thermometers, etc. Add to this his indefatigability and ambition, amiable manners and great personal modesty, together with his idealistic tendency not only to become prominent, but also useful, and one had a picture of what made a great doctor and a good citizen. It was not his love for music alone that made him keep his place as organist in St. Luke's Church fully seventeen years. He was long connected with Demilt Dispensary, with the Health Department as Sanitary Inspector, and with Prof. G. T. Thomas as his chief of clinic. His contributions to literature were largely on gynecological work. Few may know that the case of diabetes in a baby of less than two years described in the first volume of the *Journal of Obstetrics and Diseases of Women and Children*, 1868, occurred in his own child.

Charles Hersthel, 1809-1873, whose broad general education, knowledge of German, French, and Spanish, his amiability and helpfulness made him popular in all classes of the community. He was interested in the foundation of the German Dispensary, which began its work in 1857, and for many years he was a trustee of the College of Physicians and Surgeons. He was the only one of the influential German doctors in town who did not tell the timid and disheartened young emigrant that there was no room for him in New York city.

William Detmold, 1808-1895, came from Germany, where he had been a pupil of Stromeyer. He introduced subcutaneous tenotomy in America, and established the first orthopedic service in connection with the general surgical clinic at the College of Physicians and Surgeons; he also had the conrage, or good luck, to open a brain abscess in 1850. That was why he was pronounced a swindler in Germany. He also suggested that certain muscles might be directed by areas in the brain, years before this was proven. His surgical talent and his long association with the College of Physicians and Surgeons made him a conspicuous figure.

Richard J. O'Sullivan, 1833-1896, read a paper on School Hygiene in 1873 before the New York Academy of Medicine. He was Sanitary Superintendent of the Board of Health, and for many years Sanitary School Inspector, until the office was abolished. One of the results accomplished by him was this: that of 40,000 children vaccinated by him not one was taken with smallpox during the epidemic. In appreciation of his merits the Board of Education rewarded him by abolishing the office of Sanitary School Inspector. In his paper, which was discussed by C. R. Agnew, A. Jacobi, and John C. Peters, he claimed equal rights for physical and mental culture, censured the iniquitous habit of sending children to school prematurely, claiming that "seven years is an early enough age for a child to be sent to school." He insisted upon a proper division of time in schools, short lessons, etc. Within a few weeks it was proposed to insist upon an uninterrupted instruction of the unfortunate young victims of three full hours in succession. Dr. Jacobi said that if there was a more direct method of raising a nation of invalids and idiots he was not acquainted with it. O'Sullivan rejected the drill, etc., and demanded spontaneous sports and amusements, recommended measures for the protection of the eyes, and for ventilation and against the dissemination of contagious diseases. What happened? Dr. Ellsworth Eliot, president of the County Society, Dr. Austin Flint, president of the New York Academy of Medicine, Dr. John C. Peters, and many others interceded with the Board of Education in behalf of the reappointment of Dr. O'Sullivan as Sanitary School Inspector on April 12, 1873. The Medical Record of September 15, 1873, and the *Evening Post* took an able part in the discussion, but to no purpose. Thus the office created on January 1, 1871, was on April 30, 1873, abolished by the Board of Education. It was to be remembered that Dr. O'Sullivan worked and wrote for medical school inspection more than a third of a century ago, as a member both of the Academy of Medicine and of the Medical Society of the County of New York.

John C. Peters, 1819-1893, studied medicine in Berlin, Vienna, and Leipsic. In the minutes of the stated meeting of November 14, 1842, his name appeared for the first time in connection with the Medical Society of the County of New York. He was president of this society in 1866 and 1867. The example of a relative, who was an influential homeopathic physician in the city of New York, prevailed upon the young and inexperienced doctor to join the homeopathic school. He soon acquired an extensive and lucrative practice. During this period of his life he began his literary career. Between 1853 and 1856 he published books and pamphlets on apoplexy, headaches, diseases of the eye, etc. For years he was chief editor of the *North American Journal of Homeopathy*, the author of several works on homeopathic practice, and one of the leaders of that school. On August 17, 1861, he surprised friend and foe by publishing in the *American Medical Times* his renunciation of homeopathy. Many hands were raised against him, many armed with clubs. He, however, survived jealousy and injury, and enjoyed to the last the profound respect of the profession. He was one of the founders and an earnest worker in the New York Pathological Society, and for years editor of its proceedings. He was one of the founders and presidents of the Medical Library and Journal Association, which contributed much to the greatness of the library of the New York Academy of Medicine. He was interested in infectious diseases, especially Asiatic cholora, on which he began to write in 1866. Almost every year he added to the literature up to 1873, and again in 1885. He was a firm believer in the filth origin of infectious fevers.

**Objects to Be Attained by Our Society in the Twentieth Century.**—Dr. Edward D. Fisher read this paper, and stated that America had always been the land for organization of societies, political and scientific, and that it was characteristic of us to have and need bodies to take charge of our affairs. The County Medical Society was a large body, comparable to the House of Representatives at Washington, or the House of Commons in England. We were directly interested in the morals and sanitation of the public. We had for our special care the public weal, in so far as the health of the community was concerned. We were directly interested in the morals and sanitation of the public. Medical subjects of not too special or technical character were in place here. The surgeon, the physician, the specialist had an opportunity to present the end results of his experience. The value of the society to its members was that it kept them in touch with all the advances of medical science the world over. All had not the time to keep abreast with medical science by reading, and he believed that facts were more fairly represented by personal teaching than in any other way. The society, being a large one, was also one in which differences of opinion must arise, leading often to heated disputes; but man was not perfect. This very opposition had led to increased medical scientific activity among them; their best days had often been the stormiest. He would not voluntarily throw the apple of discord among them, still he would rather see the water ruffled than have them too smooth and have the members settle down into placid inactivity. They should be able to differ without causing personal differences. The society, if united, could impress itself on the community. No profession came in such close contact with the public as the medical. The doctor was a friend, as well as physician, of his clients. He was brought more intimately with the inner life and affairs of his patients than even the lawyer. Our personal touch often took us out of the more functional affairs of life. They often could not think of us as taking part in political life, and that was one reason why our influence in public life was not as great as it might be. Often it was said that doctors were in no way calculated for business. There was some truth in this. We were like the man at the microscope, with his eye constantly engaged; he saw all the details, but failed to observe the larger field. We should, therefore, endeavor to make ourselves men of the world, as well as medical men.

This had been done in other countries, as England and Germany. This was one of the lessons of the twentieth century, and we would by this be better advisers, greater benefactors to our community. The twentieth century had changed many things in our methods of living; everything was less personal and individual. The members had increased so rapidly that conditions were different than formerly. New York to-day was what London, Paris, Berlin, and St. Petersburg were then, and even more, for we had passed that stage. New York had become an authority unto itself. This condition would be more accentuated as time went on, our restless activity pushing on in a scientific way previously unknown. The future influence of the Society, united now with the Association after an artificial division of its forces, would be greater than ever, and the Empire State would take its place of permanent influence in the national body. The one hundredth anniversary of the Society showed that to-day it was as vigorous and aggressive as ever.

**Officers Elected.**—*President,* Dr. Henry S. Stearns; *First Vice-President,* Dr. Walter Lester Carr; *Second Vice-President,* Dr. William H. Park; *Secretary,* Dr. John Van Doren Young; *Assistant Secretary,* Dr. J. Milton Mabbott; *Treasurer,* Dr. Charles H. Richardson; *Censors,* Drs. Henry S. Stearns, C. G. Coakley, James E. Newcomb, H. Seymour Houghton, and Egbert Le Fevre.

## AMERICAN ROENTGEN-RAY SOCIETY.

*Sixth Annual Meeting, Held in Baltimore, Md., September 28-30, 1905.*

DR. CHARLES LESTER LEONARD OF PHILADELPHIA PRESIDENT.

**Study of Stomach and Intestines.**—Dr. HENRY HULST of Grand Rapids, Mich., spoke of the value of the Roentgen-ray in the diagnosis of diseases of the stomach and intestines, especially in dilatation and dislocation of the stomach. These organs might be inflated, but inflation was often painful, dangerous, and inadequate. The best method was to give one ounce of bismuth in a pint of milk, or bread and milk, or potato soup. Then two exposures were made, one in the erect and one in the recumbent posture. If the first radiograph was made at noon, a second was made at six, nothing having been taken into the stomach in the meantime. Thus it was possible to ascertain the size, position, and functional capacity of the stomach. If a good picture of the colon was not obtained in this way, three ounces of bismuth might be injected per rectum. It was essential to have the patient at rest. If the subject was very fat, it might be necessary to intensify the screen. This was not particularly objectionable with a sixteen inch coil, a Wehnelt interrupter, and a strong tube placed twenty inches from the skin surface. A plate could easily be made under these circumstances in a medium sized subject in one second; without the intensifying screen, in three seconds. Ordinarily he had found it better to make the exposure at twenty inches in ten seconds without intensifying screens. Good apparatus and a fair degree of skill were sufficient to secure fairly satisfactory results. The diaphragm was indispensable.

**Skeletal Development.**—Dr. P. M. HICKEY of Detroit, Mich., showed slides demonstrating the bony development of the elbow joint, and emphasized the importance of comparing the injured with the uninjured joint before attempting to make a diagnosis of fracture, because the crevices in a developing joint might easily be mistaken for fracture when it really did not exist.

DR. GORDON C. BURDICK of Chicago was able to demonstrate absence of fracture in fifteen cases where it was supposed to exist.

Dr. J. RUDIS-JICINSKY of Cedar Rapids, Ia., said that the anatomy of joints as given in textbooks should be revised to agree with the Roentgen-ray findings as demonstrated by Dr. Hickey.

Mr. M. I. WILBERT of Philadelphia emphasized the necessity of radiographing an injured joint laterally and anteroposteriorly in order to get an exact picture of the joint, and of comparing the injured with the uninjured joint.

Dr. HENRY PANCOAST of Philadelphia said that fractures of the head of the radius were far more common than was usually supposed, although only a few cases were recorded in the literature. He had had twenty cases.

Dr. K. DUNHAM of Cincinnati had found it very advantageous to take stereopticon skiagraphs of injured joints as well as the ordinary skiagraph.

Dr. GEO. H. STOVER of Denver, Colo., always made an anterior and posterior exposure of the joint and a stereoscopic picture because it gave a better idea of the relative anatomy of the joint than could be obtained in any other way.

Dr. M. K. KASSABIAN of Philadelphia made use of a small devise, an acute-angle splint, which was placed on the inside of the joint, the tube being on the olecranon side.

**Interpretation of Lung Negatives.**—Dr. GEO. E. PFAHLER of Philadelphia said that in order to study the lungs satisfactorily the negative must be made while these organs were at rest. A careful physical examination should precede the Roentgen examination to enable the radiographer to make a correct interpretation of shadows. The greatest field of usefulness of the Roentgen-ray in lung diseases was in the study of tuberculosis. Besides assisting in diagnosis, it was a most valuable and correct method of recording the lesion at the various stages of the disease. The plate was placed behind, and a second plate in front of the patient so as to give proper value to lesions lying near the surface and to recognize any thickening of the pleura. The patient was placed in the recumbent posture, except when a pleural effusion was suspected, when the patient was placed in a sitting posture. The tube was placed at a distance of 18 to 20 inches from the plate. The time of exposure would vary with the time that the patient could hold his breath. This time should be determined by testing the patient several times before attempting to make an exposure.

Dr. HENRY HULST of Grand Rapids, Mich., had found that macroscopic lesions of the lungs showed very well, also old lesions, but not recent lesions. He never exposed a chest for more than one second in order to get the detail of soft tissues. When lesions were present that the Roentgen-ray could record, the diagnosis was positive. A negative diagnosis was of only relative value. It did not exclude the existence of tuberculosis.

Dr. M. K. KASSABIAN of Philadelphia said that by means of stereoscopic pictures it was possible to distinguish consolidation from pleural thickening and from cavitation. It was better to take the picture with the patient lying on the side and not on the back.

**Diagnosis of Aneurysms.**—Dr. FREDERICK H. BAETJER of Baltimore gave the points in diagnosis between aneurysm and dilatation of the aorta. A pulsating shadow which did not disappear between pulsations was always suspicious. By means of the Roentgen-ray a diagnosis of aneurysm could be made earlier than by any other method, and the treatment could be begun earlier and could be planned more intelligently; hence the results were better. Before proceeding with the Roentgen-ray examination, the patient should be examined carefully to exclude physical deformities of the chest and spine. The patient was then placed with his back to the tube, the tube being placed at the level of the third rib, and from 20 to 24 inches from the skin surface. A second picture was made from in front. By means of transverse or slightly transverse illumination it was often possible to tell whether the object seen had its attachment in front or behind. This was especially important in determining whether the aneurysm sprang from the ascending or descending portion of the aorta. By making the examination at two different levels, a correct composite picture was obtained.

Dr. P. M. HICKEY of Detroit had found that the most disastrous results followed the disregard of the Roentgen-

ray diagnosis of aneurysm. When mistaken for tumor, an operation always proved fatal.

Dr. W. S. Newcomet of Philadelphia advocated fluoroscopy in the diagnosis of aneurysm. By means of the fluoroscope it was possible to see things that the skiagraph would not show. The main thing was to have a fluoroscope large enough to show the entire chest.

Dr. Geo. E. Pfahler of Philadelphia cautioned against exposing the body of both patient and operator needlessly to the Roentgen-rays when making use of the fluoroscope.

Dr. Henry Hulst of Grand Rapids, Mich., never made an examination of the chest without the use of the fluoroscope, although it did not agree with Dr. Newcomet. He considered the plate more accurate than the eye. It showed better detail and minute changes that were not visible to the eye, nevertheless in an examination of the lungs the fluoroscope was indispensable.

Dr. J. Rudis-Jicinsky of Cedar Rapids, used both the plate and the fluoroscope in every case.

**President's Address.**—Dr. Charles Lester Leonard of Philadelphia reviewed what had been accomplished with the Roentgen-ray since its discovery ten years ago, discussed its application in medicine, and indulged in a speculative discussion of the identity of the ray, its chemistry and physiological action. He said that improvement in technique and better knowledge of the action of the ray and its application would advance its usefulness.

**Regulation and Measurement of Therapeutic Dosage of Roentgen-ray.**—Dr. E. G. Williams of Richmond, Va., said that the more superficial the effect desired the closer the tube should be placed to the skin surface. He had found that about ninety minutes were required to produce an erythema on the surface, with a tube distance of ten inches, spark gap four inches equivalent to the resistance in the secondary circuit, and the milliamperemeter showing three-fourths of a milliampere. The safety limits were about 30 per cent. less than the number of minutes required to produce a decided erythema. The law of inverse squares helped in regulating the length of exposure and the distance of the tube from the surface. The closer the part was to the tube, the greater was the difference in the effect on the skin and the parts beneath, and inversely, the farther the part was from the part, the less was the difference between the effect on the skin and the part beneath. His rule was not to expose in ten days more than the number of minutes required to produce a dermatitis. He usually gave treatments in series of four to six exposures each, in which the sum total number of minutes equaled the number of minutes required to produce the desired effect. The tissue was also affected in proportion to the relative number of cells it contained. To measure and record a dose of the Roentgen-ray there should be noted the duration of the exposure, the distance of the surface from the platinum disk, the quivalent spark gap, and the reading of the milliamperemeter.

Dr. M. K. Kassabian of Philadelphia described the means adopted by French and German roentgenologists for determining the dosage of the Roentgen-ray, such as the use of fluorescent paper and capsules containing a fluorescent substance. His means of measuring was to keep a certain tube for certain kinds of work, and to make an exposure of a certain duration, always noting carefully the action of the ray on the skin.

Dr. G. P. Girwood of Montreal used varying thicknesses of lead foil to estimate the dosage of the ray.

Dr. Chas. Lester Leonard of Philadelphia advised studying the equation of the tube used as well as the personal equation of both patient and operator in order to avoid untoward effects.

**Technique of Roentgen Treatment of Keloids.**—Dr. O. Shepard Barnum of Los Angeles, Cal., advised using a great abundance of rays from a tube of rather high resistance, and excited by a large coil. That meant good penetration and differentiation. The tube should be at least six inches in diameter, and it must have good penetration and be not lacking in definition. He used a ray which would show the bones in the hand at twelve feet distance. He said that it was better to have the tube too high than too low. The tube distance should be from fifteen to twenty inches, with an exposure of fifteen to twenty-five minutes on alternate days for eight to ten treatments. After a rest of ten days or until one was convinced that there was no dermatitis, the process was repeated until the tumor had disappeared entirely. The treatment should be pushed for three to six months, and then tapered off until every vestige of the tumor had disappeared.

Dr. Henry Pancoast of Philadelphia advised first excising the tumor with the knife, whenever possible, and then treating with the Roentgen-ray.

Dr. Boggs and Dr. Williams agreed in this.

**Present Status of Radiotherapy.**—Dr. Gordon G. Burdick of Chicago said that there was no longer any question as to the specific field of the Roentgen-ray in all forms of acne, lupus, eczema, psoriasis, pruritus, tinea, sycosis, mycosis fungoides, senile keratosis, venereal condylomata, and hyperidrosis. Among the skin diseases that might be classed as erratic were lupus erythematosis, pigmented vascular nevi, hypertrichosis, and acne rosacea. Of the first mentioned about 18 per cent. were cured and about 30 per cent. improved. He had treated 80 cases of epithelioma involving the skin only, with no recurrence. When the tumor was situated at a mucocutaneous junction it was well to have the glands removed after a period of quiescence had been brought about by the *x*-ray. He followed this method in twenty-three cases with no recurrence after two years. He considered the Roentgen-ray sufficient treatment in the great majority of cases. The knife should be used only in such cases where the tumor was situated favorably for radical removal. In cases having the characteristic odor, he invariably anesthetized the surface and by means of the galvanic cautery drove into the tissue for a prolonged period of time zinc and mercury ions, following with the Roentgen-ray after the separation of the slough. Eighteen cases of carcinoma, treated vigorously with the Roentgen-ray, were cured; in fourteen the tumors and enlarged glands disappeared completely; in four they ceased growing. All primary cases should be rayed, excluding the knife. He did not believe in the existence of a case of sarcoma that could not be markedly benefited by a prolonged, mild radiation from an old hard tube, well coated with aluminum, the thickness depending on the individual circumstances existing in the individual case.

**Treatment of Carcinoma.**—Dr. Geo. C. Johnston of Pittsburg said that in carcinoma of the breast the application of a ray of sufficient intensity for a sufficient length of time was capable of causing a disappearance of the tumor and carcinomatous cell nests and their replacement by connective tissue, a proliferative, obliterative endarteritis, and a sclerosis of the lymph vessels and glands leading from the affected part. A course of radiation not to exceed ten treatments of twenty minutes each at a tube distance of eighteen inches was sufficient in the majority of cases to accomplish the desired result. A tube of fairly low vacuum should be employed, carrying a current not to exceed two and one-half milliamperes. On about the fifteenth day after operation postoperative treatment should be begun. Cases of extensive carcinoma might be rayed, operated upon, rayed again and freed from the disease, providing the surgeon and the roentgenologist cooperated thoroughly. Postoperative radiation was made directly over the wound through the dressings, the length of each exposure being ten minutes and treatment being given every other day for as long a time as may be necessary.

Dr. Henry Pancoast did not believe that very many cases of carcinoma of the breast recovered if there were metastases in the mediastinum.

Dr. Geo. E. Pfahler agreed with him.

**Late Results in the Treatment of Sarcoma.**—Dr. Wm. B. Coley of New York said that facts up to the present

time failed to show that the Roentgen-ray was curative of malignant growths, except those that were located superficially. No patient had yet remained free from a local or general recurrence for three years. The value of postoperative treatment was undetermined. The treatment of sarcoma by the Roentgen-ray had shown, in a small proportion of cases, that the tumor decreased in size and even disappeared in a few instances. In the small percentage of cases in which the tumor had disappeared, the universal tendency to recurrence and the danger of dissemination of the growth were sufficient reason for not advocating the method, expect in inoperable or recurrent cases.

Dr. J. Rudis-Jicinsky of Cedar Rapids, Ia., believed that the use of Coley's antitoxin precipitated the occurrence of metastases.

Drs. Bowen, Stevens, Burdick, and others reported favorable results in the treatment of sarcoma with the Roentgen-ray.

Dr. Vernon J. Willey of Ann Arbor, Mich., treated his patients for two to four weeks prior to operation, using a hard, low tube incased in a Friedlander shield, with good result. One patient treated entirely with the ray recovered after forty-two treatments with no recurrence a year later.

**Roentgen-ray in Carcinoma.**—Dr. Geo. H. Stover of Denver used a ray of good mellow quality that would penetrate the tissue. The ray might be allowed to affect the surrounding tissue to a reasonable distance, but should not be placed too near the skin because of the pressure of rays close to the woll of the tube that were of high destructiveness. All healthy parts should be protected. He rayed three times a week for ten minutes each time, the tube distance being eight to ten inches. He used shields on all treatment tubes. He advised Roentgen-ray treatment of primary non-operative and recurrent non-operative carcinomas. Where there was an equal chance between Roentgen and surgical measures, he advised operation first and the use of the ray afterward.

**The Roentgen-ray in Military Surgery.**—Dr. C. F. Stokes, U. S. N., described the equipment employed in naval hospitals and on board ship, and cited a number of cases in which the Roentgen-ray was used to good advantage.

**Treatment of Leukemia.**—Dr. J. F. Smith of Chicago added two cases to ten previously reported, and reviewed the results obtained in the entire series. The action of the Roentgen-ray seemed to be of two kinds, (1) the local influence on the spleen and glands characterized by inflammatory reaction, if treatment was pushed vigorously, and (2) the breaking down and disintegration of gland tissue and the formation of leucotoxin which either had an inhibitory action on the manufacture of leucocytes by the bone marrow or destroyed the leucocytes already formed. In no case did the splenic tumor disappear entirely. With a discontinuance of the Roentgen-ray, the disease returned after a variable interval. Acute cases were not benefited at all by the treatment; chronic cases responded more rapidly than subacute cases. The probability was that the ray held the disease in abeyance, but did not cure the patient.

**Roentgen Treatment of Hodgkin's Disease, Leukemia, and Polycythemia.**—Dr. Henry Pancoast of Philadelphia emphasizes the necessity of careful study of the effects of Roentgen-ray exposures on metabolism, particularly in connection with the treatment of the diseases under discussion. He had found that the effect of the Roentgen-ray on leukemic tissue was not the same as that on the skin in an *x*-ray burn or an epithelioma breaking down under treatment.

**Technique of Calculus Diagnosis.**—Dr. Russell H. Boggs of Pittsburg emphasized the necessity of being familiar with the densities that might appear on the plate and of being able to interpret them correctly. In over 200 cases examined there were only two unsatisfactory results. The diagnosis from the plate should never be attempted until the plate was perfectly dry. He said that it was not difficult to made a radiograph that would show the calcium oxalate and phosphatic calculi, but if the patient was large it required a great deal of accuracy to show the necessary detail and make a correct diagnosis. The Roentgen-ray was the most efficient means for diagnosing kidney stones, but experience in the use of the method was necessary to make it valuable. Two radiographs should be taken, and the shorter the exposure the better, because there was then no motion of the parts. When the rays were intense enough to make a picture in less than thirty or forty seconds, and the tube used was so much lower in vacuum, it would give greater detail and differentiation. The radiograph should be made while the patient held his breath, using a large amount of current with all the inverse discharge cut out. By using a rheostat in series with the primary of the induction coil, the milliamperage could be kept at a certain point. The bowels were emptied thoroughly first and no food or fluid was allowed for some time before the examination. The tube was placed about two inches from the plate.

Dr. Henry Pancoast of Philadelphia called attention to two sources of error in diagnosing kidney or ureteral calculi: (1) A deposit of salol in the bowel, and (2) the presence of phleboliths in the pelvic veins, both of which gave shadows resembling those thrown by calculi.

Dr. J. F. Smith of Chicago said that calcareous lymph glands and calcareous deposits in the pelvic ligaments had also been known to complicate the diagnosis of calculi.

Dr. Henry Hulst of Grand Rapids, Mich., mentioned a case in which a fracture of the transverse process of one of the lumbar vertebræ gave a shadow that was at first mistaken for a calculus until a full history of the injury that caused the fracture was obtained.

Dr. M. K. Kassabian of Philadelphia cautioned against mistaking calcified lymph glands around the lower portion of the ureter for calculi. He advised inflating the urinary bladder slowly as an aid to diagnosticating stones in the lower ureter.

Dr. Charles Lester Leonard of Philadelphia said that when there was a stone in the ureter there was always a passive enlargement of the kidney. That fact was an aid in making a diagnosis of stone in the ureter.

Dr. Sinclair Tousey of New York cited a case to illustrate that sometimes the stone was on the side opposite to the one indicated by the clinical symptoms. In such cases the Roentgen-ray was of great value in locating the stone. Radiographs for stone should include both kidneys and ureters in order to make such mistakes impossible.

**Treatment of Lupus and Rodent Ulcers.**—Dr. G. P. Girdwood of Montreal cited cases of tuberculous lupus in various stages and of varying duration, one case having existed for thirty-two years. All had been treated surgically and by applications but without avail. All had been cured by the Roentgen-ray or relieved to such an extent that a cure was almost certain in a comparatively short time. Where dermatitis was produced, healing went on more rapidly than in cases not burned, and it continued to go on without any further treatment. All his cases were treated at a distance of ten inches and for ten minutes at a time. The number of interruptions to the current was about three thousand per minute. The coils used were of the 18 and 30 inch variety; 110 to 220 V.; 2 to 6 A.; mechanical electrolytic break; no condenser, in most of the cases; 440 to 660 Watts.

**Treatment of Non-Malignant and Non-Tuberculous Skin Lesions.**—Dr. W. S. Newcomet of Philadelphia cited cases to show that in most cases of these kinds the Roentgen-ray was beneficial.

**Pathological and Physiological Effects of Roentgen-Rays.**—Dr. J. Rudis-Jicinsky of Cedar Rapids exposed guinea pigs and rabbits to intense radiation daily, first for ten seconds, and later for ten minutes, with a tube distance of six inches or less. After twenty exposures the guinea pigs partly lost their hair, and after thirty-four exposures there were two cases of bad necrobiosis, the condition being

aggravated when a very low tube was used backed by a spark gap of four inches and a very strong current. The longer this procedure was carried out, the lower became the resistance of the animals. Two of the animals were examined post mortem, and the findings were described at length. There were degeneration in the posterior horns and tracts of the spinal cord gray matter, hemorrhages in the cord and fibrous hyperplasia in the skin and the walls of the blood-vessels. Usually after a few exposures, even when the skin was intact, there was found a more or less profuse exudate of a clear, lemon-yellow fluid of a specific gravity of about 1.060, distinctly alkaline in reaction, which crystallized readily on exposure to the air, and when injected subcutaneously into mice, this fluid invariably produced death within forty-eight hours. It irritated healthy skin, acting as a coustic. The healing process began with the diminution of this fluid.

Dr. Geo. E. Pfahler of Philadelphia exhibited an *x*-ray filter consisting of a disk of sole leather about six inches in diameter and four times the thickness of the skin. A piece of pure silver might also be used. This disk was placed directly over the opening in the diaphragm. It effectually prevented tanning or burning of the skin. The leather disk was soaked in water before being used so as to resemble skin as closely as possible.

Dr. Henry Hulst used tin foil, aluminum, or some other substance for a filter, selecting the substance to be used with reference to the effect he desired to obtain.

Dr. Geo. H. Stover of Denver used aluminum foil.

Dr. F. F. Strong of Boston neutralized the superficial effect of the Roentgen-ray by exciting the Crooke's tube by means of Tesla's high frequency currents, ionizing the area in the vicinity to be treated. Since he had been using this method he had been able to treat deep seated tumors effectively without producing a burn. He also demonstrated a unipolar Roentgen-ray tube to be used for treating lesions situated on the walls of cavities and for treating the center of tumors.

Dr. G. C. Johnston of Pittsburg exhibited a new mercury interrupter.

Dr. Burdick showed a developing machine run by water power.

**Officers.**—The following officers were elected for the ensuing year: *President,* Henry Hulst, Grand Rapids, Mich.; *Vice-Presidents,* Russell H. Boggs, Pittsburg, C. E. Skinner, New Haven, Conn., E. G. Williams, Richmond, Va., and E. W. Caldwell New York; *Secretary,* Geo. C. Johnston, Pittsburg; *Treasurer,* L. E. Custer, Dayton, O.; *Executive Committee,* K. Dunham, Cincinnati, P. M. Hickey, Detroit, and J. F. Smith, Chicago.

Chicago was selected as the next place of meeting in 1906.

## NEW YORK ACADEMY OF MEDICINE.

### Section on Medicine.

*Stated Meeting, May* 16, 1905.

Dr. Charles H. Lewis, Chairman.

**Caput Medusæ.**—Dr. Lewis presented this case for Dr. Morris Manges. The patient was a man about forty years old, with cirrhosis of the liver and ascites, for the relief of which he had been tapped once. There was marked enlargement of the superficial veins of the abdomen—the so-called caput Medusæ. A loud venous hum was heard over the abdomen.

**A Case of Retrohepatic Abscess.**—Dr. David Bovaird reported this case. The patient was a man, 18 years old, who was formerly a plumber's assistant, but for the past two years had worked as an engine oiler. He had always lived in New York. His family history was negative. The patient was not addicted to the use of alcohol or tobacco, and denied venereal infection. He remembered no acute disease, but for several years he had suffered from palpitation of the heart and dyspnea on exertion. Three months ago he was compelled to give up his work because of general abdominal pains, most marked in the umbilical region. Sometimes they shifted to the right side if he slept on that side. Occasionally, they came on after eating, and were associated with bloating. His bowels were usually constipated. His appetite remained good, but he had lost 20 pounds in three months. For the past three weeks he had wakened almost every night feeling chilly, and wet with a cold sweat, followed by fever. During the first week of his illness he had vomited frequently after meals; the vomiting was apparently not related to the pains, and was not attended by nausea. When the patient was admitted to the Presbyterian Hospital, on November 23, 1904, he appeared to be fairly well nourished. There was no anemia. Heart and lungs normal. The area of liver dullness was enlarged, and there was marked rigidity and pain in the epigastrium, especially on the right side. The right kidney was palpable. On December 5 an area of liver flatness was made out beginning at the sixth intercostal space, and extending to the level of the umbilicus. There was tenderness over this area, and also over a corresponding area on the left side. There was also marked tenderness posteriorly, just to the right of the spinal column. The urine was normal. On December 22 the patient was transferred to the surgical division, and was operated on by Dr. A. J. McCosh. The abdomen was opened anteriorly, where nothing abnormal was found after careful exploration. Finally, however, he detected a mass behind the liver, which proved to be an abscess. This was evacuated and drained, and for a day or two the patient progressed favorably; then he had a profuse hemorrhage, evidently from the liver, and subsequently died from exhaustion. At the autopsy it was found that the abscess cavity lay distinctly behind the liver, and had burrowed into the posterior surface of that organ to the extent of almost two inches. The primary focus of the infection could not be found. Cultures made from the pus showed staphylococcus pyogenes aureus. The case was interesting, Dr. Bovaird said, on account of the protracted history of the case (about four months); the relative absence of any focal symptoms at the time of admission; the rather characteristic temperature chart of septic infection; the relative low leucocyte count, which only once reached 18,000 and usually ranged between 9,000 and 11,000; the location of the abscess, being behind the liver, and, finally, the absence of any primary focus or explanation of the abscess in that location.

Dr. Theodore C. Janeway thought that a low leucocyte count in liver abscess was not as uncommon as in other suppurative processes. He could recall such cases, and quite a number were on record.

Dr. E. Libman said that he too had seen a low leucocyte count in liver abscess, particularly in the amebic cases, where the process was really one of necrosis. In other types of cases, the leucocyte count depended on the stage of the disease, and was probably high in the beginning. The location of the abscess in the case reported by Dr. Bovaird was rather unusual, but rather down, behind the kidney, they were not so infrequent.

**A Case of Infective Cholangitis.**—Dr. Walter A. Basteo reported this case for Dr. H. S. Patterson.

**Epidemic Cerebrospinal Meningitis.**—Dr. John S. Billings, Jr., said that during the past forty years there had been four epidemics of cerebrospinal meningitis in this city. The first, and up to the present one the most severe, was that of 1872, when there were 782 deaths, a death rate of 8.70. In 1881 and 1893 the epidemics were not so severe, the number of deaths being, respectively, 461 and 469, and the death rates 3.70 and 2.67. The present epidemic, the severest one in the history of the city, began in the early months of 1904, and had continued into the present year. During 1904 there were 1,083 deaths, a death rate of 4.85. The winters of 1872, 1881, 1893, and 1904 were what were known as "hard winters," being cold, with considerable

snow. Each epidemic had lasted two years, and the present epidemic, contrary to the previous ones, had increased in severity during the second year. The disease had occurred among the poorer, but not the poorest classes. Dr. Billings then detailed the work of the Department of Health in connection with the present epidemic of cerebrospinal meningitis, and stated that on April 19th of the present year, it was first declared a contagious disease, with enforcement of quarantine, isolation of the patient, exclusion of other children from school, and disinfection of the premises and bedding on the termination of the disease. Previous to that date it had been classed as a communicable disease, but no attempt had been made to enforce the reporting of cases. A special history blank was also arranged, on which all the most important facts in connection with each case were recorded, and thus far 424 such completed histories had been turned in. The total mortality rate thus far this year had been 68 per cent. In the 424 cases tabulated, 59 proved not to be cerebrospinal meningitis, and by eliminating those, the mortality was 91 per cent. The majority of the cases occurred in males (56 per cent.). Sixty cases occurred under the age of one year, one case being reported at the age of five days. Five cases occurred in persons over fifty years, the eldest being 68 years. The greatest number occurred between the ages of one and five years (124). Of the 365 true cases, 299 lived in tenements. In a large number of cases there was a history of dirty halls, yards, and streets. In only 27 instances were parasites (bedbugs, pediculi, fleas, etc.) found, and in 40 instances there were animal pets on the premises (dogs, cats, parrots, etc.). In only 48 cases was there a history of other cases of the disease in the house or immediate neighborhood. In only 24 instances was there a history of direct exposure to the disease In 40 cases there was a history of inflammatory or catarrhal changes in the throat, nose, or mouth preceding the onset of the disease; 346 out of the 365 were said to have been in good health on the onset of the disease. The most constant symptom was the stiffness of the neck, occurring in 349 cases; next, severe headache (328); vomiting (326); convulsions (245). The adult cases usually failed to show convulsions. Petechial eruptions were present in 98 cases, and herpes, usually labial, in 41 cases. A nasal discharge was said to have been present in only 52 cases. Kernig's sign was noted in 217 instances, and was probably overlooked or not sought for in almost all the remainder; in only seven cases was it stated to have been absent. Leucocytosis was always present in the 42 cases in which the blood was examined; it varied from 15,000 to 35,000. The most frequent complication was that of the eyes. Lumbar puncture was performed in 113 cases, and examination of the spinal fluid showed the presence of the meningococcus in 78 instances. The treatment was usually symptomatic. The majority of deaths (47) took place on the second day, the cause of death usually given being coma and exhaustion. There were 31 complete recoveries; 19 cases recovered during the first three weeks. Diphtheria antitoxin was given in 62 cases; of these, 50 died (89 per cent.); 6 recovered, and in 6 the outcome was still uncertain.

Dr. Charles Bolduan discussed the modes of infection. He stated that so far as the bacteriology of the disease was concerned, the best statistics showed that about 75 per cent. of the epidemic cases were associated with the meningococcus, 15 per cent. with the pneumococcus, and the remaining 10 per cent. with various other organisms. Various parasites had been suggested in connection with the transmission of the disease. So far as mosquitos and flies were concerned, it would suffice to say that the disease occurred in this section during a season when these insects were practically absent. Against fleas and bedbugs it might be said that, although the disease was far more prevalent among poor and dirty people, it often occurred in homes in which vermin was practically unknown. Another and more weighty argument against this mode of transmission was the fact that the meningococcus was not regularly found in the blood of patients at all times. There was at present no evidence to support the assumption that the disease was transmitted by dogs, cats, or other household pets. It also seemed improbable that the disease was transmitted by dust, etc., as the meningococcus was very easily killed by drying and exposure to sunlight. Dr. Bolduan said he had failed to find any record of "house infections," meaning by that instances in which a case of cerebrospinal meningitis occurred in one family, that family then moving out, and the disease breaking out in another family moving into the same quarters. In the cases reported in the literature to show communicability of the disease, one usually found quite an intimate contact between the primary and secondary case, or cases. In the present epidemic in New York, there were forty-eight instances in which two or more cases occurred in one house. These had all been carefully investigated, and in thirty of the forty-eight places visited the interval between the cases, together with the surrounding circumstances, were such as to indicate strongly that the later case, or cases, had been infected by the earlier. Attention had been called to the occurrence of cerebrospinal meningitis in horses and cattle, but competent observers had stated that the disease in horses and cattle was entirely distinct from that in man. For the present, it might be said that only one mode of transmission had any real evidence in its favor, namely, through the nasal secretion of patients and of persons in direct contact with them. This did not mean that other modes of infection did not obtain.

Dr. Mary E. Goodwin gave the result of some laboratory investigations in connection with cerebrospinal meningitis. In forty-three cases of the disease in which the nasal secretion was examined, they found what they considered to be the meningococcus. In two of the forty-three they also found a micrococcus which differed somewhat in its growth from the meningococcus. In the nasal secretion of fifty-one persons who had been in contact with cases of cerebrospinal meningitis, the probable meningococcus was found in five. In twenty-three normal persons examined, an organism that seemed like the meningococcus was only found in a single instance. Twenty cultures were made from the spinal fluid of cerebrospinal meningitis cases, and there was no distinct difference between these and the nasal cultures, although the cord cultures varied among themselves even more than did the nasal cultures. Some grew more readily than others, or seemed to be more viable, or took a deeper stain. In order to test the virulence of these cultures, the best results were obtained with young puppies and white mice; in these animals the injections gave quite a good picture of cerebrospinal meningitis, with rigid neck, numerous convulsions, and death within twenty-four or forty-eight hours. These symptoms and results could be obtained by using either the nasal or cord cultures.

Dr. Charles E. Nammack said it would be very hard to convince him of the communicability of cerebrospinal meningitis by personal contact. He had seen patient after patient brought into the wards at Bellevue Hospital and placed in beds adjoining others with croup, pneumonia, and other diseases, and he did not recall a single case of hospital infection. In times of epidemic, the speaker thought there was very little danger of having the disease overlooked. On the contrary, physicians were too apt to classify other diseases, particularly the cerebral type of pneumonia in children, under that head. The same error might readily be made with cerebral typhoid, although that disease was not prevalent this time of the year. There were also other types of meningitis to be distinguished from the epidemic cerebrospinal type. As regarded the mortality, it apparently varied widely in different hospitals. In Bellevue Hospital, from the 1st of January, 1905, to the 10th of May, 1905, seventy-eight cases were received. Thirty-three of these were still in the hospital, and the final outcome in them was uncertain. Of the forty-five, forty had died and five had left the hospital cured, a mortality of 89 per cent. These cases included both children and adults. The first eighteen were treated by the expectant method, and all had died but

one. After that, Dr. Nammack said, the physicians were requested to give the diphtheria antitoxin treatment a fair trial, and he considered it one of the most cruel delusions that had been foisted upon the medical profession since the early days of tuberculin. It was not only expensive, but absolutely useless. The speaker said the one measure that seemed to give the patient the most comfort and best relieved the objective symptoms was the hot baths in the early stage of the disease.

Dr. Lewis A. Conner said that during the past ten years over two hundred cases of epidemic cerebrospinal meningitis had been treated at the New York and Hudson Street Hospitals, and during that period there had never been a single instance of hospital transmission. As regarded the diagnosis of the disease, the most difficult cases to recognize were the fulminant cases, the patients being in a condition of deep coma or wild, maniacal excitement. In the latter cases, the symptoms resembled uremic manifestations. As regarded the treatment of the disease, daily lumbar puncture had given him the most satisfactory results.

Dr. William H. Park said that, so far as he knew, there was no bacteriological or other reason for the use of diphtheria antitoxin in the treatment of cerebrospinal meningitis; the New York Health Board had never encouraged its use, but had been forced to give it a trial by the pressure of physicians. In times of epidemic, the disease was chiefly due to the meningococcus, while a certain number of the cases were the result of pneumococcus or other infection. As to the importance of the micrococcus catarrhalis in that connection, Dr. Park said that this organism had given rise to a great deal of discussion among pathologists, and its exact status was still unsettled. There were a number of organisms which resembled the meningococcus rather closely, and which might readily be mistaken for it, and authorities differed regarding the true identity of some of these micrococci. As to the communicability of epidemic cerebrospinal meningitis, Dr. Park said he did not think any one believed the disease was contagious in the sense of the exanthemata; it had simply been put under the head of contagious diseases by the Health Board so that the cases would be reported. As to the mode of infection, it was necessary for the meningococcus to find some way of entrance, and careful investigation had shown that in fully one-half, and probably two-thirds, of the cases the organism was present in great numbers in the nasal secretion during the early stage of the disease. After the fourteenth day it became comparatively rare. It was also occasionally found in the nasal secretion of those who came in contact with the patients, and in a few instances it was found in those who had not been in direct contact with the sick. The nasal secretion was the only known way in which the organism was apparently disseminated, and in those who developed the disease the germ must have found some way of passing from the nostril to the meninges. There was every reason to believe that it was wise to look after the nasal secretions of these patients during the first two weeks of the disease, and this also applied to those who were directly in contact with the sick.

Dr. F. S. Fielder, with the aid of a skeleton spine, demonstrated the method of lumbar puncture. He stated that in cases where repeated punctures were contemplated, it was advisable to make the primary puncture low down, so that "dry taps" could be avoided by going higher up, if necessary, in case adhesions formed.

Dr. O. M. Leiser said that while the disease could not be regarded as contagious in the sense of the acute exanthemata, he saw no harm in fumigation as a precautionary measure. In doubtful cases, especially in the fulminant type occurring in tenement houses, he would advise lumbar puncture to establish the diagnosis, if necessary, after death.

Dr. Edmund Le Roy Dow said the treatment by means of hot baths, to which Dr. Nammack had referred, could not well be applied to children, as they did not like them, and struggled so that the baths did them more harm than good. At Bellevue Hospital they had recently obtained beneficial results by placing the patient in a semi-upright position, thus reducing the intracranial pressure. The benefit obtained from spinal tapping had been more marked in the advanced than in the recent cases.

Dr. Thomas Darlington said the communicability of epidemic cerebrospinal meningitis had not been definitely settled, although he did not think there was any question that it was communicable from the nasal discharges and possibly in other ways, and that there was sufficient evidence to treat it as a communicable disease. He asked the cooperation of the profession in promptly reporting cases, as an aid in the collection of scientific data on the subject. A Commission had been appointed by the Health Department to investigate the disease, and their report would shortly appear in the medical press.

Dr. Charles H. Lewis spoke in favor of the hot bath in the treatment of disease, particularly in adults. It had the effect of quieting the symptoms, so that the patients were anxious to have it given. Children were not so anxious for it.

## Philadelphia County Medical Society.

At a stated meeting held September 13 Dr. Maurice Ostheimer read a paper entitled "A Note Upon Anorexia in Infants in Hot Weather." In the course of several summers he had observed about a dozen children, always under two years of age, seemingly in good condition, who suddenly or gradually began to lose appetite, without even slight symptoms of gastrointestinal derangement. When the condition persisted, the infants naturally lost weight. In the absence of an obvious cause, the disorder must be considered a functional derangement of the digestive tract. The symptoms subsided with the passing of the heated term. In some of the cases all food was withheld for a time, and barley water was given, followed by whey, with a gradual increase in the strength of the milk mixture. In others the strength of the food was more rapidly increased until the baby received a decidedly stronger mixture than it had been taking. Neither plan, however, seemed to be of much avail until the advent of cooler weather. Dr. William B. Stanton read a paper entitled "Rest and Exercise in Tuberculosis." He held that the modern treatment of tuberculosis might be considered under three headings: (1) Abundant and nutritious food; (2) a maximum amount of fresh air; (3) careful regulation of exercise. He pointed out further that while the value of exercise in properly selected cases was great, the harm done by injudicious exercise in acute cases was infinitely greater. The problem in each case was how best to obtain a state of normal or even supernormal nutrition. The amount of exercise to be permitted a tuberculous patient depended upon the temperature, the pulse rate, the respiratory rate, the degree of emaciation, the existence of complications on the part of the heart, kidneys, intestines, pleura, bladder, etc. A constant temperature above 100° was indicative of an acute and progressive process, and demanded absolute rest in bed. Ordinary remittent temperature, normal or subnormal in the morning and elevated in the afternoon, required rest in bed if the afternoon elevation was above 101 degrees. If the afternoon rise was only to about 100 degrees the patient might be permitted to be out of bed the greater part of the time, but not to take any formal exercise. When the evening temperature was under 100° exercise might be begun, if other conditions were favorable, and be gradually increased. When the pulse-rate was 120 or more in the morning the patient should be kept at absolute rest in bed; if 110 or less, he might be permitted to be up a part of the day, if other conditions were satisfactory; when the pulse was less than 100, exercise might be begun and be gradually increased. As a rule, when the respirations were more than 30 a minute with the patient at rest, exercise should not be permitted. When the patient was greatly wasted, even though the temperature and other phenomena were satisfactory, exercise should not be permitted. The

patient might be out of bed for the greater part of the time, but he should sit or recline out of doors until the weight showed a sufficient increase. At least two hours daily should be spent lying down. All tuberculous patients should have nine hours' sleep. Depressing complications required increased rest. The most common form of exercise, walking, was one of the best for tuberculous patients, and it was one of the easiest to regulate. Beginning with ten or twenty minutes daily, the exercise might be increased five minutes daily until the patient was walking for hours at a time. At first the walk should be on level ground, and be taken slowly. Intercurrent elevation of temperature or acceleration of pulse indicated a diminution or an omission of the exercise. After the patient could take a full two hours' walk on the level without disturbance of pulse or temperature, gentle elevations might be attempted. In institutions certain duties could be assigned to each patient, the length of time employed and the arduousness of the work being proportioned to the individual ability.

---

Medical Society of City Hospital Alumni of St. Louis. At the stated meeting held September 7, Dr. John Green, Jr., read a paper entitled "Glaucoma Simplex in a Young Woman Associated with Myasthenia Intestinalis." He reviewed a case of glaucoma simplex in a young woman who, at the same time, was severely constipated as the result of myasthenia intestinalis. Miotics failing to check the progress of the ocular disease, treatment directed to the constipation was instituted. Concomitant with the improvement in the general condition was observed an improvement in central vision, a widening of the visual field, and the disappearance of asthenopic symptoms. In the absence of hereditary tendency to glaucoma the assumption of the existence of an immediate etiological relationship between the general disorder and the ocular disease seemed justifiable.

---

## New Instruments.

### NEW HIGH POTENTIAL HIGH FREQUENCY "CATAPHORIC" ELECTRODE OR PHORIC MEDICAMENTAL ELECTRODE.

By WILLIAM J. MORTON, M.D.,
NEW YORK.

The cut illustrates a new High Potential High Frequency Electrode designed to secure the introduction into the living tissues of any medicament by means of the electric pressure and directional flow of high potential currents. The term "cataphoric" by usage holds its own, but results may also be due to anaphoric action. The term "phoric medicamental electrode" would probably be preferable.

The same electrode may also be utilized as a fluorescent electrode as described later on.

The cut illustrates an ordinary model of Geissler tube now commonly used for the administration of the so-called high frequency currents, more properly described in most instances as a high potential current. The innovation upon this familiar form of the electrode consists in surrounding its edge, by the glass blowers' process, with an elevated circular and inverted lip about 1-16 to ⅛ of an inch high. Together with the flat floor of the bulb the lip forms a shallow cup into which may be set at will disks of asbestos, pasteboard, or other porous material. The porous material is now saturated with the medicine desired to be introduced through the patient's skin or mucous membranes, and the electrode is applied to the part of the body desired.

Medicaments thus used may be detected quickly in the patient's saliva, blood, and urine. I subjoin one recipe which I have found extremely useful in the treatment of tuberculous glands and local and general tuberculosis, goiter, etc., by this method:

| | | |
|---|---|---|
| ℞ | Spt. Terebinthæ | ʒii |
| | Tinct. Iodinæ | ʒi |
| | Creosote | ʒss |

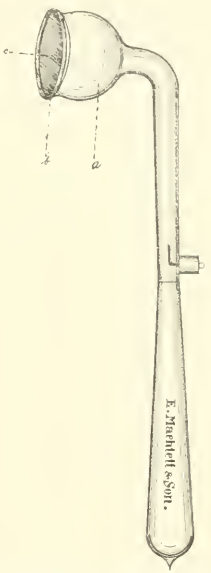
S. External use.

This mixture makes a colorless solution. If it causes too much irritation of the skin it may be diluted with castor oil, olive oil, or liquid albolene.

Another recipe I have found useful is

℞ Spts. Terebinthinæ ʒii
Thymol to make saturated solution.

The same principle of the close application of porous material to the electrode can of course be applied to any shape and form of vacuum electrode and many modifications applicable to different localities to be treated have been used by the writer, particularly a tubular electrode about which the porous material is wrapped. Throat, vaginal, and rectal electrodes are easily constructed. I have used such electrodes for producing local anesthesia, employing guaiacol one drachm, cocaine muriate five grains. (This solution



High Potential High Frequency Phoric Medicamental Electrode: *a*, Vacuum bulb Geissler type; *b*, raised and inverted lip of glass forming a shallow cup holding a disk of asbestos or other porous material; *c*, asbestos or other porous material saturated with medicament desired to be introduced by phoric action or serving as a fluorescent disk.

I had previously used for producing electrococaine, local anesthesia by the aid of the galvanic current.) Also to introduce mercurial salts, iodide of potassium, antiseptics, such as salicylates, and thymol in affected joints, and to introduce medicaments for the treatment of lupus, local tuberculosis, and cancer. I also use this electrode to excite fluorescence of fluorescing substances absorbed by the porous material. The ultra-violet rays of the electric discharge act as the exciting agency to the fluorescing solutions. Furthermore, I employ fluorescing solids in a finely pulverized or crystalline form, as may be the case, prepared on disk-shaped screens which fit the vacuum tube electrode.

The method of phoric introduction of medicines promises to have a very considerable vogue and produce important results in electrotherapeutics, and it is believed that the practical electrode above described will greatly aid practitioners. The electrode is made by Machtett & Son, 143 East Twenty-third street.

19 East Twenty-eight Street.

## Books Received.

*While the* Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

A Text-Book of Anatomy. By Dr. Cunningham. Second Edition. 4to, 1,312 pages, illustrated, muslin. William Wood & Company, New York. Cloth, $6; leather, $7. half morocco, $8.

The Inn of Rest. By Charles Wells Moulton. Volume Seven of the Doctor's Recreation Series. 4to, 267 pages, illustrated, muslin. The Saalfield Publishing Co.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 11, 1905:

| | Cases | Deaths |
|---|---|---|
| Measles | 155 | 8 |
| Diphtheria and Croup | 275 | 22 |
| Scarlet Fever | 96 | 5 |
| Smallpox | .... | ..... |
| Chickenpox | 62 | ..... |
| Tuberculosis | 335 | 160 |
| Typhoid Fever | 105 | 12 |
| Cerebrospinal Meningitis | 13 | 7 |
| Typhus Fever | ..... | ..... |
| Yellow Fever | ..... | ..... |
| Cholera | ..... | .. ... |
| Totals | 1,041 | 214 |

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the period from November 4 to November 11,

### DIFFERENTIAL DIAGNOSIS OF ECTOPIC GESTATION.*

BY

BROOKS H. WELLS, M.D.,

PROFESSOR OF GYNECOLOGY AT THE NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL, GYNECOLOGICAL SURGEON TO ST. VINCENT'S HOSPITAL, CONSULTING SURGEON TO THE BRATTLEBORO MEMORIAL HOSPITAL.

BEFORE the appearance in 1876 of Parry's classical monograph on extrauterine pregnancy little was definitely known and little attention was paid to the condition. From time to time reports appeared of lithopedion, of extruded fetal bones, of full-term fetuses found in the cavity of the abdomen at autopsy, but the far more numerous cases where death resulted from an early rupture of an ectopic fetal sac were mostly recorded as deaths from accidental rupture of a blood vessel in the pelvic cavity or from hematocele. Dr. Parry, I believe, had been coroner's physician in Philadelphia, and so had his attention forcibly drawn to the number of deaths which his autopsy-knife showed to be due to hemorrhage from ruptured gravid tubes. He collected from various sources 500 cases of extrauterine pregnancy and showed that in this series over 50 per cent. of the deaths had occurred as the result of hemorrhage from the early rupture of the tube. At this time abdominal section had been suggested for early rupture with hemorrhage, but no person had yet performed the operation, partly because of the fear of opening the peritoneal cavity, and partly because of the great uncertainty of the diagnosis.

Parry's paper drew the attention of the whole medical world to the importance of the condition, and reports of cases began to appear more frequently in the literature of the day. Diagnosis was hesitant and uncertain unless the pregnancy was far advanced, and even as late as 1889 so great an authority as Lawson Tait said, "No authentic description exists of an unruptured tube pregnancy." In the next year Baldy read a paper before the American Gynecological Society, in which he showed the possibility of a diagnosis before rupture.

The early treatment was as uncertain as the diagnosis. Injections of poisonous drugs in the fetal sac, and especially the killing of the fetus by electricity, were urged. By 1885 a number of abdominal sections had been done. In 1887 Janvrin, of New York, at a meeting of the American Gynecological Society, where nearly all the speakers were in favor of electricity, strongly advised abdominal section as the only and proper treatment. Three years later this method of dealing with the condition was practically universally recognized. From that time to the present the number of reported cases has become enormous, and what was thought to be excessively rare has, because of more certain recognition, become common. The supposed difficulties in diagnosis and operation have been in most part swept away by the flood of accumulated experiences.

*Part of a discussion on Ectopic Pregnancy before the Obstetric Section, New York Academy of Medicine, October 26, 1905.

In discussing the question of the recognition and differential diagnosis of ectopic pregnancy, it will be convenient to consider it under a number of heads, as follows: (1) Early, unruptured. (2) Early, with rupture and free hemorrhage. (3) Early, with rupture and extraperitoneal bleeding and hematocele. (4) Advanced with living child. (5) Near or after term, child dead.

**1. Early Unruptured.**—The ovum may become implanted in any part of the tube from the fimbriated end to the mucosa of the uterus. In general the danger increases with the nearness to the uterus, being least at the outer end, greater at the isthmus, and greatest when interstitial. There are no pathognomonic symptoms, and the condition is easily overlooked, unless we learn to suspect and watch for it. Some cases will give no indications which attract the attention of patient or physician until the alarming signs of rupture occur.

The patient is necessarily a woman within the limits of the child-bearing age. She has been previously in good health or at least has had no serious disorders of the pelvic organs. She has usually borne children, but may not have been pregnant for several years. She comes to you and states that she has missed one or two periods, though exceptionally there may have been no amenorrhea. During the last few days she has had a moderate bleeding from the uterus, the blood being darker than usual at menstruation, and not like her usual flow. She may have passed shreds or a decidual cast. She has had some uneasiness and griping pain in one ovarian region. She has reason to suspect a pregnancy, and often thinks these symptoms indicate an abortion.

A vaginal examination shows to one side, behind, or rarely in front of the uterus, a small, well-defined, smooth, movable, fusiform, elastic tumor, regular in outline, often with pulsating vessels, and at first not particularly tender or painful. As the villi of the fetal chorion begin to grow through the tube-wall, there is apt to be some intratubal bleeding, and the mass grows harder and becomes more sensitive. The uterus is slightly enlarged and slightly softened. The abdomen is not tender.

This history and the physical findings mean only one thing, an unruptured ectopic pregnancy, but unfortunately they are not always so clear, and, in a condition where certainty and quick action are of the utmost value, the greatest danger is in underestimating or mistaking the seriousness of the condition.

Interstitial pregnancy is almost never recognized before rupture, and is marked only by an asymmetrical development of the uterus, one cornu being prominent and very tender on palpation. The cervix is not softened as much as in normal pregnancy. There may or may not be a dark vaginal discharge.

When the diagnosis of an ectopic pregnancy is in doubt, the following conditions may have to be differentiated:

*Abortion.*—Do not depend too much on the his-

tory and symptoms, but make a careful bimanual examination. With abortion there is no mass in the tube, and the uterus is larger than with ectopic pregnancy. Caution is necessary, as the curettage indicated in partial abortion might do serious harm in ectopic pregnancy.

*Anteflexion of the gravid uterus* may occur, and may occasion doubt. Careful bimanual examination should reveal it. No vaginal hemorrhage. Watch for a time if in doubt.

*Retroflexion of the gravid uterus* should never be mistaken, as a careful examination should reveal that condition and prevent the unfortunate mistake of trying to replace a gravid tube. When there is a mass other than the fundus posteriorly, the uterus as a whole is pushed forward, the cervix looks down, and the fundus can be felt by bimanual pressure behind the pubes. A gravid uterus is often complicated by retention, an etopic pregnancy by spotting.

*Pyosalpinx.*—We find here previous ill health and long-continued tubal aching, as contrasted with the fair condition usually preceding ectopic gestation. There are no symptoms of pregnancy. There is a purulent vaginal discharge; pus in Skene's glands; a history of infection; elevation of temperature. Menstruation is usually regular and profuse, but there may be amenorrhea for several months. Both tubes show signs of disease, but one is usually much larger than the other.

*Hydrosalpinx, or small ovarian cyst* of one side with early abortion or temporary amenorrhea, may produce symptoms almost impossible to differentiate, even with closest attention to the history and physical examination.

*Myoma, sarcoman, and carcinoma* of the tube give no symptoms of pregnancy, no recent menstrual irregularities, and are hard and irregular in outline.

*Ovarian neoplasms* are rare, are more movable, are not accompanied by symptoms of pregnancy, or by temporary amenorrhea and bleeding.

**2. Early, with Rupture and Free Hemorrhage.**—The woman has nearly always had a temporary amenorrhea, her last regular flow having occurred eight to twelve weeks before. She has had irregular, moderate, rather dark bleeding, which has only attracted her attention as being different from her regular flow. She has probably had some of the signs of early pregnancy, such as nausea, enlargement and tingling of the breasts, etc., although in early rupture none of these signs may be noted.

Often she has considered herself in perfect health until seized with severe, sharp, colicky abdominal pain, followed by faintness, nausea, weakness, and pallor. At times she says something has given way inside of her. The pain continues; she goes from one faint to another; though curiously quiet and passive, she complains of an imperious air hunger; the weakness increases; she becomes more and more blanched, and finally death closes the scene, the patient's mind remaining clear until the last.

Vaginal examination usually reveals a tumor at one side of the uterus. Blood may be felt in Douglas' pouch as a boggy swelling. If the patient is stout and the bimanual examination inefficient, there may be no obtainable sign of any tubal involvement, and we may have to act, and act quickly, on the evidence afforded by the signs of internal hemorrhage alone. The temperature is apt to be subnormal.

Tubal abortion may occur when the embryo is implanted very near the fimbriated end of the tube. It occurs usually before the end of the eighth week, and is marked by sudden pain and more or less shock from intraperitoneal bleeding. It may even cause death from hemorrhage.

Rupture in tubal pregnancy may be precipitated by mechanical causes, as coitus, defecation, digital examination, falling, or jolt.

The symptoms of early tubal rupture with free bleeding are so sudden, so instant, and so characteristic, that there is small danger of their being mistaken.

One who had never seen a similar condition might think of simple *fainting from pain,* but in a faint, though the pulse may be temporarily lost, when it is felt it is slow and full, as contrasted with the increasingly rapid and weak pulse of hemorrhage.

Ectopic rupturehas been mistaken for *acute poisoning,* but the agitation of the patient, careful questioning, and the absence of the symptoms of intraperitoneal hemorrhage should render the differentiation sure.

*Attempted abortion* gives evasive answers; rise of temperature; rapid, high tension pulse; rigidity and tenderness over abdomen; not marked collapse.

*Acute gonorrheal endometritis* is accompanied by fever; there is pus in urethra; great tenderness over fundus of uterus; no marked collapse.

*Rupture of a pregnant rudimentary horn* in a bicornate uterus may present a history and symptoms impossible to distinguish from a ruptured tube unless the tumor can be demonstrated to rise from the side of the uterus near the cervix instead of at the fundus.

*Rupture or perforation of stomach, appendix, or other abdominal viscus,* when not traumatic, may closely simulate ectopic tupal rupture, but the patient is not usually so greatly collapsed; there is not the history of menstrual delay, and there is usually a record of symptoms pointing to the organ affected and a rapid onset of inflammatory symptoms.

*Small tumors of the ovary or tube* with acutely twisted pedicle may at times produce symptoms and physical conditions extremely like a ruptured ectopic tube, and may be accompanied by irregular uterine hemorrhages. The tumor, however, nearly always has more mobility and an appreciable space between it and the uterus, the history is different, the symptoms do not develop so rapidly, and the collapse is not marked.

**3. Early, with Rupture, Extraperitoneal Bleeding, and Hematocele.**—The history is the same as in the preceding forms, but the signs of internal bleeding are less severe; there is severe pain, faintness, and nausea for a few hours; then a remission of the symptoms for a variable time, with sudden repetitions of the attack. With every bleeding there is pain, weakness, and tenderness for several days. The patient becomes more and more weak and ill; she is confined to her bed; the abdomen becomes painful and tender; with the development of peritoneal inflammation pain with rigidity appears. There is increasing anemia. The pulse is quick (110-120), and feeble. There is a rise of temperature (101-102°) due to blood resorption. Where the bleeding is extraperitoneal the stripping of the peritoneal coat from the rectum is liable to cause a septic (usually colon bacillus) infection, with higher temperature and the so-called typhoid symptoms.

On vaginal examination the clear outlines of the tube are lost in the hematocele. The uterus may be pushed to one side or forward. There may be dullness in the flank that changes slowly with a change in the position of the patient. The mass of the hematocele is at first soft, but later becomes harder. It may be absorbed if small, but is apt to become infected and septic.

*Hematocele* is nearly always the result of a tubal abortion or tubal rupture, but may be caused by trauma or by the rupture of a vesesl in the broad ligament.

*Pelvic cellulitis or peritonitis* is distinguished from

hematocele by a history of infection, by a less sudden onset, more continued fever, by greater hardness, by more marked sensitiveness, by the absence of the history or signs of internal hemorrhage. It is usually bilateral.

*Pelvic abscess* may result from the breaking down of an old ectopic mass or from sepsis from gonorrhea or other infection. The history would decide.

An old hematocele that has become hard may be mistaken for a *myoma* of the uterus, but the history and the absence of recent acute symptoms and of the firm rounded nodular surface peculiar to the myoma should make the diagnosis clear.

*Malignant disease of the tube or broad ligament* gives a different history, is of longer duration, and is very hard and irregular in contour.

*Cornual pregnancy,* or pregnancy in a rudimentary horn is impossible to differentiate after rupture has occurred unless we can feel the sulcus at the fundus or can determine that the round ligament lies on the outer side of the mass, it lying to the inner side in tubal pregnancy.

**4. Advanced, with Living Child.**—*a. Tuboabdominal pregnancy.*—We have here the ordinary signs, symptoms, and history of pregnancy, with, in addition, the history of pain, sickness, and irregular bleeding during the early months. The patient complains that the movements of the child cause her more distress than in former pregnancies.

On inspection and palpation, the movements of the child are seen and the fetal parts felt with curious and extraordinary distinctness. Careful and gentle palpation shows no contractile sac (uterus) around the fetus. This is a most important diagnostic point and must be carefully watched for. The placenta is attached below and to the side. The fetal heart-sounds and placental bruit are unusually clear. Vaginal examination determines that the uterus is displaced to one side and forwards, and is distinctly separated from the child.

*b. Tuboligamentary or subperitoneal abdominal pregnancy.* In this form the conditions are more difficult to detect than in the tuboabdominal, as all the signs and movements are less easily felt. It is often difficult to hear the fetal heart. Child is contained in sac, but you find no rhythmic contractions as in uterine pregnancy. Placenta is apt to be above fetus or at least higher than in the tuboabdominal form. Hemorrhages into the sac are common. Per vaginam the uterus is felt pushed to one side and down. It is in much closer relation to the pregnancy than in the tuboabdominal form, but can usually be recognized. Douglas' pouch is occupied by a firm, rounded, immovable mass.

At term these patients have a more or less well marked false labor. There are crampy pains, vaginal discharge, maybe expulsion of membranous shreds. After several hours or days these symptoms cease suddenly. The breasts fill for a time. The signs of pregnancy disappear, and the patient may go an indefinite time before septic symptoms develop. The condition is apt to be mistaken for a false alarm preceding a normal labor, but the finding of a small displaced cervix should lead to a thorough examination.

*Normal pregnancy,* with a thin uterine wall so that the fetal parts are apparently just under the skin, sometimes occurs, and may be differentiated by feeling the contractions of the uterine wall over the fetus and by vaginal examination showing that the pregnancy is in the uterus.

*Pregnancy in a rudimentary horn* may be disclosed by finding the unimpregnated horn pushed to one side, by noting the deep sulcus between the small uterine fundus and the pregnancy, by the mobility of the pregnancy, and by the uterine contractions about the fetal sac. A double uterus would be disclosed by finding the unimpregnated half pushed forward and to the side, and by a double cervical orifice or double vagina. Both of these conditions are easily overlooked unless we constantly keep in mind the possibility of their occurrence.

**5. Near or after Term, Child Dead.**—In the tuboabdominal form a correct diagnosis is usually not difficult, even in the absence of fetal movement and heart sounds, but in the posterior ligamentary form the condition may become very obscure when several months have elapsed since the death of the fetus. There are no subjective or objective signs of pregnancy. The history is apt to be misleading, and to give no hint of a possible gestation. A careful investigation will, however, gradually make the situation clearer.

This condition is most apt to be mistaken for a *malignant ovarian tumor,* which it very closely resembles. An ectopic sac is apt to remain stationary in size or to shrink, while a tumor shows a slow, steady growth. If there is evidence of suppuration, the mass is apt to be ectopic. The condition may also be mistaken for *tuberculous peritonitis* or *fibrocyst of the uterus,* but a careful physical examination and review of the history should enable the diagnosis to be made.

523 Madison Avenue.

## SOME FACTS CONCERNING THE EARLY DIAGNOSIS OF PULMONARY TUBERCULOSIS.*

By JOHN H. PRYOR M.D.,

SARANAC LAKE, N. Y.

As a result of observation and experience gained while acting as the first medical superintendent of the New York State Hospital for the Treatment of Incipient Pulmonary Tuberculosis, the conviction that pulmonary tuberculosis is rarely recognized at an early and proper time for successful treatment has been decidedly strengthened. The organic law under which this novel institution was created provided that only incipient cases of tuberculosis could be admitted. It became necessary to devise and introduce methods by which patients suffering from that disease in the incipient stage could be secured. Applications for admission were sent to the superintendent of the institution, and arrangements were perfected by which the applicants could be examined by physicians designated as State examiners, who were appointed in each city of New York State. The blanks upon which the examiner made his report required a comprehensive study of the individual case, and included a diagram of the chest, which was filled in by the examiner, and showed the extent, location, and character of the lesion. Full instructions containing a description of what would be accepted as an incipient case were sent to the examiners and also to physicians in dispensaries, hospitals, and elsewhere for their guidance.

In the year beginning July 1, 1904, and ending July 1, 1905, the records of the institution show that 965 applications for admission were received. Of these 205 were accepted as incipient or favorable cases. An examination of the records revealed the fact that of these 205 patients at the time of admission, only 101 could be properly designated as incipient or early cases. The average proportion of incipient cases under treatment in the hospital was

*Read before the Academy of Medicine, Buffalo, N. Y., September 18, 1905.

sixty per cent., and only about one-tenth of the applications supposed to be suffering from incipient disease are included in that class. The inference seems fair that only about one-tenth of all the cases which were regarded by physicians as incipient and proper for admission could be rightfully included in that group.

During the seven years of agitation, when determined advocates were urging the necessity for one State hospital devoted to this class of sufferers, it was claimed that such an institution would not alone provide ideal prevention and rational, scientific relief, but that its chief function might be educational. Strenuous objections to its creation by the State were caused by the cry that the demand for admission from a vast number of patients in the early stage of the disease would be so great that the State could never bear the expense. The assurance that it would be difficult to fill the institution with patients if the law was obeyed was regarded as the delusion of an enthusiast.

Thus far no incipient case of tuberculosis has been denied admission to the institution, and the buildings have never contained more than one-third of the cases which could be accommodated. It may be true at the present time that patients may be denied admission because of the stupid parsimony and false economy on the part of the State officials in refusing to maintain more than one hundred patients in violation of the law, which states that accommodation should be supplied for two hundred; but the fact which I wish to emphasize is that it seems impossible to obtain enough patients in the early and curable stage of tuberculosis to fill one hospital which maintains one hundred patients and could accommodate one hundred and seventy-five. A moment's reflection will reveal the importance of this statement.

If an estimate be made by any method within our present knowledge it will be found that there are about 50,000 inhabitants of New York State suffering from pulmonary tuberculosis. During the year 1904 over 14,000 deaths were reported as due to that cause. By collecting the number of institutions for the treatment of tuberculosis in the State, and the percentage of early cases received for treatment, it will be found that only about one per cent. of all those afflicted with tuberculosis entered an institution at the proper time to obtain the highest percentage of recoveries. Furthermore, after years of effort on the part of those interested in procuring promising cases for treatment, it is found that only about twenty-five to thirty per cent. of the really favorable cases have thus far been obtained. Naturally this extraordinary condition leads to the inquiry "Why is the disease not recognized during the early stages?" and "Why are not more patients given the opportunity of receiving treatment which is the most promising at a proper time?"

In attempting to answer briefly these questions time will be saved by dismissing at once from consideration that type of doctor who dislikes to be disturbed by the introduction of progressive methods, and complains of an imaginary tendency to treat disease before it is present. There can be no question that a part of the medical profession honestly believe that a definition of incipiency may be too severe; that a diagnosis is demanded too early, or that refinements in diagnosis are required which only expert skill can supply. The transcendent importance of prompt relief at the earliest possible moment and its influence upon the result should be a sufficient reply.

Until quite recently no definition of an early, favorable, or incipient case has been accepted. During the spring of 1905 a committee was appointed by the president of the "National Association for the Study and Prevention of Tuberculosis" to prepare and present a report containing a classification with definitions for the consideration of that body at the inaugural meeting. The following definition of incipiency or favorability was agreed upon, presented to the association, and adoped for one year's trial:

"Slight initial lesion in the form of infiltration limited to the apex or small part of one lobe.

"No tuberculous complications. Slight or no constitutional symptoms (particularly including gastric or intestinal disturbances or rapid loss of weight).

"Slight or no elevation of temperature or acceleration of pulse at any time during twenty-four hours, especially after rest.

"Expectoration usually small in amount or absent.

"Tubercle bacilli may be present or absent."

If this definition serves no other purpose it will prove exceedingly valuable by supplying a standard for the statistical reports of results. The attempt to prepare a brief definition will naturally be followed by criticism, and it must be assumed that distinctions, whether based upon the extent of pathological changes or the history of symptoms, cannot be made arbitrarily. Thus, tuberculosis of both apices may be slightly manifest and the conditions truly favorable; but it must be remembered that, as a rule with few exceptions, disease in one apex follows disease in the other apex after an interval of months. Again, it is often difficult, and sometimes impossible, to recognize the presence of infiltration until pathological changes in the way of new formation sufficient to fill the air spaces and produce some consolidation have developed. Evidently the meaning is plain that this can and should be recognized during the period of invasion before any destructive process has begun.

Turban's scheme and classification which has been adopted in Europe, does not contain any description of incipiency, nor is the favorable type described. As modified by the committee of the National Association, it will furnish an excellent scheme for the recording of the results of all classes of cases. The most serious objection which is disclosed after careful study is the fact that it is based almost exclusively upon the extent of anatomical lesions.

It is probable that an examination of the records of many institutions will show that after the test supplied by this definition is applied a smaller number of early cases have been treated than have been previously reported. Inquiries submitted to a number of sanatoria in the United States to learn the percentage of incipient cases received, as defined above, reveal the fact that the average percentage of all patients under treatment which could be designated as early and favorable varies from two to thirty. An analysis of all cases treated at the New York State Hospital shows that sixty per cent. were received. To the best of my knowledge, it is the highest percentage published. The results justify the careful selection of applicants, and will be considered at another time. The reasons which may account for the failure to secure early recognition of a tuberculous lesion in the chest may be considered in the following order

The patient does not seek medical advice. This is certainly a potent factor among the poor. On the other hand, the poor patient often visits a physician who does not make a careful examination, or a dispensary where the attending physician may not be qualified to make a diagnosis until the disease is advanced.

A dispensary should be established in every city where men qualified to detect the early signs of tuberculosis are in attendance. Opportunities to become acquainted with the signs and symptoms of beginning tuberculosis at a dispensary make it probably

the best school for a young physician who is seeking instruction in that field of work.

It must not be forgotten that little or nothing could be gained by the early detection of tuberculosis among the poor until the last few years. The discovery of its presence was equivalent to a death sentence, and there was slight inducement to recognize it promptly. The time is rapidly approaching when the conditions surrounding the afflicted poor will be radically changed. The hope of recovery will encourage or compel closer attention and more experience and skill.

During the last decade efforts have been concentrated upon education and prevention, and the result, as evinced by the diminished death rate from tuberculosis, has been exaggerated; and the results of special methods of prevention aimed at that disease have long been misrepresented to a large degree. It has repeatedly been claimed that the death rate from tuberculosis was steadily diminishing in this State, in spite of the increase in population, but in the year 1904 the death rate was increased by more than one thousand, and the surprising rise in the mortality is yet unexplained. The writer has several times called attention to the constant relation between the mortality from tuberculosis and the general death rate.

This has led to a feeling that when the physician applies preventive measures he has practically done his full duty, and that it was regarded as sufficient to perceive the evidence of tuberculosis as portrayed by the picture drawn by the teacher and provided by the text book. Viewed in relation to the appearance of incipient evidence of disease, one is reminded of the days when a fatal case of inflammation of the bowels was regarded as evidence of appendicitis.

This brings me to another reason which I regard as second in importance, and it is realized that any plain speaking concerning it has long been regarded as quite dangerous. I refer to the faulty education in the medical schools, the inadequate and misleading teaching of text books and the lack of proficiency and thoroughness displayed by the medical profession concerning the early detection of tuberculosis of the lungs. This may be largely due to the recent distinctive prominence given to laboratory methods and the tendency to discard the methods of the clinician. The unwarranted dependence upon the presence of the bacillus in the expectoration, and the greatly exaggerated idea of its importance as the only reliable single sign have done immeasurable harm. While the fact that slight changes are overlooked among the poor may be understood, it is only too plain that the well-to-do often receive no more skillful attention. An acquaintance with a large class of patients sent to health resorts reveals the same failure to perceive early manifestations of the disease or to advise treatment at the proper time. This mistake simply adds hardship to affliction.

The student or young practitioner is often afforded no opportunity to examine or study a developing case of pulmonary tuberculosis. His first patient of that description offers him a new experience. The patients seen in the clinic, or the descriptions read in the textbook betray the classical features of advanced disease. The symptoms and signs accompanying early and advanced lesions are jumbled together and made very confusing. Sufficient time is not given to the examination of the healthy chest, to gain a familiar acquaintance with normal sounds. The older clinicians and the men proficient in the methods of physical diagnosis appreciated more fully the importance of comparing the sounds of health and disease.

The ear is not sufficiently trained and the hearing is not acute, and an attempt is made to make the unmusical ear detect slight changes and alterations of pitch. This can never be done without hard work and large experience. Some men can never recognize gradations of pitch because the ear is not capable of appreciating them. The art of palpation and percussion is not valued at its true worth, and the chest is not thoroughly searched.

There seems to be a widespread misunderstanding concerning the premonitory symptoms. Those considered are usually indicative of advanced disease. The fact is not emphasized that disease is present and can be detected for weeks and months before the chest is examined. From the inception of infection three to five months may elapse before the symptoms are complained of by the patient or sufficiently marked to attract attention. The prevalence of tuberculosis is forgotten and other causes looked for. Those most commonly assigned are bronchitis, a prolonged cold, or influenza. The symptoms are sometimes attributed to malaria in regions where it is practically unknown, or an apical pneumonia of small area is found; and it is not remembered that, in almost every instance, even when associated with grippe or influenza, it is tuberculous in origin. The character of the attack; the atypical nature of its course, and the distinct localization are only too plain. As illustrating the progress of symptoms and the time of their appearance, two cases under recent observation may be cited.

Both patients were sisters of consumptives, and were led to request examination by the belief that they had been exposed to infection. In both instances the physician in attendance had given no instruction in the way of prevention. The physical signs were evident at the apex. There were no symptoms whatever, both were apparently in good health. Three weeks after the first examination slight elevation of temperature occurred, and evidence of consolidation had extended somewhat. Under treatment the temperature has now subsided and the weight has increased. Thus far there has not been any cough or expectoration. These cases can be found repeatedly in persons where infection is suspected.

Mr. C. was admitted to the State Hospital. He had lost some weight and was somewhat anemic. The signs of infiltration were apparent at the apex. There was no cough and no fever. After a stay of three months the disease had apparently been arrested, when he caught a cold. Immediately fever with cough and expectoration appeared and bacilli were present in the sputa. The disease became active, later subsided, and was finally arrested.

The classical symptoms almost invariably presented in combination are loss of appetite, chlorosis or anemia, loss of weight, cough, with or without expectoration, hemorrhage, and fever. It is extremely rare that all of these are asociated at an early time. They are apt to be present at a later stage. This is particularly true of patients who have had rest, nourishing diet, and open-air treatment. Many times under these conditions few or no symptoms are apparent, and yet the disease may be progressive. The widely accepted statement that increase of weight and diminished temperature show arrest has many exceptions. It is only too common to find every general symptom of arrest with progressive physical signs, even to cavity formation. With a recent slight lesion about the only symptom observable is slight rise of temperature at some time in the twenty-four hours. Persistent fever, even with rest, is the most reliable and constant guide. It is frequently overlooked because the morning or early afternoon tem-

perature may be normal, or the temperature is not taken on several days successively.

At the State Hospital a prolonged study was made of the significance and the vagaries of fever when associated with pulmonary tuberculosis. It was found that the large percentage of patients have the highest range of temperature between 5 and 8 o'clock. Many times the temperature was one degree higher at 7 o'clock than at 5 o'clock. This rule cannot be followed invariably, and if a case is to be closely observed, the temperature must be taken every two hours. The temperature may show a decided rise at noon. Thus a patient was admitted with a history of normal temperature morning and evening. This proved to be true in the hospital, but it was observed that he lost weight, and that he complained of feeling tired at noon. His temperature was taken every two hours while he was at rest in bed in the open air, and it was found to be 102° daily betweeen 12 and 1 o'clock. The influence of external temperature must be considered, as cold weather certainly controls and has an influence upon the febrile curve. This was particularly marked during one week in June. .

The atmosphere was hot and humid. The temperature of all patients was taken several times a day and comparison made with a week in February which was cold and dry. A larger number of patients showed the presence of fever, and the average elevation of temperature was decisively higher than in the cold week. The rectal temperature is always more desirable and accurate. It is particularly true after the patient has been exposed to cold air for a length of time sufficient to produce an effect. The thermometers which are supposed to register in one or two minutes are usually thoroughly unreliable under this condition. After the thermometer is inserted for four minutes it will very often register a subnormal temperature, and after long exposure to the cold ten minutes may be required before the actual temperature can be known. This fact will also be observed when patients visit the office, and their temperature is taken after they have been for some time in the cold air. It will make a difference which should be considered whether the temperature has been taken after exercise or rest, or after a full meal in a warm room.

In children the temperature range is apt to be higher and other symptoms more marked, because the amount of disease is greater in proportion to the size and body weight. Again, in children the glandular involvement is apt to be much greater, and there may be multiple lesions instead of one.

It is not uncommon, particularly during cold weather, to find the temperature subnormal through the day and fever appear only in the evening. In tuberculous cases two of the most frequent causes of temporary elevation of temperature beyond the usual daily record are menstruation and disturbances of digestion. With few exceptions, the temperature shows an upward curve during the first and second days of the menstrual epoch. Fever due to syphilis, intestinal toxemia, or neurasthenia is apt to be one of the most puzzling features to consider and exclude.

Loss of weight may be gradual or rapid and great or slight. The standard of weight for the individual should not be fixed at the highest ever attained. Age, previous illness, habits, and environment should receive attention, and the statement of patients concerning their normal weight are often unreliable. In view of the chances for error, it seems safe to compare the present with the average weight while in health. In truly incipient and favorable cases, the loss of weight may be very slight or nil. Decided loss of weight is apt to be associated with acute, extensive or prolonged disease. Continual high temperature, often unobserved, with indigestion and loss of appetite, may have been present for weeks or months before an alleged early diagnosis is made. There is usually a difference of two or more pounds between the morning and evening weight. The loss of appetite and indigestion are more important, as bearing upon the prognosis. They are not noticeable to any great extent, as a rule, during early manifestations. Chlorosis and anemia are much overestimated as early symptoms, and are frequently due to other causes. The blood counts and the estimation of hemoglobin failed to show the decided variation from an average healthy standard which has been claimed. The fact that chlorosis and neurasthenia have a decided influence upon the prognosis is another matter.

Practically all textbooks lay stress upon cough as an early and most constant symptom. I have several times called attention to the fact that cough is apt to be due to pharyngeal irritation, and subsides after local treatment. Many times the so-called hacking cough owes its origin to nervous habit and disappears by an effort of will, or as a result of suggestion. It is not nearly so common among men as it is among women. As an early sign of tuberculosis its importance and the frequency of its presence have been much exaggerated, but it has and probably will continue to perform valuable service by directing attention to the chest.

Of the truly early cases treated at the State hospital very few coughed except infrequently. Physicians visiting the institution were forcibly struck by the absence of coughing. A dry cough, accompanied by some pain or irritation in the chest is of value and apt to be associated with localized pleurisy. When bronchial congestion with increased secretion is present the cough is more distinctive. It is not usually of a hacking character, however. The fact should be emphasized that tuberculosis is often present and can be detected before the patient gives any history or manifestations of a cough.

Hemorrhage during any stage of pulmonary tuberculosis rarely occurs in the Eastern or Middle States. A study of several hundred cases of tuberculosis in its incipiency, both in hospital and private practice, has led to the conclusion that less than five per cent. display this symptom. Its importance when other causes are excluded cannot be too strongly emphasized. In fact it is an almost positive sign. Furthermore, the history of a hemorrhage antedating by months or years more recent symptoms is always interesting and should invite a search for a previous lesion which became quiescent, arrested, or healed.

Finally, the three important symptoms which may be reliable guides are hemorrhage, fever, and loss of weight when they cannot be otherwise explained. My experience with the tuberculin test has been so slight that the expression of any views would be of questionable value. Certainly there are conditions in which a well-defined reaction may be misleading. The character of the product should be known, and the technique and what constitutes a reaction thoroughly understood. It is somewhat difficult to understand why this test is necessary except in a very small number of very puzzling cases. The desire to be ultra scientific may account for its exhibition at times. The experienced physician, trained in physical diagnosis, will find little need for its employment.

When suspicion is so strong that its use seems obligatory it may not be dismissed by a negative result. There is no positive proof that a person free from any tuberculous infection may not possibly react to a large dose of tuberculin. The tendency to

depend upon positive evidence leads to a great source of evil. I refer to the stupidity of postponing the diagnosis until the bacillus may be found. In the vast proportion of cases its presence should be regarded as a late manifestation. There are times when its appearance may be one of the first indications of the disease, but experience will show that remarkably few patients call upon a physician until physical signs are manifest. The result of prompt and scientific treatment cannot be known if the habit of waiting until the evidence of tissue destruction are apparent.

Practically all cases of pulmonary tuberculosis detected during life eliminate bacilli at some period of their clinical history. None afflicted at the New York State Hospital failed to produce bacilli at some time during their stay. The disease seems to advance to that stage, even when under treatment, but the extent of the disease and its ravages can be checked. The vast importance attached to the bacillus in its diagnostic rôle has become an excuse for carelessness, various deficiencies, and sometimes a commercial instinct.

The correspondence received from physicians showed that many physicians cannot satisfy themselves that a lung is affected by tuberculosis until the bacillus is discovered. It has been shown that even under broad and liberal construction of the meaning of the law, only about one-fifth of all applicants could be considered for admission. Several times physicians were so surprised by a refusal that the patient was sent to the institution anyway to prove that his opinion was correct. Nothing can be gained by reciting tales of frequent blunders. They are common in any line of special investigation. It may be of interest, however, to mention a few mistakes so apparent that the question of personal equation does not account for a marked difference of opinion. When patients were received, the result of the examination was compared with the findings as reported by the examiners. Errors were perceived concerning the extent, character, and location of the disease. Primary foci of disease previously existent escaped detection, and the fact that the recent lesion was secondary was overlooked. Only one focus was found where two or more existed; the lesion was sometimes located at the wrong apex or ascribed to the healthy lung. Pleurisy with effusion and even empyema were not recorded. The conditions relating to prognosis were not observed, and too much importance attached to the lesion alone. Histories were inaccurate, sometimes due to the dishonesty of patients who had been treated elsewhere, after which the disease became quiescent, and the present attack was simply due to an exacerbation and new invasion or extension. Multiple patches and the disseminated or diffused forms were almost habitually not recorded.

The inclination to regard incipiency simply in reference to time and duration was quite general. It should be obvious that a morbid process may be recent and yet active, progressive, extensive, or very grave. Associated tuberculous diseases were evidently not discovered or reported. The following complicating lesions were recognized at the hospital: anal fistula, infected cervical glands, infiltration or ulceration of the laryngeal apparatus, also tuberculosis of the epididymis and testicle. A difference in the findings was so noticeable and occurred with such frequency that attention was naturally directed to the possible sources of error. In some instances questioning of the patient elicited the statement that the chest had not been stripped. It was claimed that physicians had not insisted upon the removal of the shirt or underwear. A disinclination to bare the chests of women seems to prevail, and thoroughness is quite impossible if this is not done. There is no reason why a woman cannot expose the chest in private and place a soft towel about the lower part of the thorax enveloping part of the breasts.

The chest may be hastily examined in two or three minutes, but a careful search cannot be made in that time. In perplexing cases the mind must be concentrated and the faculty of hearing at its best. There are occasions when one will find it necessary to listen intently for minutes and go over a part of the chest repeatedly to obtain accurate information. The commonest location of beginning disease is at the apex or in some part of the upper lobes. It may be at the middle lobe near a bronchus, but the invasion below the clavicle is usually secondary or accompanied by or following pneumonia of mixed infection or pleurisy.

The tip of the lung rises during inspiration to a height of one and one-half inches above the clavicle, and sometimes a full inch into the neck. This part of the lung is often not investigated, nor is its mobility during inspiration and expiration observed. In attempting to ascertain the presence of delicate shades of sound obedience to the cardinal rule, "Compare, always compare," becomes a prime requisite. Inspection is certainly of little value except to exhibit the fact that the patient has never learned how to breathe. Some women have never taken a full breath.

The conformation of the chest may lead to suspicion, but experience has shown that any type of thorax may be invaded by the bacillus. Palpation may be so perfected that the sense of feeling becomes remarkably acute, but there are anatomical reasons why the stage of invasion cannot possibly be detected by the most proficient. It is sometimes employed and relied upon when the hearing is dull, uneducated, or the ear is not musical. Any teacher of physical diagnosis has learned that percussion is not an easy art, and that technique can only be acquired by practice. Reference to that point might seem trite were it not for the fact that improper percussion accounts for a large share of mistakes and deficiencies. The finger is not properly applied to the chest-wall; the resonance elicited is bony and the sound of a large area is enforced instead of that of a small limited locality. The light tapping, pushing blow from the wrist is not employed, and the normal differences, especially that between the right and left apex, are not diligently studied. Relative dullness, when slight, can be recognized only by distinguishing between gradations of pitch. The quality and duration of the tones may not be sufficiently or distinctly audible. By humming and attempting to imitate the pitch of sound, the difference may be made apparent when otherwise the listener will fail to appreciate any alteration. At times sounds cannot be heard one day and can be readily distinguished the next. This may be explained by temporary dullness of hearing or lack of alertness, and it certainly happens with experienced examiners. There may be men present who can recall the authentic story that Austin Flint, for years during his residence in Buffalo, played the violin daily to preserve the fine sense of pitch with which he was endowed.

The region over the tip of the lung should be percussed during inspiration and the line of highest elevation marked, if necessary, by a pencil. Infiltration and consolidation not only produce relative dullness, but the tip of the lung is apt to be somewhat immovable or retracted. This is particularly noticeable in quiescent or healed lesions, and recent disease in one apex may be co-existent with the evidence of previous trouble at the other. Quite frequently the active lesion is secondary and another can be

found elsewhere. The tendency to teach that invasion of the right apex is difficult or impossible of recognition by an examination of expiratory sounds is not only dangerous, but may be quite untrue. When the shape of the chest above the clavicle in front will not permit of satisfactory explanation, the attention may be confined to the posterior angle along the neck and over the scapula. With few exceptions, the sounds are more easily perceived, and the mouth of the patient should, as a rule, be open. At one place in this State where preliminary examinations were made prior to application for admission, I discovered that a noisy room made proper or reliable work impossible.

The selection of stethoscopes and the fitting of the ear pieces are not always considered carefully. The openings of the earpieces in the newer stethoscopes are smaller than those used in the past, and they are much more liable to be filled with wax and dust, which escapes notice. Wax may accumulate in the ear and plug part of the opening of the ear-tips when they are applied. The practitioner who returns to work after a long vacation finds that the hearing must be tuned up again. This point is touched upon to illustrate the importance of practice and the necessity for opportunity to educate the ear constantly.

It seems highly probable that an unknown percentage of the students and physicians have never heard the natural vesicular murmur. They have always listened to the transmitted nasal or buccal sound produced by the friction of the air current. This factor is mentioned because the changes in the respiratory murmur can be detected at times only when this transmitted sound is introduced. The diagnosis of infiltration by auscultatory signs offers scope for discussion. The Germans rely very largely upon what is called "harsh," "roughened" breathing. We are acquainted with the following four types of breathing, which may be considered: First, vesicular; second, vesiculobronchial; third, bronchovesicular; fourth bronchial. The distinction between the second and third is arbitrary, and the element of personal equation exists as an indeterminate factor. It must be admitted that any change in the nature of harshness or roughness must be manifested by a change in quality, duration, and pitch or it could not be differentiated. Furthermore, the alteration must be more evident at the time of expiratory effort. I fail to see how anything but confusion and obscurity could follow the introduction and use of this term. Certainly the word bronchovesicular is preferable, and it is sufficient and explicit. It is enough to recognize the fact that the expiratory sound is prolonged, changed in quality, and higher pitched; and that the transition is due to the increased transmission of the tubular or bronchial breathing through a medium undergoing a difficult pathological change.

The essential difficulty is found in being able to perceive distinctions when the change is slight, and then comparison is the chief aid. Although any change is much more difficult to discern and is more unreliable at the right apex, the effort should not be discouraged and certain puzzling conditions exaggerated. A few of the older textbooks contain a reference to the normal relative increase of the bronchial element at the right apex, and state that the evidence of tuberculosis as revealed by change in the expiratory sounds may not be accepted as a reliable guide unless râles appear. In the last edition of Cabot's Physical Diagnosis the following statement bearing upon this point may be found:

"When some râles are present at the apex of either lung the diagnosis of tuberculosis is almost certain, but if, as not infrequently occurs, there are no râles to be heard over the suspected area, our diagnosis is clear *only* in case the sign occurs at the left apex. Precisely the same signs if present at the right apex leaves one in doubt regarding the diagnosis, for the reason that, as has been explained above, we find at the apex of the right lung, in health, signs almost exactly identical with those of a slight degree of consolidation. Hence if these signs, and only these signs, are discovered at the right apex, we cannot feel sure about the diagnosis until it is confirmed by the appearance of râles in the same area of the left side, whether under the influence of iodide of potassium or spontaneously, or by the finding of tubercle bacilli in the sputum."

After reading this quotation, the deduction seems warrantable that an opinion or conclusion may be delayed until some softening has occurred or the signs of a possible destructive process are divulged. On the contrary, the signs of old or recent consolidation are often perfectly apparent in the right apex when no râles are present. When in doubt, comparison should be made with adjoining portions of the same lung, and the mobility of the apex and the character of the whispering voice sounds especially should be noticed. Again, the extension of consolidation in the right apex with the characteristic sounds which denote it can be followed, and repeated examinations are apt to reveal a decided change in the size of the area involved. The difficulty in recognizing bronchovesicular breathing is not so great as that encountered when the breathing is partially suppressed, and the percussion note and the whispering sound become quite valuable.

Cogwheel respiration and the transmission of heart-sounds are often purely nervous in origin. Cogwheel breathing may have little diagnostic value or significance except to arouse suspicion and lead to further examination. If the heart-sounds are transmitted more clearly to the right apex than to the left, it is entitled to some consideration. As a rule, however, the transmitted heart-sounds are only noticeable after considerable consolidation, and they may be present one day and absent the next, depending upon the nervous excitement sometimes caused by undergoing examination.

One of the most reliable signs of slight consolidation is surprisingly neglected. I refer to the transmitted whisper produced by the patient whispering the word ninety-nine. The variation in pitch and the prolongation of sound are far more easily detected than when the speaking voice is employed. I regard this sign as one of the greatest value, especially when attempting to define the limit of an affected area. Finally, it must be remembered that the duration of the expiratory sound cannot be properly measured if the patient is not allowed to breathe naturally and preserve the rhythm. By forcing the patient to breathe rapidly, as is frequently done during examination, the full length of expiratory effort is curtailed. The older English and American writers employed a term most concise and descriptive. The moist sounds were alluded to as "clicks" and "râles." The word click should be preserved as descriptive of the tones heard at an early period and indicative of an abnormal amount of mucus or mucopus which coats the mucous membrane. These fine moist bronchial râles can usually be heard at an early period during infiltration and deposit by obliging the patient to cough, otherwise they will escape observation. Without cough the mucus may not be dislodged or the agglutinated surfaces separated. Their localization, when absent elsewhere, is an important aid in diagnosis. They are fugitive and scarce, and râles of the character which should be designated as crackling or moist râles appear later in large numbers, due to fluid in the bronchioles and the smaller bronchial tubes when softening has occurred.

Perhaps localized sibilant breathing has been assigned too much importance as a sign of tuberculosis, particularly in a person suffering from a cold, lithemia, influenza, or grippe. On the other hand, a localized bronchitis should be watched, and may lead to the detection of other signs and symptoms as they appear.

One word in reference to the term "dry râle." It seems to be gaining general acceptance. Thus far the most labored explanation fails to excuse its adoption. One refers to its causation as pleuritic and uses it as synonymous with the pleural crepitation or fine friction sounds. Another attempts to discriminate between dry bronchial râles and moist bronchial râles. I confess to a feeling of confusion and a strong antipathy to the term. It seems to have no pathological basis, and it is hard to conceive of a dry rattling in the bronchi.

In closing, permit me to explain that I present this paper largely because the time seems ripe for a discussion of surprising conditions only too prevalent. A widespread growing movement has been inaugurated to provide proper care for the consumptive. At present this subject is being agitated in most of the States in this country, and many of them will build institutions in the immediate future. To attain lasting results the case should be reached early. There will certainly be a reaction when the tendency to relapse is fully appreciated and statistics of so-called arrested cases have been carefully scrutinized. The prediction that great difficulty would be encountered in securing cases for treatment at the proper time has been verified, and the opinion that the medical profession requires education as well as the public has not been relinquished. Evidently renewed attention must be directed to the vital importance of a more thorough and accurate study of the physical signs.

## A SUBMUCOUS RESECTION OPERATION FOR DEVIATION OF THE NASAL SEPTUM; WITH THE DESCRIPTION OF SEVERAL NEW INSTRUMENTS.*

By LEE MAIDMENT HURD, M.D.,
NEW YORK.
ASSISTANT SURGEON, MANHATTAN EYE, EAR AND THROAT HOSPITAL.

Cases of this class were formerly corrected, more or less satisfactorily, by some one of the fracturing methods, namely, the operations of Asch, Gleason, Roe, and others.

Gibb of Philadelphia, in the *Journal of the American Medical Association* October 29, 1904, reports the results of 100 cases of septal deviations treated by the methods of Asch, Watson-Gleason, and the saw. Sixty-five cases were operated upon by Asch's method in which a good result was obtained in 47 cases. He qualifies the words "good results" by saying, that "it does not mean that in each case recorded as good, a perfectly straight septum had been secured, nor that each case has been entirely uneventful in its course." But out of 65 cases 47 were good, 11 fair (fair means "those which could not be considered successful either from an artistic or functional standpoint, but in which better breathing space and more comfort to the patient was secured"). I personally would consider these cases pretty near failures; and the 3 remaining cases were failures. In one of the failures a Watson-Gleason operation was subsequently done successfully. Of those treated by the Watson-Gleason method, 19 resulted good, 3 fair, and 1 unknown. In the remaining cases the projection was sawn off. He also states in his conclusions, that "A certain number of cases are inoperable." I quote only Gibb, as his results seem to be better than the average. So much for the results obtained. Some of the disadvantages are, that a general anesthetic is necessary, the after-pain is considerable, and the removal and reintroduction of the hard rubber splints daily, as is the custom of most operators, is extremely painful. Rarely do the splints used fit the nose, and having it plugged with a hard rubber tube for several weeks is far from pleasant, and then, after all this discomfort only to get good results in about two-thirds of the cases. By the submucous window resection a local anesthetic only is required. There is practically no pain, and the nose is packed for one day, instead of hard rubber splints being worn for four or five weeks; and the results, as you will see later, are uniformly good.

The submucous resection was first performed by Suckstorff; Hartmann, Roux, Juracz, and Krieg were pioneers. Krieg removed the divergent part of the septum, but also removed the mucous membrane on the convex side as well. This destroyed the secreting surface on one side of the septum and left a large granulating wound that healed slowly. Killian and Hajek later used a single buttonhole incision and preserved the mucous membrane on both sides

About the same time, Freer of Chicago perfected his method, which also aims to save all the mucous membrane. Freer recently reports 116 cases with uniformly good results; the only complication were 13 perforations, six of which occurred in the first 15 cases. I may say here that a perforation of the nasal septum seldom gives any trouble. Killian reports 220 cases operated upon in his clinic and he mentions no poor results.

Indications for the submucous resection are the same as those observed in the Asch or Gleason methods plus many cases that were formerly classed as spurs but which are really deviations either of the cartilage or of the bone and sometimes of both. Experience with this method has shown that there are comparatively few real septal spurs. It is now recognized that they are deflections with some slight thickening along the ridge or angle. In these so-called spur cases the more prominent portion of the convexity and overlying mucous membrane is removed with the saw, which often results in a dry spot on the septum that forever afterward has an annoying crust formation.

There is another class of cases in which the cartilaginous septum is considerably thickened naturally, or in consequence of some previous inflammation or traumatism, and in this class only a submucous resection will relieve the condition Forming another class are neuroses due to nasal irritation from the deflected septum pressing against a turbinate. In this case one should straighten the septum rather than destroy the turbinate. There are also cases of accessory sinus disease, which probably are caused by a deflection which prevents drainage and treatment of the sinus intranasally.

It makes no material difference whether the deviation is due to traumatism or faulty development. There is no case inoperable so far as the condition of the septum itself is concerned, but there are a few contraindications that, as a rule, would apply generally to any operative procedure—advanced tuberculosis for example;

*Read before the Essex County (N. J.) Medical Society at Newark.

but patients who have pulmonary trouble with a fair prognosis may be greatly benefited by increasing the calibre of their nasal passages. Any infective process on or near the nose, such as lupus or furunculosis, would jeopardize the result; also constitutional diseases such as diabetes and active syphilis should prevent any operative procedure.

Patients suffering from acute coryza should be allowed to recover before being operated upon, and where there is purulent secretion the nose should be treated first to reduce the pus as much as possible before proceeding; but when the septal deviation prevents drainage from an accessory sinus, and the treatment of the sinus disease is hindered by the deflection, I believe in going ahead and performing the resection under as nearly aseptic conditions as can be obtained.

Fig. 1. Myles' Septal Knife.

Technique of the operation. Nearly every operator has perfected a method of his own. Krieg, for instance, removes the membranous flap, leaving but one thickness of mucous membrane, namely, that on the concave side. Under these conditions the raw surface has to heal by granulation and if not well watched the result is not always good. Killian uses a straight incision running from the floor "about one-half a centimeter back of the movable edge of the septum, not parallel to it, but a little oblique. The upper end is one centimeter or more further back than the edge of the cartilage." Hajek makes his incision along the free border of the cartilage; this brings it into the mucocutaneous portion of the septal membrane. Freer uses an L-shaped, an oblique, or an inverted T-incision, according to the nature of the deviation. I use a slightly curved incision, differently placed, according to the nature of the deflection, extending from the nasal floor upward and forward to the junction of the septum with the lateral wall.

Preparation of the patient: Have the face washed well, then follow by an application of bichloride of mercury, 1 to 5000 solution. Cover the hair and clothes with aseptic towels. If the membrane of the nose is normal the nasal cavity needs no preparation; if there is evidence of any infective secretion a douche of physiological salt solution should be given.

One of the most important points in the technique is the cocainization. It will repay one for the time expended to do this thoroughly, for the comfort of both the operator and the patient. I first spray both sides of the nose with a solution of an adrenal extract, 1 to 1000 containing 1 per cent. of cocaine, I then pack both nostrils, if the deflection will permit, with cotton saturated with 5 per cent. cocaine solution and leave it in about twenty minutes. If the deviation is so extreme that it is impossible to pass the cotton pledgets, I then use a small silver cannula and inject a small quantity of 5 per cent. cocaine past the deflection several times during the twenty minutes. On the removal of the cotton, spray with adrenal extract 1 to 1000, and then submucously inject, at several points along the line of the incision, a few drops of 1 to 1000 adrenal extract, containing one-half per cent. cocaine. If this method is used there will be absolutely no pain experienced. I operate with the patient in the upright position.

Instruments used. It is apparent that special nstruments are required and different operators have devised sets ranging in number from five to over twenty for use in this operation alone. I will describe the ones used by me, which comprise five special instruments supplemented by three others that can be found in any rhinologist's armamentarium. A large number of instruments is often confusing to the operator, and in addition causes loss of time in selecting the one desired. I will describe the different instruments as they are used in the course of the operation.

Having the nose perfectly anesthetized, as described, the incision is made in relation to the character of the deflection. If the free border of the quadrilateral cartilage is deviated, I start the incision on the floor of the nose and extend it along the deflected free border forward and upward to the junction of the septum with the lateral cartilage. If the deflection begins further back in the cartilage, the incision starts at the nasal floor about 3-16 of an inch in front of the deviation and runs upward to the junction of the septum with the lateral wall. The incision is given a slight curve forward to facilitate the elevation of the membrane and to increase the area of cartilage exposed. The cut should pass through both the mucous membrane and the perichrondrium and a little way into the cartilage to make sure that the perichrondrium has been divided along the entire length of the incision. I use for this purpose Myles' septal-knife which is semicircular in shape set at right angles to the shank. I use this knife as it is the most convenient instrument I have found for this purpose, but an operator can use any knife that is most convenient for him. I find it nearly impossible to incise accidently the mucous membrane on the opposite side with Myles' knife. Now I am sure that the perichrondrium has been divided. Next I use the sharp end of my elevator, which is a double ended instrument, the sharp end resembling a Volkmann curette, except that the cavity of the spoon is filled with metal. At first I used the curette for this purpose, but later had the elevator made like his curette without hollowing out the spoon. I have recently found out that Hajek's elevator closely resembles this instrument, the only difference being that mine is somewhat smaller. The other end of the elevator is made of copper and is blunt and rounded. The flexibility of the copper allows this blunt end to be bent in any way desired so as to reach the posterior portion of the greatest angular deflection. The sharp end of the elevator is now inserted into the incision and worked along until the perichrondrium is elevated back about one-third of an inch, then the blunt end should be used

Fig. 2. The Author's Submucous Elevator.

to continue the elevation over the entire cartilage on the convex side. The next step is to penetrate the quadrilateral cartilage. This I do just in front of the deflection with an ordinary bone curette as suggested by Yankauer, scraping through the cartilage until the membrane of the other side appears. I find this the safest way, as the membrane is pushed before the curette and not wounded, as is frequently the case when a knife is used for this purpose. Having exposed the membrane for about three-eighths of an inch vertically, I pass the elevator through and separate the mucous membrane from the concave side. Care must be used in elevating the membrane in order not to perforate it, as it may mean a permanent perforation. The cartilage now being free from membrane on both sides, the

Fig. 3. Bone Curette used for scraping through the cartilage.

Fig. 4. Ballenger's Swivel Knife.

next step is to remove the deflected portion. Some operators use punch forceps for this purpose, biting the cartilage out in small pieces; others use small knives, set at different angles to their shanks, and cut the cartilage out in one piece, but the best instrument, in my opinion, for this purpose is the swivel knife, devised by Ballenger of Chicago. This is a small U-shaped knife about three mm. wide, which swings between two prongs like a tuning fork; the ends of the U or stirrup knife are hinged to the ends of the prongs so that the cutting edge follows the direction of the pressure at the ends of the prongs. With this swivel knife the cartilage can be removed in a few seconds, while the other methods take minutes, and it leaves a smoother edge on the remaining portion. The Ballenger knife is so placed that the blade is against the edge of the cartilage where it has been perforated with the curette with one prong of the instrument on either side. The blade is pushed back along the incisor crest of the superior maxilla and the superior border of the vomer until the perpendicular plate of the ethmoid is reached, then upward along the perpendicular

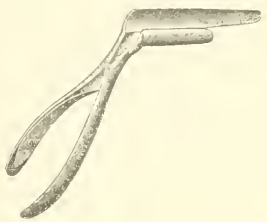

Fig. 5. The Author's Submucous Nasal Speculum.

plate as high up as the deviation extends, then forward to within about an eighth of an inch of the junction of the septum and the lateral nasal wall, then downward until the blade emerges where it entered the cartilage. This all takes but three or four seconds in an uncomplicated case. The deflected cartilage can be removed *in toto* with dressing forceps. The cartilage is thoroughly removed by the sense of touch. Now the cavity is inspected to see if the cartilage alone is deflected; if so the operation is completed, but if we find that it extends into the bone we proceed with the removal of the bony deflection. For the purpose of inspecting this cavity caused by the removal of the cartilage, some operators depend only on the ballooning out of the mucous membrane by the patient's inspiration, but as the patient cannot inspire all the time it strikes me that the operator must make slow progress. Killian uses his nasal speculum, which holds the membranes apart with its long blades. I have a speculum with a long upper blade and a short lower one, thereby rendering the aid of an assistant unnecessary. All

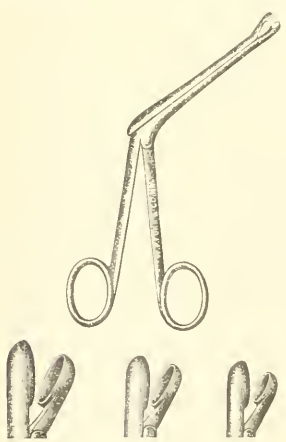

Fig. 6. Grunwald's Forceps.

the operators with whose writings I am familiar, require at least one, sometimes two, assistants, but my speculum separates the two membranes without possible injury and holds up the tip of the nose at the same time. The long blade is passed between the membranes and the instru-

ment is used with the long blade uppermost at all times. This instrument is not intended for use until the cartilage has been removed, which allows for the entrance of the long blade. With this speculum in place the interior can be easily seen at all times, and the bony deflection attacked in full view.

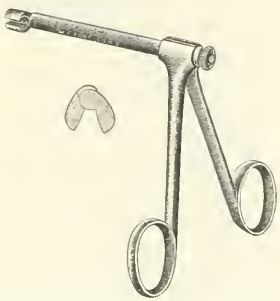

Fig. 7. The Author's Down-cutting Forceps for attacking the Septal Ridge.

Of the instruments used at present for removing the bony portion probably the best is Grunwald's forceps, which bites out that part of the perpendicular plate and vomer that is deflected, but there is no forceps yet described that will satisfactorily remove the incisor crest of the superior maxilla or a low deflection of the vomer. Most operators use a chisel or gouge. Chiseling the bone from the nasal floor in this way requires at least one assistant, and there is also thereby a fairly good chance of injuring the membrane. After the bone has been freed from the floor it is still attached behind, where it has to be broken off. For this purpose I have devised a cutting forceps on rather novel lines. It easily separates the membrane from the bone without causing it any injury, keeps the parts well in view, is worked without the aid of an assistant, and in addition secures a much smoother surface than that obtained by the use of the chisel. Now place the two septal membranes in apposition and if they are perfectly in the median

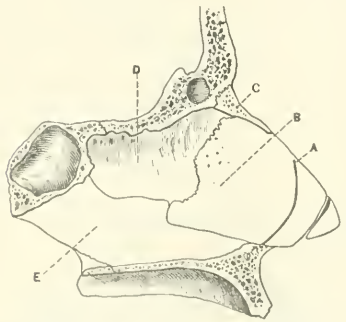

Fig. 8. Nasal Septum. A, Curved incision; B, quadrilateral cartilage; C, nasal bone; D, perpendicular plate of ethmoid; E, vomer.

line with no prominences, the septum will be straight when healed. I now wash out the cavity with peroxide of hydrogen and follow with a nasal douche of physiological salt solution. I then place a small Bernay sponge in the side operated upon, taking care to keep the edges of the wound in apposition. I also place a Bernay sponge in the opposite side to keep the membranes in the median line and prevent the formation of a hematoma. The sponges are to be saturated with some nasal wash that contains a small amount of formalin; this causes the sponges to swell and holds the septal membranes firmly, preventing hemorrhage. The patient is then

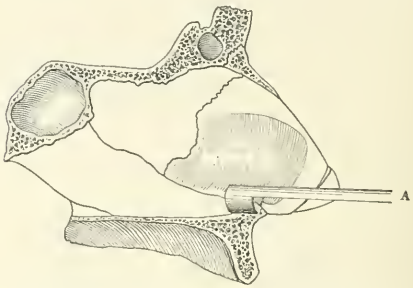

Fig. 9. The shaded part shows the portion of the cartilage removed. A, the cutting forceps engaged on the anterior nasal spine or incisor crest and the vomer.

allowed to return home. Some operators put their patients to bed for a day, but as there is no shock in the average case, and with my method of using cocaine, but little depression, I think they are better off out of bed. I remove the Bernay sponges on the next day. The patients are provided with an ointment, consisting of salicylic acid and menthol, each five grains; lanolin and vaselin each half an ounce, to use liberally in the nose for the next twenty-four hours, and then I have them gently douche the nose twice daily with physiological salt solution. As the normal function of the elevated membrane does not return for several weeks the use of the ointment is continued, which overcomes a tendency of the mucous membrane to become dry and crusted. Some swelling is liable to occur after the removal of the Bernay sponges, which gradually subsides at the end of from ten to fifteen days. The one unpleasant complication that may arise is septic infection, but

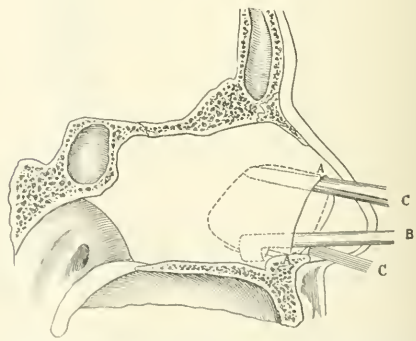

Fig. 10. A-A shows the incision held open by the long blades of the speculum C-C; the dotted enclosure indicates the amount of cartilage removed; B, down-cutting forceps attacking the lower deflected border.

if the patient is properly prepared and the surgeon's hands and instruments are sterile it should not occur; if it does, there is only one thing to do, and that is to open up the wound and drain. Another less serious complication which has happened to me once, is to have a hematoma form between the membranes after the removal of the

sponges. If this occurs and is neglected the clot probably will organize and the nose again become occluded; but it amounts to nothing if recognized and properly treated by compression between Bernay sponges for a day or two.

The after-results and permanency. Killian seems to use the submucous window resection to the exclusion of all other operations for a like condition in the septum. Freer's first cases of nearly three years' standing are in excellent condition, septum being firm and giving him the impression that the cartilage and bone had reformed. In one of the cases, in which a perforation occurred, it was found free from crusts and gave no trouble whatever. I removed a piece of the septal membrane in one of my cases over a year after the initial operation, and subjected the specimen to microscopic examination, but could find no evidence that the cartilage was reforming, yet the septum in some of my other cases seems firm to the touch and leads me to believe that cartilage does form. I have done this operation thirty-one times, the youngest patients were 12 and 14 years of age, the oldest 60 and 63 years. I do not consider the extremes of age a contraindication as some do, except that very old people have tolerated their condition so long that it does not seem necessary to change it for an additional year or two. In very young subjects this condition is rare and sometimes the deflected septum is a part of a more extended deformity of the facial bones. Quimby (*Medical News*, March 12, 1904) reports the case of his own child who developed a deflected septum with a high narrow palatal arch; spreading of the teeth brought down the arch and so relieved the pressure on the septum that it finally became normal.

The possibility of weakening the nose or destroying the nasal profile. No one has, as yet, so far as I am able to find, reported a case in which the nose has been depressed by any injury after the operation. Freer reports four cases, in which severe blows were received upon the nose subsequent to the operation, with no ill effects. As to the sinking in or change of the nasal profile, most operators have not observed the slightest alteration in contour. However, Menzel and Mueller think they have seen some slight depression follow removal of the cartilage from under the lateral cartilages, but as many others have done this without recording any ill effects, and as it is not necessary in the majority of cases to go right up to the attachment of the septum with the lateral cartilages, I think this is no danger as long as primary union is secured. If the whole truth could be known it would probably be found that an infection caused fibrous tissue to form which contracted and pulled down the superior lateral catilages, thereby changing the nasal profile somewhat.

Time consumed in performing the operation. Killian claims the average of twenty minutes; Freer averages forty-five minutes. As long as one is not hurting the patient, a saving of time is not so very essential. The one keynote to success in throat and nose surgery is to have the patient thoroughly cocainized and take the time to see what one is doing. Do not work at the bottom of a dark cavity filled with blood, if you expect to achieve good results. My shortest time was ten minutes and my longest nearly an hour. Sometimes the elevation of the mucous membrane is difficult and tedious, but more often the time is taken up in removing the deep osseous deflections, for this, as a rule, is rather slow work Inasmuch as this operation has come to stay it will in time probably supplant the crushing operations of Asch, Gleason, Roe, and others, entirely. However, it is a much more difficult operation to master thoroughly than the above mentioned, and in consequence of these technical difficulties it may not be as universally employed for some time as its merits justify.

15 East Forty-eighth Street.

## REMARKS ON CONSERVATIVE GYNECOLOGY.

By CHARLES GREENE CUMSTON, M.D.,

BOSTON, MASS.

EX-VICE-PRESIDENT OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS, HONORARY MEMBER OF THE SURGICAL SOCIETY OF BELGIUM, ETC.

The usefulness of the ovaries is no longer a matter of doubt and they are certainly possessed of a regulating and dynamogenic function analogous to other glands of the body, while pathologic disturbances occur in subjects after ablation. In this short paper I intend to discuss those lesions for which these glands have been removed, and endeavor to ascertain if a large number of females who have undergone irreparable mutilation might not have recovered and been mothers if other operations or treatment had been carried out. In going over the literature from 1882 to 1892, one would be led to suppose that there are few cases where a temporizing and conservative treatment is justifiable. During this decade it is to be noted that operation was resorted to, not only in serious cases, but even for very trifling lesions. Not only were quantities of healthy ovaries removed, but mistakes in diagnosis led the most expert surgeons to remove healthy adnexa, and it is unfortunate, but yet true, that even at the present time ovariotomy and hysterectomy are still being done for simple metritis, catarrhal salpingitis, hydro or hematosalpinx, bilateral or unilateral cystic transformation of the gland, ovarian neuralgia, so called, generalized pains of nervous origin, hysteria, insanity and even nymphomania and masturbation. Then, again, all types of prolapsus and displacements have been subjected to hysterectomy, which can hardly be called a rational procedure in these cases. In every other branch of surgery, modern technique has resulted in conservatism, and it seems most curious that gynecology alone, is the exception to the rule, and has not followed this conservatism since the discovery of the antiseptic and aseptic technique. At the present time, instead of amputating, the surgeon endeavors to preserve the limb intact. Cavities are drained, abscesses and joints are curetted, and it is always the function and importance of the organ which guides the surgeon in his acts. To remove is not to save, and one should endeavor to obtain a satisfactory result by every possible means, before undertaking an operation which, besides its inherent gravity, will place the woman in a condition of marked inferiority from a social point of view. Conservative surgery is, without any doubt, much more difficult and arduous, and far less brilliant than the other, but it appears to me far more scientific and fruitful in its results. The future will without doubt show this, and so great an authority as Emmet hoped that future generations would not have to undergo castration, because he believed that surgeons would become better equipped for treating disease. It has been upheld that it is because the profession in general is not sufficiently well educated, skillful, or patient enough to treat clients by

simple means, and that physicians are in a hurry to have recourse to both violent and dangerous procedures.

On the other hand, although the operating surgeon has many causes to complain against conservative treatment in many acute abdominal cases, and to reproach conservative operators for their lack of power in certain surgical conditions, it may be said in reply that, this is still one more reason for endeavoring to improve a method which, in spite of its imperfection, or rather its nonperfection, has already given such splendid results, and which will enormously diminish the cases justifiable for ovariotomy or hysterectomy. Although it has been upheld that many affections, which are a despair to medicine, are easily recovered from by surgical treatment, in reply to this it may be said that at the present time many diseases which were the triumph of surgery, can be cured by medical treatment, and that not infrequently hot vaginal irrigations, revulsion, rest in bed and simple means are quite sufficient for avoiding an operation which has been advised. For that matter, the greater number of surgeons who currently advise major interference are becoming more and more conservative, having experienced all the inconveniences and delusions, and they now operate only when absolutely necessary, in the first place endeavoring to treat the case by milder means. This tendency towards surgical conservatism is becoming more marked every day, and many prominent operators are endeavoring to preserve the physiological function of the ovaries.

The theory which gave rise to hysterectomy, that is to say, the formation of a large opening, which would give issue to intraabdominal collections of pus, is now giving way to curettage and drainage by incision through the posterior cul-de-sac. The pathogenesis of infection being better known, has revealed the fact that the uterus is invariably the primary starting point, and that inflammation of the ovaries, salpingitis, and generally speaking all the various inflammations of the adnexa are merely the consequence of a metritis or some uterine infection, which has developed from most varied causes. Whether the infection extended by the way of the lymphatics, as it is the present tendency to admit and as seems to be proven by the evolution of the process, or has followed the veins as certain authorities still uphold, it has been demonstrated that, if a curettage is done and a careful antisepsis of the uterine cavity carried out, not only will the lesion of the uterus be cured, but the infectious phenomena by propagation are capable of subsiding little by little, and finally completely disappear. The salutary influence of a well-directed intrauterine treatment, that is to say, conducted with every possible care and persistency from the very minute that the first sign of infection makes its appearance in the genital apparatus, cannot be too greatly insisted upon, and curettage, free dilatation, and drainage of the uterus, represents a very effective treatment. It is not at all doubtful that when they are rightly handled the cases which have been considered as requiring the major interferences may be greatly reduced, and from our knowledge of the pathogenesis of lesions of the female genitals, it has been demonstrated that the therapeutics of affections of the adnexa are intimately united to pathologic processes in the uterus so that, under these circumstances, it is easy to understand how certain types of tuboovarian inflammatory processes, such as catarrhal salpingitis, purulent salpingitis at the beginning, and hydrosalpinx, may be greatly improved or even completely cured by simply treating the concomitant uterine lesions. It is only logical to maintain that in the treatment of periuterine inflammation serious interferences, such as laparotomy or hysterectomy should always be reserved for those cases in which it is manifestly impossible to resort to conservative surgery.

The uterus being the cause of infectious processes arising in the female pelvis, it was naturally logical to look in the first place for means of preventing this infection, or to control it if it had already developed, and all conservative operators have practically returned to the older procedures which had been abandoned. Hot vaginal irrigations, curettement, drainage, the various amputations of the cervix and intrauterine applications were taken up and some method having been applied to these various procedures, it was not long before all these conservative means were again adopted in current gynecological practice. The best conservative treatment is that which does not allow the lesions to develop, and consequently the prophylaxis of the various forms of metritis will certainly diminish the number of cases requiring major interferences; but this teaching, although perfectly true in theory, is in my way of thinking, very difficult to accomplish in practice. This may be accomplished in cases of metritis arising from postpuerperal infection, but one will always meet other cases which arise from causes of a more or less complex nature. For example, the gonococcus has a large share in the pathogenesis of pelvic inflammation and all the various microbic associations are quite capable at a given time of causing various complications to make their appearance, which may be attributed to a kind of latent microbism, a sort of virtual infection waiting for some pathologic change to arise in order to develop. All reflex congestion produced by affections of the ovaries or tubes, excessive coitus, fatigue, and traumatism, are so many more causes quite impossible to prevent. As far as metritis is concerned, the results obtained by curettement are excellent, and it is well known that even when other infections do not exist it is nearly always a cause of sterility. Owing to the acid secretions given off by the inflamed uterus, the obliteration of its glands, the excessive proliferation of its epithelium, and by the mucous plugs obliterating the cervix, the organ becomes incapable of receiving the spermatozoid, and even if it should allow its entrance, cannot preserve it alive in its cavity. And still more, when there is a metritis, it is almost always accompanied by a certain degree of salpingitis on account of the continuity and contiguity of the tissues. The question consequently comes up as to whether or not the lesion can be cured by the various means that I have mentioned, and if, for example, by destroying the uterine mucosa, the seat of the lesion, one might not permanently remove the power of gestation from the uterus. In reply to this it may be said that beside the numerous instances of pregnancy arising after this treatment, and which have settled the question, many authorities have experimented on animals, and have found the uterine mucosa endowed with a surprising vitality, and that it is not long in becoming completely regenerated after having been removed by the curette. In dissecting metritis, which is a very rare lesion in which part of the muscular layer of the uterus is also eliminated with the mucosa, regeneration becomes an impossibility, but in all the other types of metritis, even when large strips of mucosa have been expelled, *restitutio ad integrum* occurs.

From the purely physiological and functional standpoint the numerous writings of Schroeder, Martin, Durclius, Benicke, Henricius and others have demonstrated that after curettement, conception can perfectly well take place, while gestation

will undergo its regular evolution. Out of a total of 56 patients treated by curettement, Henricius found that 16 became pregnant, in other words 32 per cent.; while de la Torre was able to obtain 11 pregnancies out of 48 interventions of this kind, which practically represents the same percentage. Among the patients treated by Henricius, pregnancy took place in two, five weeks and in one eight weeks after curettement, which would seem to show that very little time is required for complete regeneration of the uterine mucosa. In 13 cases of metritis complicated with catarrhal salpingitis, in which the patients had been advised radical operation, I was able to obtain a cure by thorough curettement and antiseptic treatment, and three of these patients ultimately became pregnant and went to term. In several other cases of unilateral or bilateral purulent salpingitis, when I deemed removal of the tubes necessary, and where the operation was refused by the patients, I did a thorough dilatation and curettement, and found that the tubes discharged by way of the uterus, and ultimately recovered perfect health, although I am unaware that any of these ever became pregnant.

The therapeutic results of curettage are too numerous and well known to require further discussion as to the value of this operation, but I would point out that when contrasting it with hysterectomy, it is far superior if the desired result is obtained by it, because it in no way disturbs the physiological functions of the organ, and in certain cases even, it appears to awaken them. Many cases of sterility might be quoted which have been overcome by this operation, and in my own notes I have two cases of women who had been married respectively three years and five years, who had remained sterile, and who conceived within four months after they were curetted. For example, in glandular cervical endometritis, which gives rise to hardly any painful phenomena, having no influence on the general health and simply giving evidence of its presence by a slight discharge, or by a little mucous plug obstructing the cervix, finally leading to stenosis, pregnancy will frequently take place after curettage, dilatation, and removal of a portion of the cervical mucosa.

Personally, I believe that in cases which have reached the stage where they are giving rise to symptoms, there are several lesions in the genital apparatus, and that the success obtained by operation depends entirely on the rational treatment of all the lesions met with. To this complex condition a complex treatment is required and each element should be carefully treated and, if all the indications are not taken into consideration, an unsuccessful outcome will be the result. For example, the uterine mucosa and parenchyma must be attended to, the position of the uterus corrected, if displacement exists, and intraabdominal adhesions broken down, if they are present. It was these very indications that caused Schroeder to invent his operation, Emmet to practise his well-known operation of trachelorraphy, and Bouilly to remove a portion of the cervical mucosa in order to open the deep-seated culs-de-sac and attend to the stenosis of the cervix or amputation of the cervix performed at different parts of the organ, by all the well-known procedures. If, for example, we take a complete metritis with laceration of the cervix and perineum, prolapsus of the vaginal walls, and backward displacement of the uterus, a cure can be obtained only by curettage followed by Schroeder's operation with a plastic operation on the vaginal walls, and some method of shortening the round ligaments. If one of these procedures is forgotten, the result will be that the patient will continue to suffer as she did before the operation, and I have come to the conclusion that a large number of cases considered as incurable and in which every conservative treatment had been tried without effect, have been submitted to a major operation only because the operator had omitted a certain point in the treatment which he considered perhaps as of too little consequence.

I have already pointed out that metritis rarely exists without some salpingitis, and, although the uterus is the starting point of the infection, the process does not always remain localized to the mucosa of this organ, because it invades the tubes, and from the periuterine parenchyma extends to the ovaries and peritoneum, so that when this has taken place one will be dealing with a salpingitis combined or not with inflammation of the ovaries and pelvic peritonitis, forming those cases presenting serious symptoms; in other words, a pelvic peritonitis. Now, it is just in these cases that I am of the opinion that a radical operation is far from being always indicated, and that more conservative measures may result in cures which can hardly be expected. I am firmly convinced that in the treatment of inflammation of the adnexa, whether this has or has not extended to the pelvic peritoneum, a certain proportion of patients may be cured by medical treatment, particularly so in infection from the gonococcus, even when very severe peritoneal symptoms are present, which might lead the inexperienced surgeon to believe that the ultimate consequences would be serious. In point of fact, evidences of a former pelvic peritonitis will be met with in a very large proportion of autopsies, although the subjects have entirely recovered from the process which apparently has given rise to little disturbance during life. Experience demonstrates that a large percentage of patients presenting these conditions recover, and some even to such an extent that they not only have no discomforts from their affection, but they have even conceived at a later date, and have been delivered at term. It would, however, be most illogical to suppose that each and every case will recover simply by *vis medicatrix naturæ* aided by conservative treatment.

Drainage in cases of metritis with inflammatory lesions of the adnexa, has been a most effective treatment, and numerous recoveries without further operation have been recorded, and I have no doubt whatsoever but that drainage of the uterine cavity with gauze may result in a cure of pyosalpinx in not a few cases, and that not infrequently the patients may ultimately conceive and go through a normal labor. Whatever material is used for drainage, be it silkworm gut, iodoform gauze, or rubber drains, it certainly favors the discharge of the mucopurulent secretions, and by acting favorably on the circulation of the uterus, the muscular tonicity of the organ is awakened and the menstrual functions finally return and are carried on normally.

In a certain number of cases of encysted collections, surrounded by masses of dense false membrane, which might seem at first to require laparotomy or hysterectomy, recovery may in some few instances be secured by drainage of the uterus, and on several occasions I obtained excellent results in cases of suppurating salpingitis by dilatation, curettage, and drainage of the uterus, the purulent collections in the tubes being emptied out through the uterine cavity, although this process has been denied by a number of eminent authorities. It was formerly thought that curettage should never be undertaken when lesions of the adnexa were present under the pretext that these lesions might be aggravated by the operation, but on this

point I cannot agree, as I have seen great improvement or even recovery follow this operative interference under these circumstances.

It may be questioned why one should be desirous of preserving the organs, which, when patients are relieved of their pathological process, will be of little or no use, because they are forever afterwards incapable of accomplishing their functions. Now, it is quite certain that after a salpingitis the tubes do not always return to their normal state, and that by a fibrous or sclerous process their lumen becomes closed, so that a functional impotency results, producing sterility. Although this may be a general rule, I would point out that sterility does not appear to be an absolute consequence of salpingitis, and the tube may remain perfectly patent and never become obstructed. Even admitting that following some suppurative process, the lumen of the tube becomes occluded, it may nevertheless be hoped that this mechanical or pathological obstruction will in time disappear, as the lesion regresses. If the lesion is unilateral, as is often the case, it is evident that the healthy tube will continue its normal function, and no surgeon ever dreamed of removing both testicles when only one was the seat of an orchitis or an epididymitis under the pretext that the healthy organ would no longer be useful, and it is of every-day observation to find that after an inflammatory process the genital power has been preserved.

The pavilion of the tube may be compared to the epididymis, and in point of fact an analogy exists between tuboovaritis and epididymitis, and there is no doubt in my mind but that certain lesions, such as catarrhal salpingitis, perisalpingitis, and periophoritis may be recovered from, the patient retaining her reproductive functions. I have notes of two cases seen in consultation of pregnancy following salpingitis, in which conservative treatment was used, so that it seems possible that, under the influence of some conservative treatment, such for example as curettage and drainage, the uterine ostia of the tubes may become free of their obstruction, and by the action of the drainage the lesions regress sufficiently for permeability of the lumen of the tube to result. Assuredly, when in presence of serious suppurative processes in the uterus and adnexa, one should not be prevented from acting by a mere philosophical consideration, but such consideration, although no longer philosophical and in reality practical, is to be seriously considered when the suppurative process does not place the life of the patient in danger.

In this short paper it is not my intention to consider all the various conservative treatments, because given the great variety of pelvic suppurative processes, it at once becomes evident that one must make a choice of technique. I would, however, refer to posterior colpotomy in suppurative lesions, a subject to which I have given much thought, and with which I have had no little experience. The various changes this technique has undergone and the brilliant results it has given at the hands of many operators, make it at the present time a most valuable procedure. In the very acute cases, when it would be hazardous to open the abdomen with the purpose of performing any radical interference, drainage through the posterior cul-de-sac will relieve the patient of her septic symptoms, and place her in a condition such that later on she will be able to undergo a radical operation with all possible chance for a successful outcome.

Upon several occasions when I have done an exploratory laparotomy, the result has been fortunate, and, although nothing radical could be attempted, abdominal incision, followed by drainage, has worked marvels. Many similar examples have been published by other operators who, after having attempted removal of the diseased organ, were obliged to give up on account of the difficulties presented, and still, much to their surprise, within a short time, the process disappeared and the patients completely recovered. Whether or not the fact of opening the peritoneum has a revulsive effect on the lesions, producing a kind of irritation, greatly changing them, and even causing them to disappear, is an hypothesis which has been admitted, but not generally accepted.

As has been said, metritis is usually the direct cause of sterility, but it occasionally happens that this process gives rise to a retroversion of the uterus, and it is this displacement that is the hindrance to fecundation. Consequently, if the uterus is replaced surgically, there may be some prospect of conception taking place.

871 Beacon Street.

## TRYON, N. C., AS A CLIMATIC RESORT

By HENRY J. GARRIGUES, M.D.,

NEW YORK.

CONSULTING GYNECOLOGIST TO ST. MARK'S HOSPITAL, CONSULTING OBSTETRIC SURGEON TO THE MATERNITY HOSPITAL.

Tryon is situated in the western part of North Carolina, at the foot of the steep slope forming the connection between the mountainous region and the lowland, slightly above the 35th degree of north latitude, at an altitude varying from 1,000 to 1,200 feet above sea level, and about 250 miles from the Atlantic.

Its scenery is beautiful—not one of those amazing natural phenomena like Niagara Falls, Yellowstone Park, Yosemite Valley, or the Grand Cañon in Arizona, that almost overwhelm one, and are too grand for daily use. Tryon's landscapes are of a decidedly feminine character. Everything is near and cosey. From all the hills, upon and among which it is built, the eye glides quietly over wooded or cultivated valleys, and is soon arrested by mountains not passing the modest height of 2,500 feet. The longer one looks at it the more it gains on one. One absorbs it; it becomes part of oneself.

From all I have been able to gather by studious inquiry of persons from different parts of the country, of people who have traveled all over the states, and from my own personal experience, I conclude that Tryon has the best all-year-round climate in the United States. It is mild and dry. Half a dozen chains constituting the southwestern Appalachian Mountains give the little village shelter from the cold northwest winds blowing over the plains from North Dakota, and from the wet northeast winds laden with the fogs of the Newfoundland banks, and it lies thus in a haven open only toward the southwest. The prevailing wind is a soft breeze moving from the southwest fast enough to keep the air fresh, and slow enough not to make one feel chilly. It rains little, and mostly at night, or as part of an afternoon thunderstorm. The number of totally or partially sunny days is very great; in the year from September, 1904, to and including August, 1905, there were 296 such days. Even in summer the air is light, sunstroke and overheating, which may kill several hundred persons in New York in twenty-four hours, are unknown; and the nights are always cool, affording restful sleep.

Northerners are inclined to expect too much, and they are sorely deceived when they think that here is no winter. Sometimes it freezes, very rarely it snows, and most people enjoy a fire in the stove during seven months of the year; but the real winter

is short, lasting little more than two months, and, compared with that in the more northerly states, is exceedingly mild. Cold snaps that extend their devastating influence down into Texas and Florida reach Tryon so mitigated that they are hardly perceived. On the other hand, summer heat is never oppressive. Even in July and August, the inhabitants of the states lying south of North Carolina, find Tryon a pleasant, invigorating summer resort, free from any kind of fever. Spring and autumn are indescribably beautiful. In April the trees begin to bud, and soon leaves of rare beauty and enchanting flowers afford never-ceasing, daily-renewed joy. In October the leaves turn, but cling long to the trees, some even all winter. During the autumn one can follow the transition from green to red and yellow in endless variety.

The temperature avoids extremes. The lowest degree I have seen was 14° F. above zero, the highest 98°, but the change occurs quite gradually. Drops of 40° within a day, which are not rare in New York, are unknown here. Last winter, which was an exceptionally severe one, the thermometer went below 32° F. in the daytime on only eighteen days, and the preceding winter on only fourteen.

Drainage is perfect. The surface being hilly and the soil sandy, all water runs off to the numerous creeks and branches, or sinks into the ground. Hardly has the last drop of rain fallen, before one can walk about dryshod. Nowhere is there any stagnant water, therefore mosquitos and clothes moths are rare.

The woods offer a happy combination of hardwood trees and pines, so that the scenery remains green all through winter.

A point of great importance is the moderate distance from the large cities of both North and South. A person can come from New York in 25 hours, with only one change of car for the last 26 miles, and with all conveniences as to meals and other comforts.

My personal experience in Tryon has been most satisfactory. I left New York two years ago so sick a man from rheumatism and goutiness that I could be transported only in an invalid's chair to the stations and in a so-called drawing-room, with bed and lounge, in the train; and now I can work for hours with spade and mattock.

The dry, mild climate allows even delicate persons to spend a large portion of the day in the open air. Some even make up their beds on the piazzas or sleep in hammocks in the open. The place is, therefore, particularly recommendable to rheumatic and gouty people, to convalescents after serious diseases or operations, to anemic persons, to those who suffer from a broken-down nervous system, to those affected with tuberculosis, heart disease, or any ailment of the respiratory tract.

Tryon is a place that is being sought both from the North and the South, and would be much more so if the great advantages it offers as a health resort were more generally known.

---

**Report of a Case of Traumatic Asphyxia.**—R. H. Birge describes this interesting case. The patient, a large, muscular man, was caught and pinned down against the sharp edge of a platform by an overturned car loaded with steel rods. The writer reached him just as he was being extricated from his perilous position. The patient's face was rapidly becoming a bluish black. The eyes protruded, there was a slight flow of blood from the nose and mouth, and he was unconscious for a few minutes after being released. From the level of the nipples upward over the neck and face and into the scalp the skin had a dusky, bluish, mottled appearance. When pressed by the finger the color became only slightly paler, and when pressure was removed the original tint slowly returned. On the supposition that the patient was cyanotic, artificial respiration was administered, but with this treatment the appearance of the skin became even worse. It was evident that cyanosis was not the cause. Uniformly distributed all over the skin were tiny areas of natural skin tint surrounded by an indefinite bluish border, these borders uniting in a meshwork. After about three days this peculiar appearance of the skin began to disappear, although it was four weeks before its normal appearance was resumed. The color did not go through the usual stages of extravasated blood, but gradually the normal areas of skin became larger until the blue points had disappeared. Recovery was uninterrupted, and eight months later the patient was back at work. The writer says that the gross cause of this curious clinical picture is forcible compression of the chest, extending over some minutes, accompanied by entire cessation of respiration. Microscopic study of skin taken from such cases has shown no signs of blood in the tissues outside the blood vessels. As to the cause of the sharp limitation of the color to the head and neck, the writer is inclined to ascribe it to the lack of valves in the jugular and facial veins. It seems rational to suppose that the immediate use of artificial respiration and oxygen, and possibly adrenalin, might resuscitate certain of such cases, could it be applied at once. The secondary treatment, aside from combating shock, must be symptomatic.—*The Cleveland Medical Journal.*

**Acute Anasarca in Recent Malaria.**—A. Masucci describes anasarca as one of the rare manifestations of malaria, which develops independently of any renal alteration. It has been little studied and its pathology is obscure. The author reports the case of a patient who had had mild malarial attacks for a month, and who, after exposure to cold, was the subject of a general anasarca, beginning at the feet and ascending to the other parts of the body. It was noticeable that the edema increased with an attack of fever, and lessened after it was past. There are several there may be edema, not due to renal, lesions, in malarial These are the renal, that there has been a latent kidney trouble; the hydremic, that it is the result of the poverty of blood due to the fever; the cardiac, that it is due to transitory heart weakness; the arterial, that it is due to changes in the vessel walls. The author concludes that there may be edema, not due to renal lesions in malarial cases; it may occur, after exposure to cold, in persons weakened by poor food and bad hygiene living in malarial localities who have not been treated for the disease. It is a complication of malignant tertian fever. There is a hydremic condition of the blood, due to the parasite, combined with severe gastrointestinal disturbances. It may also be produced by a direct action of the parasite on the endothelium of the vessels. There may be trophic and vasomotor disturbances of the parts of the body affected by the edema.—*Annali di Medicina Navale.*

**Eclamptic Convulsion Occurring Fourteen Days After Confinement.**—George Cuscaden reports this case. Fourteen days after the patient's confinement, on her return from a call across the street, she was seized by an epileptic form of convulsion lasting thirty minutes. Six hours later another fit, lasting twenty minutes, occurred. The muscles of the nostrils and the face moved spasmodically, and the mouth was drawn to one side. The tongue was bitten, the thumbs were applied to the palms with the fingers over them, and the forearms were flexed. A condition of slight coma followed. The patient became half conscious and answered when spoken to. The urine contained albumin. The temperature after the fit was 102°, and the pulse was 120. Several fits occurred later, but were not so severe as the first one. The patient is now in good health and eats and sleeps well. There is no albumin in the urine. This patient was thirty-three years old and a primipara. The important factors in the causation of eclampsia are faulty metabolism and impaired secretion. The writer states that he has had good results with thyroid extract treatment. In the present case he advised rest in bed with milk diet.—*The Australasian Medical Gazette.*

# MEDICAL RECORD.

New York, November 25, 1905.

## THE MEDICAL DISCOVERY OF OLIVER WENDELL HOLMES.

THE name of Oliver Wendell Holmes is held in high honor by the medical profession in America, and we are proud to remember that this most genial of poets was one of us by title. We are wont to think of him, however, as a literary worker simply, and most of us have forgotten, if we ever knew, that he had claims to the gratitude of the world as a life-saver and a medical discoverer. In an address recently delivered before the Trowbridge Division of the Bath and Bristol Branch of the British Medical Association (*British Medical Journal*, November 4, 1905) Dr. Charles J. Cullingworth reviewed the almost forgotten essay of Holmes on the contagiousness of puerperal fever, in which he revealed, with the clairvoyance of the poet, the true nature of this murderous disease. The paper was read before the Boston Society for Medical Improvement and was published in the *New England Quarterly Journal of Medicine and Surgery* for April, 1843, some years before Semmelweiss, to whom the credit for the discovery is usually given, proclaimed his theory. The journal in which this essay was published unfortunately died at the age of one year, and Holmes' discovery was buried with it. So completely has it been forgotten, indeed, that some of the latest American textbooks on obstetrics do not even mention it.

Holmes' attention was first directed to the subject by an incident informally related by a member at one of the meetings of the Boston Society for Medical Improvement. The narrator told of a physician who had made a post-mortem examination of the body of a puerperal fever patient, and had himself died in less than a week, apparently in consequence of a wound received at the examination. In the meantime, he had attended several women in confinement, all of whom were said to have been attacked with puerperal fever. The one who related the incident failed to see its significance, but the quick perception of Holmes grasped it, and he set about to collect the evidence upon which to base his theory of puerperal infection. There was an abundance of material, and in the essay which followed there was an array of facts that should have left no doubt in the mind of the reader that the disease was communicable. But, like all revolutionary discoveries, it was received with incredulity, and the theory was actively opposed by the leading obstetricians of the day, the bitterest among them being the celebrated Hodge of the University of Pennsylvania and Meigs of the Jefferson Medical College. Holmes was no fighter, and though he continued to teach medicine for many years, his heart was more inclined to the gentler art of poesy, and he made no strenuous effort to uphold his views, contenting himself with a general review of the objections raised by Meigs and a few quiet remarks on the worthlessness of the negative testimony upon which the opposition was chiefly based. "No man," he said, "makes a quarrel with me over the counterpane that covers a mother with her newborn infant at her breast."

We cannot quote more extensively from Dr. Cullingworth's interesting review of this epoch-making essay, which we hope will be republished in a form more accessible to American readers, but we cannot forbear reproducing the conclusion of Holmes' paper. These conclusions and rules for preventing the spread of puerperal fever were: " (1) A physician holding himself in readiness to attend cases of midwifery should never take any active part in the post-mortem examination of cases of puerperal fever. (2) If a physician is present at such autopsies, he should use thorough ablution, change every article of dress, and allow twenty-four hours or more to elapse before attending to any case of midwifery. It may be well to extend the same caution to cases of simple peritonitis. (3) Similar precautions should be taken after the autopsy or surgical treatment of cases of erysipelas, if the physician is obliged to unite such offices with his obstetrical duties, which is in the highest degree inexpedient. (4) On the occurrence of a single case of puerperal fever in his practice, the physician is bound to consider the next female he attends in labor, unless some weeks at least have elapsed, as in danger of being infected by him, and it is his duty to take every precaution to diminish her risk of disease and death. (5) If within a short period two cases of puerperal fever happen close to each other, in the practice of the same physician, the disease not existing or prevailing in the neighborhood, he would do wisely to relinquish his obstetrical practice for at least one month, and endeavor to free himself by every available means from any noxious influence he may carry about with him. (6) The occurrence of three or more closely connected cases, in the practice of one individual, no others existing in the neighborhood, and no other sufficient cause being alleged for the coincidence, is prima facie evidence that he is the vehicle of contagion. (7) It is the duty of the physician to take every precaution that the disease shall not be introduced by nurses or other assistants, by making proper inquiries concerning them and giving timely warning of every suspected source of danger. (8) Whatever indulgence may have been granted to those who have heretofore been the ignorant cause of so much misery, the time has come when the existence of a *private pestilence* in the sphere of a single physician should be looked upon not as a misfortune but as a crime, and in the knowledge of such occurrences the duties of the practitioner to his profession should give way to his paramount duties to society."

With the addition of a few remarks on the bacteriology of puerperal sepsis and the insistence on antiseptic precautions, these rules might have been

written three score years later, and would be accepted as truisms. In the words of an English correspondent: "It seems to be a reproach to us English-speaking doctors that we have forgotten the illustrious autcrat's original medical work as we have basked in the sunshine of his literary presence. It is true that his medical discovery dates a long way back and a new generation of doctors has arisen, fed on text-books only, but there are still many who care for medical history and who should delight to remember the poet's early medical work."

## STAINS FOR SPIROCHÆTÆ.

During the past few months the various staining methods that different observers have advocated for demonstrating the *Spirochæta pallida* have been abstracted in the Medical Record, but for the convenience of our readers we reprint several of the more important. The stain recommended by Schaudinn and Hoffmann in their original publication, and which most other observers have been using, is a modification of the Romanowski method devised by Giemsa for blood films and described by him in the *Centralblatt fur Bakteriologie*, Vol. XXXII, No. 4, 1902. The improved form which the inventor gave to this two years later is the one now commonly used, and the formula for this, which was reproduced in the Medical Record Vol. LXVII, p. 280, is as follows: Three grams of azur ii-eosin and eight-tenths of a gram of azur ii are exsiccated, finely pulverized and sifted, and then dissolved in 250 grams of chemically pure glycerin at 60° C. When solution is complete, 250 grams of methyl alcohol at a temperature of 60° C. are added; the whole is well shaken, allowed to stand for twenty-four hours, and filtered. The films are first fixed in methyl or ethyl alcohol and dried with blotting paper. The stain is diluted with distilled water in the proportion of one drop to one cubic centimeter of water, and is poured over the preparation. For blood films staining requires from five to fifteen minutes, at the end of which time the preparation is washed thoroughly under a jet of water and is dried. In applying the stain to the search for the spirochætæ the time of contact with the dye must be very greatly prolonged, however, and different observers recommend leaving the preparations in the mixture from one to twenty-four hours. Giemsa in a later publication (*Deutsche medizinische Wochenschrift*, No. 26, 1905) advises the addition of one to ten drops of a 1-1000 solution of potassium carbonate to the water with which the stain is diluted in order to obtain more rapid action, and he states that by this means the spirochætæ may be demonstrated after fifteen minutes of staining, though to secure the best results an hour's contact with the dye is preferable.

Other procedures have also been suggested in the effort to save time. Oppenheim and Sachs (*vide* Medical Record, Vol. LXVIII, p. 272) describe their technique as follows: The smears are dried in the air and then without previous fixation are flooded with an alcoholic solution of carbol-gentian violet. This is made by adding ten cubic centimeters of concentrated alcoholic gentian violet solution to one hundred cubic centimeters of five per cent. watery carbolic acid solution. The preparation is warmed until it steams, is washed gently with water, and dried. The spirochetes are stained blue, and the authors claim for the method the advantages of simplicity and rapidity. Reitmann (*vide* Medical Record, Vol. LXVIII, p. 110) advocates another plan. The smears are fixed for ten minutes in absolute alcohol, are washed with distilled water, and placed for five minutes in a two per cent. solution of phosphotungstic acid. This mordant is washed out with water and seventy per cent. alcohol, and the preparation, after rinsing with water, is stained with the ordinary carbolfuchsin solution, heated till it steams. The excess of dye is removed with seventy per cent. alcohol, the preparation is washed with water, and dried. The spirochetes are stained red. Dudgeon (*vide* Medical Record, Vol. LXVIII p. 390) recommends a modification of the Leishman stain, and various other combinations have been suggested. It is not yet certain, however, that these several procedures are as reliable as the Giemsa method, although this is open to objections on the score of the length of time required to effect staining, and because its constituents are difficult to prepare, so that it is advisable to purchase it ready made.

A method which is said to give ample staining in fifteen minutes is one described for blood films by F. C. Wood in the *Medical News* Vol. LXXXIII, p. 248. Dr. Wood has furnished the following details regarding the application of his technique to the demonstration of *Spirochæta pallida*: The smears are fixed in strong methyl alcohol for five minutes and dried with blotting paper. The stains are then applied in succession: First, a few drops of a 1-1000 aqueous solution of yellow, water-soluble eosin are spread over the smeared surface with the tip of a pipette; then, four or five drops of a 3-1000 aqueous solution of methylene azur ii are added. The two dyes are thoroughly mixed by spreading over the slide or cover and tipping it backward and forward. The mixture is then allowed to stand for ten minutes. At the end of this time the stain is washed off with a strong stream of tap or distilled water and the smeared surface dried with blotting paper and examined with an oil immersion lens directly without mounting, or mounted with xylol dammar. The ordinary Canada balsam bleaches these preparations very rapidly, as does also oil of cedar. Usually any precipitate which forms can be removed from the slide by a strong stream of water, but if there is a considerable amount, or if specially clean preparations are desired, the precipitate may be removed by dipping the specimen for one second into ninety-five per cent. alcohol and immediately washing off with water. The examination of such smears is exceedingly tedious and a severe strain on the eyes. A mechanical stage should always be used, and artificial light is much more satisfactory than daylight. The best form of artificial light is a Welsbach mantle burner placed quite close to the microscope. The diaphragm of the Abbe condenser should be fully open, and a greenish yellow screen interposed between the light and the microscope. Such screens not only reduce the brilliant white of the Welshbach to a green tone, which is much less trying to the eyes, but in-

crease the contrast between the background and the stained spirochetes. The organisms usually take a carmine red color, which appears almost black when a suitable greenish screen is used. The screens made for photomicrography or for three-color photography are quite satisfactory. Screens are easily made by mixing a one per cent. solution of tartrazin and a two per cent. solution of patent blue (Hoechst). The mixture can be placed in a small bottle with plane sides and suitably diluted to reduce the depth of the color. If preferred one cubic centimeter of each of these solutions may be mixed with twenty cubic centimeters of eight per cent. gelatin. This is sufficient to coat two ordinary 5 by 7 photographic plates. The hot gelatin is poured on the plates and allowed to dry. Two of these plates are cemented together and the edges bound with paper. This forms a permanent screen, which does not lose its color.

### A Suit Against the Health Department.

A case, the outcome of which will be of much importance to the Department of Health and its physicians, has been moved for early trial before the Supreme Court. On July 19, 1905, a little girl who was suffering from diphtheria received an injection of diphtheria antitoxin given by a physician of the Health Department. He also administered to a sister of the patient, who had been exposed to the contagion, a prophylactic dose of antitoxin. According to the complaint, immediately after the injection of antitoxin the child became ill and complained of terrible pains and of burning sensations, and immediately thereafter passed into convulsions, and died within fifteen minutes. The father is suing the Health Department and the physician to recover $50,000 damages for the death of his daughter, which he alleges was caused by the improper injection of antitoxin. The case is said to be the first of its kind ever brought in the courts of this State. From the published accounts of the fatality it would appear that the little girl was one of those unfortunate subjects affected with the status lymphaticus who are likely to die suddenly on being subjected to any physical or emotional shock, and who furnish so many of the cases of death in the early stages of chloroform anesthesia. If the autopsy findings have revealed such a condition it is hard to see how any blame can be imputed to the physician, and while such terrible accidents are always deplorable in the extreme, they are fortunately so very rare that they cannot be brought forward in opposition to a practice that is admittedly so valuable as the protection by antitoxin injection of those exposed to diphtherial contagion.

### An American Invasion Turned Back.

What with the tuppenny tube, the big hotels, sewing machines, typewriters, poker, quacks, and peeresses, the American conquest of England is almost complete, but in one skirmish we have to record a signal defeat for the Yankee forces. The Britons have swallowed a good many things made in America, but they have revolted at the quick lunch counter. Two attempts have recently been made to feed Londoners on surpassing coffee and sinkers, but they have come to grief. One such place was opened, against the protest of *The Lancet*, on the Strand two years ago. It struggled manfully against the competition of the A. B. C. establishments, went through two bankruptcies, and has finally succumbed. Despite this warning another was started a few months ago, and this has now gone under, with a load of debts and no assets beyond a few pots of Boston baked beans. Whether the British mind revolted at the idea of a "quick lunch" or the British stomach could not digest pumpkin pie, waffles, baked beans, and butter cakes, emphemiously styled "sinkers"—we do not know—but the venture has failed. The beef of old England is American, as is the wheat that makes what is called bread in that benighted country, and perhaps if the "sinkers" had been called Yorkshire pudding, and cranberry pie tarts, they too would have gone down with the other Yankee products. The promoters of the scheme were, however, too aggressively American; they called their establishments quick lunch restaurants, they gave Yankee names to their dishes, and they went bravely down to defeat. The moral is evident and should be taken to heart by future purveyors to British appetites.

## News of the Week.

**The Tuberculosis Exhibition** under the auspices of the National Association for the Study and Prevention of Tuberculosis and the Committee on the Prevention of Tuberculosis of the Charity Organization Society will be opened at the Museum of Natural History on Monday, November 27, and will continue until Saturday, December 9. Among the exhibits will be models of tents, balconies, shacks, and other outdoor living places. The New York Health Department will show various phases of its work, and the Tenement House Department and the tenement house committee of the Charity Organization Society will exhibit models of old and new tenement houses. This exhibit will show a typical dark bed-room alongside of a lighted room of the same character, after a window has been put in by order of the Tenement House Department. Models of cells in Clinton State Prison where most of the consumptive convicts are kept, will be shown in comparison with the ordinary cells, which are held responsible for the large death rate from consumption among prisoners. There will also be pathological exhibits from various cities of the country. Public addresses will be given on four evenings. On November 27 Talcott Williams of Philadelphia will make the opening address. On November 29 Samuel Gompers, Prof. Graham Taylor, J. W. Sullivan, and Prof. E. T. Devine will speak on the labor aspect of tuberculosis. On December 1 Drs. Lawrence F. Flick of Philadelphia, William A. Evans of Chicago, A. Jacobi of New York, Vincent Y. Bowditch of Boston, and others will speak on the medical side of the subject. On December 8, Dr. S. A. Knopf will talk on the teachers' part of the campaign against tuberculosis. The exhibition and lectures will be free, the object being educational, and every effort will be made to attract the public.

**New York Red Cross Society.**—The first annual meeting of the New York State Branch of the American National Red Cross was held on November 14 at the residence of Mr. and Mrs. Douglas Robinson. Col. William Cary Sanger of Dangerfield, N. Y., president of the State branch, was present and delivered the opening address. It is the intention of the State branch to organize subdivisions throughout the State. There are already subdivisions in Buffalo, Islip, L. I., and Westchester county. A Brooklyn subdivision will be organized soon and others are under way in Syracuse, Rochester, and Rome. A feature of the work is the enrollment of nurses and doctors for emergency service. Dr. Samuel N. Lambert, Dr. George E. Brewer, and Dr. John W. Brannan have consented to act on the advisory committee. Miss

Laura D. Gill is the chairman of the committee for the enrollment of nurses.

**New York Foundling Hospital Praised.**—The New York State Board of Charities has investigated the criticisms directed against the New York Foundling Hospital for its manner of placing the children under its care in families in the western States. Secretary Robert W. Hebberd of the State Board of Charities and Commissioner Michael J. Scanlan of New York city recently made a ten days' inspection trip, going as far west as North Dakota, where the homes of families in which these children are placed were visited in order to investigate the truth of the assertions that children were being placed in the care of those unlikely to give them proper treatment. In a report on this subject, which has been approved by the State Board of Charities, they say that from personal observation and reliable information they have been convinced that the homes had all been carefully selected and were of satisfactory character, and that they could discover nothing to indicate that the children had been taken with any unworthy object in view.

**A New Wound Dressing.**—Dr. Aymerd, in an article in *The Lancet*, advocates the substitution of plain glass for gauze in dressing wounds. He describes an experiment with a piece of thick window glass, the edges of which were ground smooth. He smeared the glass with an antiseptic preparation and applied it to the wound, which healed quickly, without leavinga scar. The author claims for his method that it enables the wound to be examined without the removal of the dressing, that it relieves pain, promotes healing, and is economical.

**Radium in California.**—It is reported that a prospector has discovered in Kern County, California, a deposit of ore, apparently of volcanic origin, which contains uranium. Among the constituents of the material are said to be uranite, carnotite, and pitchblende, all of which contain salts of uranium rich in radium. This is the first deposit of this ore found in California and the second in the United States, others being in Gilpin county, Colorado.

**Dr. Hemmeter Honored.**—On November 15 Dr. John C. Hemmeter of Baltimore was presented with a portrait of himself which was the gift of ninety-five of his professional friends in this country and Europe, in commemoration of the twentieth anniversary of his doctorate. The presentation was made by Surgeon-General Walter Wyman of the United States Marine Hospital Corps.

**Dr. Joseph Price.**—On October 30 and 31 last, at Dallas, Dr. Joseph Price of Philadelphia was a guest of the medical profession of Texas, and numerous courtesies were extended to him by the Dallas County Medical Society, of which Dr. A. M. Elmore is president. Dr. Henry K. Leake was chairman of the Committee of Arrangements.

**Dr. A. H. Andrews** was elected to a professorship of Otology and Rhinolarynology at the regular meeting of the Board of Directors of the Chicago Eye, Ear, Nose, and Throat College.

**Yellow Fever in Cuba.**—So far appearances seem to show that the health officials of Havana are acting with commendable zeal and judgment in their efforts to avert the threatened yellow fever epidemic. Although a number of new cases of the disease have been reported during the past week, the morbidity is no greater than natural under the circumstances, and the risk of a serious outbreak still seems remote. A quarantine has been declared against Havana, applying to all Gulf ports and to all Atlantic ports south of the southern boundary of Maryland.

**No Yellow Fever in Mexico.**—The officials of the Mexican Health Department have announced that not a single case of yellow fever exists in the Republic. Statistics show that while there were 635 cases of yellow fever last year, for nine months of the present year there were only 70 cases, of which 33 were fatal.

**State Charities Conference.**—The sixth New York State Conference of Charities and Corrections was opened on November 14 at the Carnegie Lyceum. Health Commissioner Darlington and Mr. Joseph H. Choate delivered the opening addresses.

**Tuberculosis Notification in New Bedford, Mass.**—By a recent action of the board of health of New Bedford, this city takes rank among the few communities in Massachusetts which require physicians to report cases of pulmonary tuberculosis.

**Tri-State Medical Association.**—At the session of the Tri-State Medical Association of Oklahoma, Indian Territory, and Texas, held at Oklahoma City, November 8 and 9, it was decided to hold the next meeting in South McAlester on October 16 and 17 of next year. The election of officers resulted as follows: *President*, Dr. George W. West of Eufaula, I. T.; *Vice-Presidents*, Dr. G. H. Moody of San Antonio, Tex., Dr. E. H. Troy of South McAlester, I. T., and Dr. R. T. Edwards of Oklahoma City, O. T.; *Secretary and Treasurer*, Dr. R. J. Craybill of Allen, I. T.

**Ambulance Accident.**—Owing to the lack of experience of a substitute driver an ambulance of the Lebanon Hospital was run into an elevated pillar at Third avenue and 169th street by the spirited horse drawing it. The surgeon and the driver were thrown out and slightly injured, and a policeman drove the ambulance back to the hospital.

**A Novel Use for an Ambulance.**—When an ambulance of the Williamsburg Hospital recently reached the house from which a call had been sent the surgeon found that he had been summoned by the mother of a bad little boy who was refusing to take a dose of some needed household remedy. The mother had carried out her threat to call the ambulance if he "wasn't good," and calmly asked the irate doctor to carry out his role of "bogey man."

**Jewish Hospital Fair.**—Preparations for this fair, which is to open on November 27 are being made on a large scale. Gov. Higgins has consented to the use of the Forty-seventh Regiment Armory, and will be present with his staff on the opening night. The hospital is to be ready for occupancy early next spring, and when completed the building will probably be the most modern one in Brooklyn. The total cost, including the necessary capital for the reception of patients, is $311,000. Of this amount there is still a shortage of $111,000. To help raise this amount the fair is to be held.

**Pure Food Bill.** The New York Section of the Council of Jewish Women invite the medical profession to attend a mass meeting in support of pure food Saturday evening, December 2, 1905, at 8 P. M., at Mendelssohn Hall, 113 West Fortieth street, New York City. Addresses will be delivered by U. S. Senators W. B. Heyburn, P. J. McCumber; Dr. Harvey W. Wiley, Chief of Bureau of Chemistry, Department of Agriculture, and others.

**Measles in New Jersey.**—An epidemic of measles has been in progress since early in the month at Highlands, N. J. Over a fifth of the 125 children in the public school have contracted the disease, and the school has therefore been closed until December 4.

**Bequests to Hospitals.**—By the will of Mrs. Harriet H. Wilcox the New York Skin and Cancer Hospital has received a legacy of $35,000, in addition to $20,000 previously received from the same estate. During the past year the hospital has also received $5,000 for another endowed bed from Miss Emily Watson. By the will of George Finkelstein of Philadelphia the sum of $100 each is bequeathed to the Mt. Sinai Hospital and to the Jewish Sheltering Arms. By the will of Frank F. Risinger of York, Pa., the sum of $500 is bequeathed to the York Hospital. By the will of Mrs. Nancy King of Doylestown, Pa., the sum of $5,000 is bequeathed to the Episcopal Hospital of Philadelphia for the endowment of a free bed. The Presbyterian Hospital of Chicago, according to the will made by the late Mr. James C. King, receives $10,000, and in addition to that a second sum of equal amount was left to this hospital as an endowment for a free room for such patients as might require a private room, but be unable to pay for it. The Hahnemann Hospital also receives $10,000.

**Tuberculosis in Iowa.**—This State has joined the list of those that exclude tuberculosis from the public schools, and the State Board of Health has issued an order notifying the superintendents of schools throughout the State to exclude all teachers, pupils, and employees suffering from the malady.

**A Subterfuge of the Quacks.**—The ingenuity of some sharp lawyer has enabled the quacks of Boston to add another difficulty to the task of convicting illegal practitioners. The trick is in putting the word "office" after the name. "The Dr. John Blank office" may be any sort of an office, whereas just Dr. John Blank would be much simpler to proceed against. As these offices are usually run under an assumed name, it is impossible, of course, to prove "Dr. John Blank" is guilty of anything, and against the person who is conducting the business, definite proof must be had, which is extremely difficult.

**Varioloid in School for the Blind.**—The State School for the Blind at Janesville, Wis., has been quarantined owing to the discovery of one case of varioloid and eight or nine other suspicious cases.

**Harvard Medical School Buildings.**—It is stated the project of adorning each of the new buildings of the Harvard Medical School with the names of some branch of medical science such as "Medicine," "Pathology," etc. has been abandoned on the ground that such inscriptions would be out of keeping with the architecture. One set of the large letters, representing "Pharmacology" has already been placed in position, but will be removed.

**Ohio Valley Medical Association.**—At the seventh annual meeting of this association, held in Henderson, Ky., on November 8 and 9, the election of officers for the ensuing year resulted as follows: *President*, Dr. D. M. Griffith of Owensboro, Ky.; *First Vice-President*, Dr. Brooks F. Beebe of Cincinnati, Ohio; *Second Vice-President*, Dr. H. P. Sights of Paducah, Ky.; *Third Vice-President*, Dr. Duncan Pope of Louisville, Ky.; *Secretary and Treasurer*, Dr Benj. L. W. Floyd of Evansville, Ind.

**Worcester County Homeopathic Medical Society.**—The thirty-ninth annual meeting of this association was held in Worcester on November 8. The election of officers resulted as follows: *President*, Dr. R. G. Reed, Woonsocket, R. I.; *First Vice-President*, Dr. Edwin Roy Leib, Worcester; *Second Vice-President*, Dr. Ellen L. Keith, Framingham; *Secretary* and *Treasurer*, Dr. Albert E. Cross, Worcester.

**The Cost of Drugs.**—In the suit of a Philadelphia cut-rate druggist against the firms who are endeavoring to maintain a uniform scale of prices, the counsel for the plaintiff produced statistics by which it was attempted to show that in six years, since the druggists began their fight against cut rates, the public has paid $96,000,000 more for drugs than it did before.

**Chicago Coroner's Report.**—The Coroner of Cook county, Illinois, has investigated 285 deaths during the month of October, 52 of which he finds were due to natural causes; suicide claimed 35, and homicide 17. Of the suicides, 16 died by shooting, 3 by hanging, and 7 by poisoning. Of the latter, 4 employed carbolic acid.

**"The Central States Medical Monitor"** is the title given to the journal formed by the recent union of the *Central States Medical Magazine* and the *Medical and Surgical Monitor*. Dr. S. E. Earp was editor of the former and Dr. S. P. Scherer was editor of the latter. The new journal will have Dr. S. E. Earp as editor and Dr. S. P. Scherer as associate editor.

**St. Louis' Black List.**—Under the title of the "St. Louis Medical Credit Guide" a list of the local residents who have failed to pay their doctors' bills is being prepared and will soon be published. The book is being compiled from the records of a collecting agency which devotes itself to this class of business. and the 15,000 names it contains are the fruit of three years' experience in collecting the bills of 500 physicians. The book is also to contain the names of 70,000 persons who are "good" in the sense that they have property and are responsible. It is to be kept up to date by the issuance of a monthly sheet, and will be revised once a year, like a city directory.

**South Georgia Medical Association.**—This society was organized at Cordele, Ga., on November 2, with the following officers: *President*, Dr. J. T. Gammage of Pineview, Wilcox County; *Vice-President*, Dr. Archie Griffin of Luke, Turner County; *Secretary and Treasurer*, Dr. T. J. McArthur of Cordele, Crisp County; *Board of Censors*, Dr. V. O. Hardvard of Arabi, Dr. J. A. Ward of Cordele, and Dr. L. A. Williams of Abbeville.

**Obituary Notes.**—Dr. CHARLES H. LANGDON, who for many years had been a member of the medical staff of the Hudson River State Hospital near Poughkeepsie, N. Y., died at that institution on November 15. Death was caused by exhaustion following a second operation for appendicitis, which was performed two days ago. The first operation was performed on October 2, but last week the second operation became necessary. Dr. Langdon graduated from the College of Physicians and Surgeons of New York and entered the State Hospital shortly after it was opened.

Dr. CHARLES M. ZEH of Newark, N. J., died in that city on November 12 of diabetes. Dr. Zeh was born in 1827 at Knox, Albany county, N. Y., and attended the Knoxville Academy, Albany Medical College, and Castleton Medical College of Vermont, from which he was graduated in 1848. Then he went to Port Huron, Mich., and practised there until 1852, when he went to Newark. He was a member of the Board of Health, and Health Officer for many years.

Dr. Henry J. Sanders of St. Mary's Parish, La., is dead in Cincinnati. He was eighty-two years old and his life covered almost the entire history of Louisiana in its identification with interests solely American. Dr. Sanders was born on a sugar plantation, where the town of Franklin now stands. He had long retired from active practice, but was one of the leading physicians in the yellow fever epidemic of 1878.

Dr. Alexander Tunstall of Norfolk, Va., died on November 10, at the age of sixty-two years. He received his diploma from the Bellevue Hospital Medical College in 1868 and began to practise in Norfolk in 1870, in association with his father. He retired from active work in 1899.

Dr. Thomas W. Jones of Columbus, Ohio, died on November 6 at the age of eighty-three years. Dr. Jones had resided in Columbus since 1878. He was a native of Chillicothe and was educated in his profession at the Medical College of Ohio, Cincinnati, and at the University of Pennsylvania. He was active in his practice until eight years ago, when he was stricken with blindness.

Dr. Geo. W. Larrick of Middletown, Va., died on November 6 at the age of fifty-three years. He was a graduate of the University of Maryland in the class of 1878. For a number of years he was a member of the board of visitors to the Western State Hospital at Staunton, Va., a Baltimore and Ohio Railroad physician, and a member of Frederick county board of health.

Dr. F. K. Castelhun of San Francisco, Cal., died on November 1 at the age of seventy-seven years. He was born in Germany but came to this country at the age of twenty years and was graduated from the University of Michigan in 1852. He practised for a time in St. Louis but came to San Francisco in 1875. He was known as a writer of German poetry.

Dr. Paul Grossman of Omaha died on October 13 at a town in Brandenburg, where he had gone in the hope of recovering his health. Dr. Grossman was graduated from the University of Breslau in 1870, and was for a time a Prussian army surgeon. He came to Omaha many years ago and was a prominent member of the German community of that city.

Dr. Edwin Curtis Bidwell died at Vineland, N. J., on November 14, at the age of eighty-four years. He was graduated from the University of Maryland Medical School in the class of 1844. He served as surgeon in the army during the Civil War.

Dr. George Reed Morehouse died at Philadelphia on November 12 at the age of seventy-six years. He was born at Mount Holly, N. J., and was graduated from Princeton University in 1848 and from Jefferson Medical College in 1851. Subsequently he took a special course in the University of Pennsylvania. In collaboration with Drs. Weir Mitchell and W. W. Keen he made a study of the surgical injuries of nerves during the Civil War.

Dr. William Tait of Galesburg, Ill., died in St. Louis on November 8 as the result of a facial epithelioma from which he had long suffered. He was born in Scotland, June 21, 1836, and came to America with his parents when three years of age. He served through the Civil War, and for a number of years he was assistant surgeon at the Soldiers' Home in Quincy.

Dr. J. H. Austin died at Toronto, Canada, on November 5 at the age of thirty-four years. He was graduated from Toronto University in 1893, and practised for several years in Kansas City, Mo., but was obliged to give up his work six years ago on account of ill health.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

ARMY NURSING HOMES—TREVES ON THE ARMY SERVICE—INFLAMMATION AND PERITONITIS AS PHYSIOLOGICAL PROCESSES—HUXLEY MEMORIAL LECTURE—NEW SCIENCE ORGANIZATION — CORONER TROUTBECK — SIR BATTY TUKE — OBITUARY.

London Nov. 3, 1905.

So much dissatisfaction has been expressed with the arrangements for the new Army Nursing Home that the public attention, so slow to arouse, has been awakened. Whether the Queen's name should have been introduced into the dispute may be questioned, but it is well that the public should know that Her Majesty's desires have been set at naught by the War Office, which has thereby added another blunder to the many that it has accumulated. The Queen, it is stated, actually offered to give a sum of £2,000 to meet improvements she deemed important, but the War Office declined and persisted in carrying out the plans it had adopted, but which have not obtained the approval of eminent sanitary architects or engineers. And it should be remembered that the Queen is not a novice in nursing matters. When the Army Nursing Board was formed Her Majesty at once became its president, and has all along taken a deep interest in its proceedings, frequently appointing one of the members to express her views and always having the minutes sent to her for inspection. In fact, there is no movement in connection with this service with which the Queen-President is not kept informed.

Turning to the Army Medical Corps, which has been for years a burning subject, no doubt much has been accomplished in the way of reform since the Advisory Board was established, but not a little remains to be done. Last week Sir Frederic Treves, who is a member of the board, gave an address at the Sussex Medico-Chirurgical Society, taking the Army Medical Service for his subject. Having pointed out the improvements which, he said, would leave little to be desired in time of peace, he asked how it would do in war time. He replied that by a curious arrangement that rested not with the corps, but with a body which had nothing to do with it—the Army Council—he felt bound to declare that that body had yet to make arrangements to enable the medical service to cope with a great war. Among the anomalies he noticed was that the medical service is under the control of an officer who is not a medical man, *i.e.* "the chief doctor of the army is not a doctor." Another is that the Director-General of the service has no direct access to the Army Council or to the War Secretary, his only access being through a non-medical officer. A third curiosity is that the money voted for the medical service is not administered by that department, but by the Adjutant-General and the Quartermaster-General. "Would there not be difficulties in any household if money set apart for the kitchen was administered by the coachman and gardener?"

That the medical department requires a freer hand was illustrated in the late war by the fact that nearly half the total losses by death were due to preventable diseases. They would be prevented if the doctors had a free hand, but there is no preparation in peace to cope with the problems of war, and the doctor's power is practically nil. Of course the service cannot be kept always on a war footing, and there must be a reserve. The military doctors had done their best, but their schemes were pigeonholed somewhere in the War Office. Sir Frederic declared that (1) the director-general of the Medical Corps should be the head of the department, responsible for its efficiency; (2) he should have direct access to the Army Council and Secretary for War; (3) he should control the money voted for it; (4) an efficient reserve must be formed; (5) combatant officers should have a knowledge of hygiene applied to campaigning and barrack life. Like knowledge, but more elementary, should be possessed by the privates; (6) the army medical officer should have authority and be provided with a personnel, suitable for carrying out the sanitary arrangements in the field which are necessary to reduce the loss from disease to a minimum. The public was deeply interested in the medical service during the war, but soon after forgot it. "That is an old story," said the lecturer, as appears from the last sentence of the "History of the Peninsular War"—"Thus ended the great war, and the veterans were soon forgotten."

"Inflammation and Peritonitis Regarded as Physiological Processes" was the subject of a paper by Mr. Malcolm at the Medico-Chirurgical Society. He objected to the common view that microorganisms were always concerned in simple inflammation, which he rather regarded as a normal process, but when extensive or severe became associated with increase of tissue change throughout the body, this increase constituting fever whether the tempera-

ture was raised or not. In support of this view the changes in twisted pedicle and in ruptured gestation sac were advanced. In such conditions the evidences of peritonitis are clear, and in the midst of the inflamed area there is a strangulated tumor, or a dead fetus, or a mass of blood. These are favorable conditions for microorganisms, but often no putrefaction occurs. It was held, therefore, that they were not septic in origin, but they produce adhesions and may be compared to the changes that occur in union by first intention of a simple incision. So acute septic peritonitis may be regarded as related to the adhesive form in the same way as suppuration in a wound, healing by first intention. In both cases all gradations between complete union and none at all are to be observed. Dealing with febrile reaction, Mr. Malcolm was dissatisfied with the notion that substances circulating in the blood acting on a heat center caused it. A rise of temperature from an injury gives rise to exudation into the tissues instead of absorption from them. The stability of temperature in health and the immediate increase of heat production following a lowering of the superficial temperature suggested that damaged tissues rather send messages to the heat center that they are cold so long as they are not revived, absorbed, extended, or marked off, but either of these may occur in a moment if the center is unable to counteract. The processes seem to take about three days, during which the temperature rises. In fine, inflammation, whether septic or aseptic, might be defined as a series of phenomena necessary for removing, or attempting to remove, effete and irritating matter from a damaged area by the physiological processes of absorption, extravasation, demarcation, or revival, or by one or more of these.

Mr. Doran supported the view proposed by Mr. Malcolm by quoting two conditions in which rise of temperature without septic infection occurred. These were twisted pedicle and ruptured tubal gestation.

Mr. L. S. Dudgeon said an incision with aseptic precautions brought about increase of leucocytes very quickly, as also did injection of certain sterilized fluids into the blood. Many so-called aseptic wounds have been proved to contain staphylococci albi. Then the peritoneal exudate may be sterile when the great omentum shows staphylococci albi. It was also constantly present in ruptured gestation as well as in twisted pediele.

Sir L. Brunton held that ferments played a part in the production of variations of temperature.

Dr. Herman believed that local peritonitis followed abdominal section in every case. It was always present if the abdomen was reopened within three weeks.

The sixth Huxley memorial lecture was delivered on Tuesday by Dr. John Beddoe, at the Anthropological Institute, in which the lecturer and Huxley were long associated. The subject selected was "Color and Race," and in discussing it Dr. Beddoe drew attention to the color connection between the people of central Europe and the British Isles. He suggested an anthropological survey of complexion and other physical characters. His own investigations had proved the existence of red-haired persons in negro tribes, and that there was much red pigment in hair, which we commonly call black. Blondes seemed to persist in southern Europe, but only by reinforcements from the north. The varieties in the British Isles were accounted for by the intrusion of races and tribes of a light complexion, the early inhabitants being believed to have been dark. It was remarkable that there was a preponderance of dark hair among criminals and the insane.

The Huxley memorial medal was presented to the lecturer after the address.

The British Science Guild was duly inaugurated on Monday, under the presidency of the Lord Mayor. The object of this new organization, as stated by Sir Norman Lockyer, is to promote the application of scientific knowledge and methods to all branches of human industry. Mr. Haldane, M.P., was elected the first president, and a member of vice-presidents and officers were appointed. The new president said the guild would endeavor to bring thinking and method into the management of public affairs and private industries. He commented on the ignorance of science in our various Government departments.

An inquiry is being made by the local Government Board auditor, at the instigation of the British Medical Association, as to the legality of Mr. Coroner Trontbeck's allocation of fees to his brother-in-law, Dr. Freyberger, for post mortems and evidence at inquests.

Sir J. Batty Tuke, M.D., M.P. for the Universities of Edinburgh and St. Andrews, who has been one of the most active of the medical members in all matters of interest to the profession, is to be opposed at the next election, on behalf of the thoroughgoing free traders, by the editor of the *Spectator*, who, though a prominent journalist, has no connection with or experience of medical matters.

Dr. Wm. Carr Sprague died on Tuesday, aged 39. He was formerly in the Indian Medical Service. After retiring from it he practised at Saffron Walden. He qualified at Edinburgh in 1887 and took the M.D. in 1890.

Liverpool has lost Dr. J. N. Cregreen, at the age of 69, a very highly esteemed practitioner, who died on the 27th ult. Two days later, also at the age of 69, died Dr. J. K. Smith, J.P., another esteemed Liverpool practitioner, for twenty years surgeon to the Stanley Hospital. Miss Alexander, L.R.C.P., of the Liverpool Medical Mission, died on the 18th ult., from accidentally swallowing a fish bone, for which an operation was performed without avail.

Dr. J. O. Brookhouse, physician to the Nottingham Hospital, died on the 27th ult. He was one of the founders of the Eye Infirmary, and at one time surgeon to it. He was M.D., St. Andrews, 1862; F.R.C.S., 1868; M.R.C.P., 1874.

---

## DR. HENRY G. DAVIS.

To the Editor of the Medical Record:

Sir:—Since the publication of my contribution to the memory of the work accomplished by the father of orthopedic surgery in America, in the Medical Record of August 19 last, I have received several letters of inquiry as to the dates of birth and death and as to something of the personality of this man. One of our foremost surgeons who is prominent also as an author, said that he had been unable to find anything in medical literature which gave so much as a glimpse of the *ipse* of Dr. Davis. After some effort, I am able to give, upon the best of authority, some of the events of his life. That all who wish to do so may profit by this search, and that they may be the better preserved, I send them to you for publication in your columns.

Henry Gassett Davis, M.D., was born at Trenton, Me., November 4, 1807. His parents were Isaac and Polly (Rice) Davis, his father being a brother of Gov. "Honest John" Davis, and his grandfather, Deacon Isaac Davis of Northboro, Mass., was a descendant of Dolor Davis, who came here from England in 1634. Isaac Davis was a manufacturer and the mechanical ingenuity of his son, Henry, was doubtless due in great part to that fact. Theré is reason to believe that Henry would not have taken up the study of medicine, except for a mere coincidence. He was on his way to the South to establish the manufacture of cotton bagging, and stopped, en route, to visit a sister who was under treatment for scoliosis. The treatment she was receiving so impressed him as lacking in scientific principles, that he immediately gave up his intended career and began the study of medicine. He attended the Yale Medical School, graduating in March, 1839. A portion of his clinical training he received at Bellevue Hospital. He began active practice in Worcester, but soon moved to Millburg. Here he remained until 1855 when he left for New York City. For the following fourteen years he was continuously active, in mind and body, attending to a large private practice and never ceasing in his original researches.

Upon the urging of physicians, and partly for the accommodation of patients from abroad, of whom he had a great many, Dr. Davis opened a private hospital at the corner of 37th Street and Madison Avenue. In 1866 Dr. Davis proposed to the profession and to their benevolent friends, the establishing of a hospital for those suffering from pulmonary consumption. I have not been able to ascertain what results his efforts in this direction produced, but the sincere attempt, in a printed appeal which I have before me, establishes his right to be called the pioneer in this great field of sanatorium work against tuberculosis.

In 1869, having laid aside a competence for his family and himself, and his health beginning to show the strain of his active life, he returned to Massachusetts. He died at his home in Everett, November 18, 1876. Until his death he continued his interest in the profession, and the new American Orthopedic Association elected him an honorary member in 1895.

It may help, in our estimation of the man, to know that he was an active member of the Congregational Church, and those who knew him considered him gentle, kind, and loving toward his fellowman. At this writing his widow, a son, and two daughters survive him. It is of interest to note that among the things outside of his profession, which bear the marks of his genius, it was he who first suggested the raising of the outer rail upon railroad curves; a simple but unthought of and most valuable expedient. His chief publication was his "Conservative Surgery." However, he contributed to the medical journals during the period of his greatest activity, especially for the purpose of making his methods of treatment of orthopedic cases known to the profession. For these articles, and reports in reference to his methods, the reader is referred to the Bulletin, Vol. I, of the Academy of Medicine; the *American*

*Medical Times*, Vol. II; *American Medical Monthly* (1856-1859); *New York Journal of Medicine* (1859) and the *Philadelphia Medical and Surgical Reporter* of 1861.

John Joseph Nutt, M.D.

The Seminole,
Broadway and Sixty-ninth Street.

## SYPHILIS AND TABES.

To the Editor of the Medical Record:

Sir:—Apropos of the paper of Dr. F. von Raitz and the letter of Dr. Collins, in your issues of October 21 and November 4, I would suggest that tabes dorsalis is a pretty well distributed disease. Lues is also so generally distributed that the human race may be said to be syphilized as well as civilized. In support of this statement witness the mild and curable form in which it now occurs as compared with its frightful ravages in earlier times and its febrile fatal nature in races virgin to it. Being so exceedingly common, ordinary experience shows that in almost any condition syphilis may be found to have existed in the patient previously, but this would not justify its being given as a cause. The neurologist, having exhausted his ingenuity in finding a cause for a condition, is prone to turn to syphilis on account of its extreme frequency. Alcoholism and neurasthenia are often used in the same way.

In the case of tabes dorsalis the most recent argument is about as follows: *a*. Given 1000 tabetics. Eight hundred show a history of syphilis. In 200 syphilis is denied, or the cause is unknown. Efforts to inoculate these 200 with syphilis fail. *b*. Given 1000 non-tabetics. One hundred show a history of syphilis. Nine hundred deny syphilis, or it cannot be made out. *c*. Hence, syphilis is always the cause of tabes. Of course this argument is illogical, and moreover such investigations are always more than liable to be erroneous, still we all acknowledge that tabes does frequently occur in persons who have had syphilis, and that in many such the latter may have a predisposing influence. There is nothing characteristic of syphilis in the lesions of tabes, it is not benefited by specific treatment, and there are certainly many seemingly sufficient exciting causes for the disease, which simply cannot be overlooked, such as injuries, exposures, and excesses. Dr. Collins, by his able, critical, and somewhat dogmatic letter, does not lessen the value of Dr. von Raitz's excellent, though perhaps slightly positive, paper.

The neurological specialist deals largely with obscure and oftentimes incurable maladies, his output of opinions and theories is voluminous, and like other men in special fields of work, he is liable to suffer from a resulting condition of autosuggestion, which leads him to believe that his theories are facts. In the present instance, it may be his opinion that syphilis is the causative influence in tabes; let him use this opinion for his guidance in handling the case, but under no circumstances let him attempt to stigmatize a possibly innocent patient by the unguarded enunciation of his theories, Gowers, Erb, Fournier, and others to the contrary.

The occasion of this letter is the wish of the writer to express the conviction that while there may be ground for opinion, there is no ground for dogmatic assertions, and further that the time has not yet arrived when a medical man is justified, in the face of the patient's denial, in stating that because he is a tabetic he must be a syphilitic. Such a course is outside of the limit of justice, may lead to the most unfortunate social results, and in case of litigation, would perhaps be held to be libellous, if not criminal on the part of the physician. In closing, it may be added that statistics can be made to prove anything, their value depending on freedom from bias. The writer has heard some of the distinguished men above mentioned make out syphilis when there was absolutely no positive evidence to justify it

George Franklin Shiels, M.D., C.M., F.R.C.S.E.
39 W. 35th Street

## A SUIT FOR ALLEGED DAMAGE FROM SKIN-GRAFTING.

To the Editor of the Medical Record:

Sir:—In the Medical Record of November 4, page 745, it is stated that suit has been brought against a physician of Spokane, Wash., for removing 150 square inches of skin, it being asserted that the surgeon promised to remove only two or three strips an inch wide and three or four inches long, etc. The article does not quite do justice to the physician, who happens to be myself. I wish, therefore, to publish the facts. In the first place the man had no conversation with me or my agent prior to the operation, therefore no agreement existed. He was the third to donate skin at this sitting, and being a great friend of the family requested that as much be taken from him as possible. Second, he was the last suitable subject at hand, neither of the other two presenting themselves being in good health. Third, instead of 150 square inches of skin being removed, only one-half of that space was denuded, simply of the superficial layer. Thiersch's method was used and no ill effects followed, contractures or other permanent deformities being impossible after simple removal of the epidermis. The same amount was taken from the patient's husband, and a corresponding amount from the brother (he being a small man) and no ill effects were produced upon either of them

The facts are, this party was seeking some cheap notoriety and is not satisfied with the amount he got, and he is now trying to get some cash which he has not earned, and it is due to the medical press as well as the Profession to see that he makes a failure of it, otherwise no physician is safe

Spokane, Wash. C. P. Thomas, M.D.

## RADIOACTIVITY.

To the Editor of the Medical Record:

Sir:—The action of radium and of radioactive solutions has been carefully studied. There is no doubt that these agents do sometimes influence the growth and development of normal and tumor tissues; but there is no evidence obtained that radium emanations have any elective or special action on tumor tissues while the amount of radioactive solution necessary to produce any curative action is far in excess of the quantity that can be safely introduced into the human system. The disappointment following the use of the radium rod in the treatment of cancer one would imagine would lead to its abandonment, except perhaps as a show piece in the hands of those persons who like to shine by the electric light

Port Chester, N. Y. W. H. Gregg, M D.

# Progress of Medical Science.

*Boston Medical and Surgical Journal, November* 16, 1905.

**Technique Employed in the Last One Hundred Laparotomies, with a View of Restricting the Employment of Drainage.**—The experience of L. J. Hammond has led him to dispense with drainage wherever possible. In the cases of the present series, it was entirely avoided. Four cases were fatal, one of which was a case of appendicitis, drained; a second, a suppurating fibroid, and two typhoid perforations. But one case of post-operative hernia occurred in the entire series. The technical steps of operation on the abdominal cavity are summarized by the author and cannot be detailed here. Suffice it to say that he divides separately each layer of the abdominal wall (after the external oblique fascia is reached) between tissue forceps. After the peritoneum is divided, it is allowed to go free until the operation is completed. The incision is large enough to admit the whole hand, provided one or two fingers are not sufficient to detect the disease. Every effort is made not to loosen the peritoneum from the underlying tissues. Dry gauze sponges used with the greatest gentleness are used to dry the peritoneal cavity, from which all irritating solutions are rigorously excluded. The author avoids separating adhesions that hold together such tissues as the omentum, mesentery, and broad ligaments, preferring to remove the entire mass after ligation above and below the points of adhesion, in this way lessening the risk of scattering infective products. Whenever possible the laparotomy is carried on extraperitoneally. Unyielding adhesions may prevent this. Then perfect walling off is substituted before any step is taken toward removing the offending condition. Hammond emphatically condemns the gauze drain, except in cases in which there is partial necrotic tissue not removable from the abscessed site, and in one or two special conditions, such as a pyemic gall bladder, etc. He believes that its presence not only lessens the power of resistance of the peritoneum, but goes far towards keeping up shock, encourages the excessive formation of adhesions, and is the commonest of all causes of about all of the post-operated hernias; and the argument that is used by some, that gauze drainage is useful because nature builds a wall around the infected area, can be logically employed as an argument against its use at all, as the fact that nature does shut it out from communication with the general peritoneal cavity shows clearly its utter worthlessness.

*New York Medical Journal, November* 18, 1905.

**Case of Transposition of Viscera, Showing Heredity.**—The patient of B. M. Randolph was a boy of nine years, with pertussis. Routine examinations showed trans-

position of the viscera. The cardiac apex beat was located one-half inch within the right nipple line, and one inch below the nipple in the sixth intercostal space. From the relative intensity of the various valvular sounds, the inference was that the transposition was symmetrical, the ventricle of the aortic or peripheral circulation being to the right or outside, and that of the pulmonary circulation to the left or inside. A skiagram gives a good illustration of the intrathoracic relations. The more particular point of interest in this case is that the maternal grandfather of the boy also had transposed thoracic viscera. The author has failed to find any hereditary connection recorded between two cases. All the rest of the patient's family circle were normal, as to chest topography.

**A Plea for Routine Examination of the Middle Ear.**—E. Danziger reminds us that the middle ear of infants and young children is especially liable to pathological changes, because it contains at birth an embryonic jelly-like substance and a highly succulent serous membrane, which rapidly undergoes retrograde changes, and tissues under such active metabolic conditions are liable to inflammation. Again the pharyngeal mucosa is richly supplied with blood vessels and lymphoid tissue, and the Eustachian lumen is narrow and slit like. The slightest swelling will occlude the ostium, a vacuum tends to form in the middle ear, blood is sucked into the tympanic capillaries, and small serous transudations occur into the cavity. Finally, the tube of a young child is wide and nearly horizontal; when the child lies on its back the ear cavity is lower than the pharyngeal opening of the tube. Hence inspection is easy. The author then summarizes the clinical conditions under which inflammation of the middle ear is likely to occur, enumerates the symptoms, and reminds us that ninety per cent. of all cases shows the pneumococcus in the discharge. Nothing new is presented under the head of treatment, but insistence is laid on the fact that increasing pain, fever, and a red, bulging drum call for early paracentesis, especially in scarlatinal otitis, where this treatment often forestalls irreparable harm.

*Medical News, November 18, 1905.*

**Further Evidence of Immunity Against Cancer in Mice after Spontaneous Recovery.**—G. H. A. Clowes and F. W. Baeslack report a continuance of their work along the lines suggested by the title of their paper. They have previously reported that the serum of spontaneously-recovered mice exerted an effect on growing tumors in other mice, but have admitted that the method employed failed to prove the existence of a specific immune body because of the impossibility of determining the cause of development which a tumor would have taken if untreated. They have, therefore, (1) reinoculated spontaneously-recovered mice and have (2) mixed cancerous material previous to inoculation with the serum of recovered mice, the results being controlled by mixing material from the same tumor with normal serum or salt solution. Their recent experiments are detailed and their results tabulated. They summarize by declaring that (1) evidence has been afforded that mice which have recovered from cancer possess an active immunity against further inoculation and (2) by mixing cancer materials previous to inoculation with the serum of such spontaneously-recovered mice, and comparing its effect with that of cancer materials from the same source mixed with serum from normal mice, it has been shown that the former exerts an inhibiting effect, and that the percentage of tumors is much smaller and the percentage of mice surviving the treatment is larger in the immune than in the normal series.

**Diplococci and Pneumococci; their Pleomorphism Virulence, and Mode of Causing Disease.** E. Palier gives the details of his experimental studies. He declares that the germ commonly known as the pneumococcus is polymorphous and that when obtained from man it is virulent only in young cultures of the first, but not of later generations. It causes pneumonia, therefore, only under exceptional circumstances. As to its frequency in the sputum of healthy people, Palier believes that it is found in one form or other in the expectoration of every healthy human lung. In some conditions, as catarrh and asthma, it is increased, while in advanced tuberculosis it may be diminished. Tuberculosis bacilli are very apt to be scanty where the above-named microorganism is abundant. Palier suggests that the latter, which are our habitual guests, perform rather a useful function, something like the leucocytes. He thinks we are justified in believing that neither the sputum nor the cultures therefrom of healthy people, nor of those suffering from pneumonia, are virulent enough to cause pneumonia, that is, general infection, of man, who is considered among the most resisting animals to this microbe. In order to do so, the pneumococci, or, as he calls them, the diplo-lanceo-bacilli-cocci, must pass first through an animal most susceptible to them, like the house mouse, for instance, whereby the virulence of these germs is greatly enhanced. And hence, mice, in his opinion, are the main factors, if not *the* factors, in causing pneumonia.

*American Medicine, November 18, 1905.*

**Clinical Experiences with Certain Drugs in Heart Disease.**—Thomas E. Satterthwaite calls attention to the facts that in the year 1900, according to the last census, as many as 70,000 persons died of heart disease in this country. Also that of the nine principal causes of death, heart disease was third on the list, in point of frequency; tuberculosis holding the first place and pneumonia the second. And now that apparently successful efforts have been directed against tuberculosis, and pneumonia has been investigated by a commission, heart disease should logically be next attacked. Insofar as drugs were concerned he regards suprarenal gland as the most powerful heart stimulant known. As to the dangers from the nitrites and nitrates, about which much has been written, he finds their effects are always evanescent. Ordinarily in angina, hypertension and arteriosclerosis they are useful but if they produce violent pulsations in an arteriosclerotic they should be suspended. For advanced cases of this affection the tetranitrate of erythrol was specially adapted, owing to its prolonged action. But after all iodin in some form or other should be the main reliance. Strychnine is a reliable heart stimulant, but should be used with discretion and in moderate doses. Larger doses produce nervousness and insomnia. It should never be continued more than a couple of weeks at a time. Cactus he finds a good heart regulator, and strophanthus is excellent if prompt action is needed. Digitalis acts best when the arteries are flaccid, and just enough is given to restore normal tension. If the drug produces too much tension, the work of the heart is unnecessarily increased. In acute endocarditis, the fat heart, fatty degeneration, advanced arteriosclerosis, aortic diseases, and cardiac neuroses, digitalis may do serious harm. In deficient or failing compensation digitalis is useful up to the point of producing normal arterial tension, after which its action is harmful, except insofar as it may increase diuresis. Circulatory depressants such as antimony, veratrum, pulsatilla, and hellebore are out of date in the treatment of cardiac diseases. But aconite is useful certainly in cardiac neuroses. There are some drugs in particular the action of which requires further investigation, because we are not sufficiently acquainted with their active principles or modes of action. These are adonis vernalis, trythropleum epocynin, and cretegus.

**The Retroverted Uterus.**—A. P. Stoner asserts that in many cases of recent dislocation in which the pelvic floor is intact, the uterus may be replaced and retained without the use of instrumentation or operative procedure. A few such patients are permanently cured by prolonged rest, faradism, hot douches, and tamponment with gauze saturated with ichthyol and glycerol. The tampon should be changed daily and snugly packed in front of the cervix, in order to prevent it from rotating forward, and thus aid in supporting the uterosacral ligaments. Nearly all supports act largely by their pressure upon the uterosacral ligaments, which, in being rendered tense by the posterior upright bar of the pessary the cervix is swung upward and backward. When, however, the pessary is withdrawn, the ligaments relax and the cervix drops downward and forward. Thus it is plainly seen that so far as the uterosacral ligaments are concerned, such pessaries as the Albert Smith or Thomas, the kind commonly used, actually interfere with the recovery of the tensility of these ligaments.

**Struggle Against Tuberculosis in Pennsylvania.**—Jonathan M. Wainwright says that local Boards of Health take no cognizance of tuberculosis except in Philadelphia and Erie. In Scranton and Pittsburg sputum is examined. In both State prisons efficient measures are being taken to prevent the spread of infection. Five societies have been formed to combat tuberculosis. They are in Philadelphia (State Society), Pittsburg, Harrisburg, Reading, and Scranton. An obstacle to progress in this work is the very general failure to make an early diagnosis and indifference to preventive measures when it has been made. Another serious menace is the general medical dispensary. In one dispensary in Philadelphia, last year nearly nine hundred people of the poorer classes were treated, and in none of them was tuberculosis diagnosed. Dr. Wainwright recommends: 1. A State commission on tuberculosis should be appointed to frame legislation governing health boards and to determine the best system for sanatoriums. 2. Compulsory divisions for diseases of the lungs should be enforced in all dispensaries receiving State aid directly or indirectly through the hospitals or schools to which they belong. 3. The State Society for the Prevention of Tuberculosis should be put on a State basis with annual meetings

at the same time and place as the State Medical Society; this society to collect material for an exhibit to be given together with public lectures in each city in which it meets. In this way each large city in the State would be reached in a few years. The State society should do missionary work and establish local societies in communities now without them.

**Mental and Moral Effects of the Removal of Adenoids.**—Edward A. Huntington gives the history of three interesting cases prepared in connection with the psychological clinic conducted at the University of Pennsylvania The patients were children who, because of incorrigibility and backwardness, were sent to special schools from the regular elementary schools. They were under careful observation before and after the removal of the adenoids, and their mental, moral, and physical improvement recorded.

*Journal of the American Medical Association, November 18 1905.*

**Uterine Displacements and Plastic Gynecological Surgery.**—Daniel H. Craig advocates greater conservatism in operating for retroversion of the uterus. He protests against the not uncommon notion that the multiplicity of operative procedures indicates that no one satisfactory operation has as yet been devised. In his opinion, it testifies to the infinite variety anatomically manifested in these cases, and to support his view he has addressed questions to the devisers of different operations, asking them as to their own opinions of the limitations of their respective methods, and publishes their replies. These, he thinks, establish his contention that no one operation fulfills all conditions, and that a multiplicity of methods is essential to a broad success. He also pleads for the utilization of normal structures as against unnatural uterine supports. He does not say that ventral and vaginal suspension and vaginal fixation are absolutely unjustifiable operations, but holds that they are performed altogether too often, and that the only cases in which they are advisable are those in which from concomitant or prior operations, developmental arrest, atrophy from untreated disease or senile degeneration, the normal supporting structures of the uterus were absolutely unavailable. It is the duty of every surgeon operating in these cases to familiarize himself with all the methods and to be able to use any or all of them, governed by the needs of each individual case. The same principles apply to all plastic operations for the repair of injuries to the birth canal. The individual case should determine the method for each tracheoplasty or cervical amputation for the relief of laceration, and only principles, not details can be definitely described for the repair of the lacerated perineum.

**Blood Cultures from Typhoid.**—R. Duffy believes, from his observations here reported, that blood cultures afford a surer and earlier diagnosis of typhoid than the Widal reaction and are perfectly feasible in family practice. In his 88 cases, the Widal test was positive in all but two, and in 18 the blood cultures showed bacilli before the Widal test. The cases were not selected, but were taken as they came. Eleven were fatal. The blood was taken from the arm veins and cultivated in bouillon (1-50th dilution) in the incubator for 48 hours. In a few cases positive results were obtained only at the end of four days. In 36 cases in which the temperature was above 102 the bacilli were present in the blood in every case, and in 23 cases in which the temperature was 100 or 101 F., the bacilli were cultivated from the blood in 10 cases, or 43 per cent. Other organisms than the typhoid bacillus were found in the cultures after the second week with the temperature 103 or over, but none before. His conclusions are given as follows: "1. *Bacillus typhosus* is present in the blood in all cases of typhoid fever in the second and third weeks, when the temperature is 102 or over. 2. Bacilli of the enteric group of bacteria (*Bacillus alcaligenes*) are present in a considerable percentage of the cases after the second week, at first accompanying *Bacillus typhosus*, then supplanting it. 3. Later in the disease, cocci may be present in the blood. 4. *Bacillus coli communis* is never present in the blood of typhoid patients." In the cases in which the typhoid bacillus was isolated no control cultures were made to exclude the possibility of air contamination.

**Methyl Alcohol Amblyopia.**—C. S. G. Nagel believes that wood alcohol amblyopia sets in first through a defective local blood supply consequent on disturbances in the general circulation. The first symptoms are therefore due to what Graefe has described as ischemia of the retina, and it would be of great interest if contraction of the blood vessels could be ophthalmoscopically demonstrated during the attack. The later eventual attack of grave amblyopia Nagel attributes to the later cumulative action of the poison shown by Pohl. As the prognosis in the incipient cases is so bad, he would advise prompt iridectomy or at least keratomy, to lower the intraocular pressure. He asks whether so-called simple glaucoma might not come about sometimes under normal intraocular pressure if the optic nerve or lamina cribrosa has lessened resistancy. Settling this, he thinks, would help to clear up the vexed question concerning the therapeutic effect of operative measures in glaucoma simplex.

**Quinine and Iron in Pneumonia.**—C. F. Nieder reports that he has treated six cases of pneumonia according to the method of Galbraith, with large doses of quinine and tincture of chloride of iron with very satisfactory results. Histories of three of the cases are given. He remarks especially the effect of this treatment on the circulation Instead of the high-tension pulse usually present in pneumonia, the pulse was of nearly normal tension and of good volume. Cyanosis, when present, was promptly relieved.

*The Lancet, November 11, 1905.*

**Abscess of the Spleen in Typhoid Fever.**—A. W. Harrington presents notes of two cases. Case one was that of a woman of forty-six years, who was admitted to hospital in what was said to be the fifth week of her illness. She was delirious, had bed sores, and foul aural discharge. No enlargement of the spleen could be detected at the time, but progressive increase in size was detected later. She had several rigors, continued high temperature, and died on the seventeenth day after admission, of intestinal hemorrhage. Autopsy revealed typical typhoid lesions in the bowel. The spleen was much enlarged and showed numerous adhesions at its upper end. On incision an abscess cavity containing a large quantity of pinkish thick pus was opened up. This cavity hollowed out practically the entire organ. The other organs showed the changes incident to continued fever, the heart muscle being very soft and pale. A culture from the spleen proved the presence of abundant staphylococcus pyogenes aureus and bacillus typhosus. Case two was that of a man, aged thirty-three years, who, on the fifty-eighth day of a typical typhoid course, complained of severe pain in the left hypochondrium. The symptoms suggested some infection, and a week later a swelling was detected below the costal margin, and three days later a portion of the twelfth rib was removed. Punctures of the spleen revealed pus at its lower portion where it was adherent to the kidney. A tube was inserted and the wound packed. The patient made a slow recovery, which was interrupted by an osteomyelitis of the upper third of the right femur, from which a large sequestrum was removed. Staphylococcus aureus and streptococci were found in the femoral wound, the same having been found also in the splenic abscess.

**Extraordinarily Rapid Diminution of Renal Dropsy under Citrate of Caffeine.**—The patient of H. D. Rolleston and J. Attlee was a man of thirty-six years, who, when first seen, presented edema of the legs, which gradually extended, in spite of vigorous diuretic measures, up to the angles of the scapulæ. There was considerable free fluid in the abdominal cavity and signs of double hydrothorax. The face, eyelids, hands, and arms, were practically free from any puffiness. At the time the caffeine was commenced he was passing two pints of urine daily. The remedy was then commenced in doses of seven and a half grams t. i. d.; so continued for nearly a month, when it was gradually diminished, and finally stopped. During this time his fluid ingesta amounted to twenty-eight fluid ounces daily. The effect of the caffeine on the urinary output was manifested immediately. The quantity steadily rose to seven and a half pints, and then gradually diminished to four pints, when there was only a slight edema of the ankles remaining. When seen several months later, he was free from edema, in excellent health, and actively at work. The urine had a gravity of 1,017 and presented only a faint trace of albumin, whereas at the commencement of his illness it contained ten parts per thousand by the Esbach test

**The Parathyroid Glands in Graves' Disease.**—This question has been investigated by L. Humphrey. So far as the results of parathyroidectomy on animals are concerned, he notes a practical agreement of all authorities on the following points: (1) Removal of the parathyroid glands together with the thyroid produces in a large number of cases very acute symptoms and a fatal result; (2) removal of all four parathyroids, the thyroid being left intact, produces the same acute symptoms, but with a less frequently fatal result; (3) removal of the thyroid alone, leaving the parathyroids, is followed by chronic symptoms of myxedema and by trophic lesions. He records two fatal cases of Graves' disease, both running an acute and unusual course. In both the parathyroids showed extensive fatty infiltration, the fat being intruded between the columns of gland cells, and in places only a few scattered epithelial

cells were left between the masses of fat. The author has examined the human parathyroids in twenty-six cases of death from various causes, and gives the directions for finding these structures on dissection. In none of four cases of Graves' disease examined did the parathyroids show any signs of compensatory hypertrophy or any evidence that the glands were becoming more specialized, and forming colloid. He declares that it is difficult to say whether the fatty infiltration is preceded by atrophy or degeneration of the gland cells, owing to the want of opportunity of obtaining fresh specimens in the human subject. He notes that the hypothesis that this gland is merely compensatory to the thyroid appears to be losing ground, and the facts that it develops in chronological advance of the thyroid, that it has an epithelial structure which somewhat resembles the suprarenal, and that its removal in the hands of most observers gives rise to definite and severe symptoms in animals, suggest that it should be regarded as an independent and essential gland. The parathyroid may have some specific function in relation to the thyroid gland and its secretion, and if it can also be proved that pathological changes occur in the gland in persons dying from Graves' disease, it would have an important bearing upon the acute toxic symptoms in this complaint.

*British Medical Journal, November* 11, 1905.

**Exophthalmic Goiter and its Treatment.**—George R. Murray says that some enlargement of the thyroid gland is one of the most frequent symptoms of exophthalmic goiter. In all cases of this disease there is an increased frequency of the pulse. Although exophthalmos is so obvious when present, it is entirely absent in many cases. The mental condition in this affection is peculiar, and in some cases is noted before the appearance of the other signs. In its typical form it is a state of subdued excitement or nervousness, such as is seen in a person undergoing some trying ordeal. It varies in different cases. Actual insanity develops in a few cases. One of the most constant symptoms of exophthalmic goiter is a fine regular tremor of the hands. The skin, as a rule, is rather pale, although it is sometimes flushed. It is often moist or greasy in appearance from the increased sebaceous secretion. Pigmentation is observed in a few cases. The treatment of this disease is a matter of considerable difficulty. The combination of rest with open-air gives excellent results. One of the most valuable methods of treatment is the systematic application of a faradic current. This treatment should be perseveringly given. In certain cases the *x*-ray has met with good results. The results of the administration of small doses of arsenic have proved this medicament to be one of the most useful drugs in this disease. In some cases, suprarenal and thymus tablets have been of service. The writer believes that the risk of surgical treatment is so great that he does not consider partial thyroidectomy advisable in exophthalmic goiter. As yet no serum or other animal product can be considered to give better results than general hygienic treatment combined with the use of electricity and certain drugs.

**Remarks on the Treatment of Syphilis by Intramuscular Injection of Mercury, with an Epitome of 3,230 Cases.**—F. J. Lambkin describes the various preparations of mercury used for intramuscular injection. He believes the best to be metallic mercury. It is sufficiently active and practically painless. Its greatest advantage is that it is very slowly absorbed. After being injected into a muscle, it remains there for some time and is very slowly, gradually, and evenly, absorbed. It is to this property that it owes its great influence over the disease. The mercury is used in the form of a cream. In compounding it, the mercury and lanolin are rubbed up together in small quantities in a glass mortar until no particle of the former can be seen. This trituration will generally take two hours, but it is absolutely necessary. At this stage, carbolized liquid paraffin is added. The cream, after being well stirred, is poured into a specially-made glass-stoppered bottle, with a very wide mouth and no angles. Before being used, the cream is stirred with a glass rod, which is first dipped into boiling olive oil. The gluteal region is the best for the injection. The needle ought to be driven straight into the muscle with one thrust. It is impossible to lay down any hard-and-fast line with regard to dosage. Each case must be treated by itself, as the results in different patients are most variable. The average time of treatment is from six weeks to two months, when the injections are given once a week. Then they are given once in two weeks for three months. Two months are devoted to repose from treatment, followed by a three months' course of fortnightly injections. Two months are again given up to rest from treatment. Even then the patient is not said to be cured, but is kept under strict observation, and, if necessary, treatment is resumed. Two years is the average length of treatment altogether. The writer also employs hot-air baths extensively. The patient's general health must be carefully looked after. Special attention should be paid to the condition of the mouth. The "inunction method" is regarded by the writer as more or less an adjunct to the intramuscular method. He concludes that on the whole, his success from this method of treating syphilis is out of all proportion to that which was obtained in days gone by, when the older methods were used.

*Berliner klinische Wochenschrift, October* 23 *and* 30, 1905.

**A Case of Somnolence Due to Metastatic Carcinoma of the Brain.**—Blum describes this case, which presented several unusual features. The patient was a woman of forty-six years, whose illness began with frontal headache which hindered sleep for two weeks. Then an apoplectiform seizure developed, but the resulting hemplegia improved greatly within a few days. When taken to the hospital six weeks after the first symptoms she was in a state of continual drowsiness from which she could be completely aroused into full possession of her faculties. At first there were no occular manifestations, but ten days later optic neuritis was present and the pupils ceased to react to light. Motor symptoms also developed in the arms. The condition of somnolence persisted for over a month, at the end of which time death ensued through respiratory paralysis. The autopsy revealed a tumor of the cerebral cortex as large as a cherry and situated in the upper part of the left central convolution. On examination this was found to be carcinomatous, and the primary focus was then discovered in the middle lobe of the right lung where it had not given rise to any physical signs.

**Experiments on Ascending Urogenital Tuberculosis.**—Baumgarten reports on experiments undertaken to determine the possibility of the advance of tuberculous infections of the urogenital tract in the upward direction; *i. e.* against the current. Ligatures saturated with an emulsion of perlsucht bacilli were tied about the ureters of rabbits, close to the bladder, and about the vas deferens. In the case of the experiments on the ureter the results were strikingly severe, but the infection of the vas was less pronounced. The upward extension of the process to the kidney was much favored, the author believes, by the stagnation of the urine, with its consequent hydronephrosis, and the absence of this feature, owing to the low secretory pressure in the vas, determined the nature of the process in that situation. While this experiment proves the possibihty that under certain conditions the infection may travel up the ureter or vas, it does not follow that this is also possible against the stream, for in the case of the animals the current had artificially been cut off. Such conditions occur but rarely in human beings, and it must be concluded that the usual path of dissemination in spontaneous tuberculosis of the urogenital tract is in the descending direction.

**The Refractometer.**—Perlmann recounts all the disadvantages attending the usual method of estimating errors of refraction and describes an invention of his own, by means of which these inconveniences can be avoided. The ordinary refraction frame is difficult to center, is hard to fit to different faces, and to keep vertical, the lenses are difficult to place in position quickly, so as to allow of accurate comparisons by the patient, the lenses easily get dim and scratched, etc. The author's apparatus consists of a frame having adjustments, permitting it to be adapted to faces with any degree of interpapillary distance, nasal depression, etc., and bearing in front of each eye two disks, which carry a series of lenses six mm. in diameter. These are arranged like the lenses in an opthalmoscope, so that all combinations from − 8 to + 7 diopters may be obtained by gradations of .5 diopter, and the extremes to − 21 and + 20 diopters, by gradations of 1 diopter. Provision is made for the insertion of stenopeic slits, which are used in the estimation of astigmatism. A shutter to cut off the vision of the resting eye is provided, as also a quadrant in which cylindrical lenses may be inserted to test the accuracy of the determinations made with the stenopeic slit. One of the chief advantages of the apparatus is the rapidity with which it permits the refraction to be tested, and while it is actually equivalent to an entire set of lost lenses it may be carried in the pocket. A red glass and maddox's rod are included. The author has used the instrument in 2,000 cases and has compared the results obtained with those gotten by the usual method, in order to see whether the small size of the lenses interfered with the accuracy of the determinations, but found that no discrepancy worth mentioning could be detected.

*Münchener medizinische Wochenschrift, October* 24 *and* 31, 1905.

**Local Eosinophilia.**—Stäubli refers to the experiments of Pröscher, who, after injecting an emulsion of teniotoxin into the peritoneal cavity of guinea pigs, obtained an

exudate rich in eosinophile leucocytes. Staübli says that guinea pigs make admirable experiment animals for this purpose, as their eosinophiles are perfectly typical and vary in number in different animals, so that individuals with low or high percentages, as the conditions of the experiment may require, are easily obtainable. In studying the peritoneal exudate induced in guinea pigs infected with trichinæ, he found large numbers of eosinophile cells, but on investigating the peritoneal fluid of normal animals, he discovered that practically the same conditions were present, and he therefore concludes that Pröscher's observations are not altogether correct, as the normal guinea pig's peritoneal cavity contains 20 to 40 per cent. of eosinophiles as well as transitional and mononuclear forms, he concludes that this membrane may form a source of origin of these cells as well as the bone marrow. On injecting dead or living cultures of bacteria into the peritoneal cavity, the eosinophiles disappeared and were replaced by polynuclear neutrophiles. In the mesentery, however, the eosinophiles were still present, showing that in this situation, as in the bone marrow, they found the conditions for existence particularly favorable.

**The Symptomatology of Barlow's Disease.**—Schlesinger says that orbital hematoma is often one of the earliest lesions of this disease, and exophthalmos, therefore, may give the first warning of the incipient malady. The case he describes illustrates this feature, as well as the unusual location of the femoral ecchymoses at the upper instead of at the lower extremity of the bone, where they usually occur. The upper zone is affected in this way so seldom that in fifty-four cases Heubner found the neighborhood of the knee involved forty-seven times. The author goes on to say that the disease is commonly encountered about the eighth month of life in infants belonging to the better classes, evidence of rachitis is often absent. Hemorrhages into the gums occur only if teeth have been cut. Enteritis precedes the malady in about one-fifth of the cases; profuse occipital sweating, rapid heart, and albuminuria at the height of the disease are other frequently observed manifestations. The disease is due to some error in diet, depending on the use of too dilute milk, of overheated milk, or of an infant's food not containing milk. Improvement follows with marvelous rapidity when raw milk is substituted for the unsuitable food.

**One-Day Pneumonias.**—Bechtold enumerates a large number of reports from the literature, which show that pneumonia of one day's duration is not as rare as might be supposed. In the medical clinic at Würzburg, however, of 1,057 pneumonias observed during the years 1887-1905, only ten were of the one-day variety. These ten cases had in common the initial chill, high temperature, and crisis usually with sweating, but they showed great disparity in the remaining symptoms, which, in some cases, were very slight or even entirely absent. The disease began with the usual evidences of an infectious disease—headache, vomiting, etc., and usually with piercing pain at the site of the lesion. The percussion note was found very variable, ranging from normal to pronounced dullness, and on auscultation crepitant râles were oftenest heard. Bronchial breathing was detected only twice. In two cases pleuritic frictions were heard later on, showing that the inflammatory process had reached the surface of the lung. Bronchophony was elicited in four cases. Leube considers that this sign is an earlier and more reliable evidence of beginning infiltration than bronchial breathing. The sputum was not very characteristic, only once was it rusty, and in another case it was blood-streaked. The question of whether the pneumonia runs through the usual stages in twenty-four hours, or whether it ceases to develop at a certain stage, is undecided, as owing to the benign nature of the sickness, anatomical observations have not yet been made. In many instances, no doubt, increased powers of resistance on the part of the patient determines the abortive nature of the infection; but in four of the author's cases he believes that the prompt crisis was due to decreased virulence of the organisms.

**Enteritis Due to the Balantidium Coli.**—Nagel says that enteritis due to this protozoan is a more serious condition than that caused by the anchylostoma duodenal. The organism was first observed in the stools, by Prof. Malmsten of Stockholm, in 1856, and since then a number of other authors have reported cases. Lately Jacoby and Schaudinn have discovered a new species, the *Balantidium minutum* in diarrheal stools. *Balantidium coli* has a round or oval body .09 mm long and .06 mm. wide. A mouth and anal opening may be distinguished. A nucleus and one or two vacuales can usually be demonstrated. The organism gives rise to constant diarrhea, with more or less bloody stools, which often contain pus. In advanced cases severe types of anemia and cachexia are seen. The author describes a case occurring in a miner of thirty-eight, who had never left his home in Westphalia. His illness began with obstinate diarrhea, which was later accompanied by weakness and prostration, which was not relieved by treatment. A year and a half after the beginning of the trouble he came under the author's care, and was then extremely anemic. Treatment with calomel, quinine enemata, etc., has only brought about temporary decrease in number of infusoria present in the stools. The author advises a search for this malignant parasite in all cases of obstinate diarrhea.

*Deutsche medizinische Wochenschrift, October 26, and November 2, 1905.*

**The Spirochæta Pallida.**—Hoffmann reviews the results obtained by the various observers who have published the one hundred or more articles on this organism that have appeared during the few months since he and Schaudinn presented their first report. A study of the descriptions, and in many instances of the preparations, of those investigators who have reported the presence of the spirocheta in the lesions that were not syphilitic leads the author to believe that the structures referred to were not of the variety *pallida*, and he maintains that so far this form has been discovered only in the infectious manifestations of syphilis, and never in other conditions. He summarizes his position by saying that the *Spirochæta pallida* is being found with great regularity in the most varied products of the disease, so that now its constant presence may be asserted. In uncomplicated cases of acquired syphilis it has been demonstrated in the depths of the primary lesions, in the lymph glands, in the secondary exanthem, and in many cases also in the blood, in pure culture uncontaminated by other organisms. Numerous authors have also succeeded in finding it in the inner organs in the exanthem, and in the blood of children infected with congenital syphilis. While observations on healthy monkeys have never revealed it, the spirochete has been identified in the lesions of monkeys that have been infected with human virus, and also in those that have been inoculated from other infected animals. He therefore concludes that there is now but little doubt that the *Spirochaeta pallida* is the cause of syphilis.

**The Experimental Production of Aneurysms.**—Fischer describes investigations on the mode of formation of aneurysms which he has carried on by injecting various substances into the circulation of rabbits. The attempts of older investigators to cause lesions of this class by traumatism of the vessel wall have been unsuccessful, as the process of regeneration promptly and completely cures the injury. Aneurysms have been produced by cauterizing the vessel walls locally with certain chemicals, causing circumscribed areas of necrosis, but the author has succeeded in accomplishing the same result by purely general means and without any local manipulation whatever. This is by the intravenous injection of 1-1000 adrenalin solution, twenty or more injections being made of from .3 to .5 c.c. each. The effect of this is first to cause a necrosis of the muscle bundles of the media of the vessel walls, followed by dilatation of the wall and straightening of the normally contorted elastic fibers. The necrotic area becomes calcareous so that a compact plate is formed in the media. The process is different in its nature from human arteriosclerosis, owing to the preliminary necrosis, and the author applies to it the term arterionecrosis If the process has gone on to the extent of causing destruction of the entire thickness of the media, aneurysm formation takes place owing to the complete loss of elasticity of the elastic fibers. The calcification is advantageous and tends to protect the vessel from rupture, a contingency that occurred in one of the author's cases in which for some reason no deposition of lime salts took place. The author's experiments with the injection of mineral poisons gave negative results, but in one instance he was able to cause aneurysm formation by the injection of a digitalis preparation. In applying to human pathology the principles illustrated by the experiments the author thinks that the two chief factors concerned are shown to be disease of the media and a heightened blood pressure.

**The Treatment of Pseudarthrosis.**—Jottkowitz refers to a method of inducing callus formation in cases of delayed union after fractures, which was first described by Gwyon It is much simpler and is just as efficient as the plan advocated by Bier as the most satisfactory. This consists in taking a large syringeful of blood from the patient's median vein and injecting it immediately, before clotting can take place, between the bone fragments. Guyon's plan is to inject iodine between and about the fragments Jottkowitz employed this procedure in two cases with excellent results In one he injected 2 c.c. and in the other 4 c.c. of tincture of iodine without causing much pain or undesirable local reaction.

**Permanent Cutaneous Changes Following the Use of Radium.**—Schmidt calls attention to the fact that very undesirable after-effects may appear long after the application of radium rays. The usual atrophic and white scar which follows burns due to prolonged exposure becomes the seat of telangiectoses which may be very disfiguring, and even the site of a moderate exposure gives evidence of vascular new growth and dilatation. The author thinks that this is an attempt to compensate for the malnutrition which first follows the action of the rays. He, therefore, warns against attempts to treat nevi etc., by this agency in situations where cosmetic effect is of importance, as it may easily happen that the cure will be worse than the disease.

**Wind and Draughts.**—Herz analyzes the conditions present when air impinges in the body: first, in the direct forcible manner attendant on exposure to out-of-door air currents, and second, in the localized feeble streams called draughts. The difference between the two is so striking from a hygienic standpoint that he attempts to show in what physical properties they may be distinguished from each other. He comes to the conclusion as the result of observation and experimentation that while wind is accompanied by compression of air, drafts are the result of suction in the more or less remote neighborhood, so that rarefaction takes place near the body and waves of this attenuated air play over the exposed surfaces. He compares the injurious effects of such rarefaction to what occurs on the large scale in caisson workers who are obliged to spend their time in the exhausted air of diving bells. In other words, a draft is a current of air of lower tension than that of the surrounding space, and it is this peculiarity that gives it its physiological significance rather than its temperature, which is of little consequence.

*French and Italian Journals.*

**Tuberculosis of the Mamma in the Cow.**—Peyronny states that up to recent times the milk of cows showing tuberculous mammitis has alone been considered dangerous. It has been considered that the milk of cows which reacted to tuberculin or even of those which were clinically infected, but without mammary lesions, was not harmful and would not give rise to any trouble. Of late years various experimenters have demonstrated that these theories are false. They have noted from animal experiments that the milk of cows which have reacted to tuberculin was sometimes capable of causing tuberculosis when used for inoculating the peritoneum. It may be suggested that tuberculosis, while being produced by such a severe method, would not be contracted by animals who merely took such milk into the stomach. But recent work along these lines has demonstrated that calves have been infected by merely drinking such milk. This whole question, then, is a far more serious one than has been generally supposed. The writer finally emphasizes the necessity of the surveillance of milk.—*Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, October 1, 1905.

**Tuberculous Bacillemia.**—André Jousset, after having studied by various methods the blood of fifty tuberculous patients, has formulated certain conclusions: In chronic ulcerative tuberculosis the blood very exceptionally contains bacilli. In acute or subacute tuberculosis the blood is very often charged with bacilli. This occurs in almost half of the cases. Especially in caseous pneumonia is this phenomenon noticed, in which it is far more frequent than in "galloping" ulcerative tuberculosis. Whatever may be the type of tuberculosis in which the condition of bacillemia is found, the latter constitutes an epiphenomenon of limited duration but essentially recurrent. These discharges are characterized by their irregularity. They cannot be foretold.—*La Presse Médicale*, October 4, 1905.

**Defibrinated Animal Blood as a Local Hemostatic in Cases of Hemophilia.**—Perthes has employed defibrinated blood still containing the ferment capable of coagulating fibrin, in the case of an obstinate hemorrhage in a hemophiliac. The patient was a young boy (whose brother had died from a hemorrhage following an accidental wound of his under lip) who for three weeks had been bleeding freely from the gums. He was in a condition of extreme anemia. Cauterizations, tamponage, adrenalin, and subcutaneous injections of gelatin, had not succeeded in arresting the hemorrhage. The writer then injected into the gums of the patient one cubic centimeter of blood taken from the carotid of a rabbit and carefully defibrinated in a sterilized vessel. The hemorrhage was arrested. It began again, however, eight days later, but was once more stopped by an application of cotton dipped in the defibrinated blood. Three days later it started up again. This time it was absolutely stopped by the same means.—*Revue Française de Médicine et de Chirurgie*, October 2, 1905.

**Malaria with the Symptoms of Acute Peritonitis.**—Gillot has observed four cases of this extremely rare type of malaria. Such a patient shows the classical symptoms of peritonitis—meteorism and pain in the abdomen, incessant vomiting, small pulse, and characteristic facies and voice—and the clinical picture looks like that of perforation of the intestine. A surgeon would not doubt for an instant the necessity of a laparotomy. This type of the disease may be seen at the period of its invasion or after it has already existed for some time. These symptoms begin rather brusqely at the beginning or in the course of continued or remittent malarial fever. Early correct diagnosis is most important in these cases. All of the modern means of investigation should be employed to determine the true nature of the infection. The possibility of the absence of the malarial organism from the peripheral blood should be remembered, for the patient may have been treated by quinine. The prognosis must be conservative, for the outcome may be serious, or it may not be alarming. On account of the possibility of the occurrence of these cases, quinine should be made use of at the beginning in the treatment of acute peritonitis in a malarial climate and season.—*Caducée*, October 7, 1905.

**Metatarsalgia.**—F. A. Michele Daniele has made a study of seven cases of metetarsalgia, a rare disease, whose pathology is still unsettled. By some it is believed to be true neuralgia, by others it is stated that there are always osseous lesions, or even affections of the small joints of the foot. The symptoms consist of pain, intense and tormenting, occurring suddenly and periodically in the metatarsal region, especially at the articulation of the fourth and fifth metatarsal bones. Pressure increases the pain, and there is tenderness over the affected articulations. It is increased by much walking or heavy labor. Walking becomes impossible when the pain is severe. In some of the author's cases there was considerable articular deformity, as was shown by the *x*-rays. The author believes that the malady may vary in its etiology. It may be simply neuralgic, or alterations of structure may go with it, as well as a profound trophic disturbance. It may be in some cases a morbid entity, a neuralgia of the plantar surface. In other cases it is a symptom of more or less profound osseous alterations of the articulations. Radioscopic and radiographic examination should always be made. In neuralgic cases electrical treatment, after the method of Picinnino, will produce a cure.—*Annali di Elettricità Medica e Terapia Fisica*, August, 1905.

**Action of Formate of Sodium on the Blood.**—Francesco Marine calls our attention to the use of formate of sodium, which has been used under the name of formagnolo, in chronic infective maladies, such as cancer and tuberculosis. It has a marked diuretic action, increasing the amount of urine immediately on its administration, the action ceasing at once on the cessation of the drug. It also diminishes the amount of albumin in kidney diseases. Urea is increased, while uric acid remains unchanged. The acidity is diminished. The drug is quite harmless. Clement states that it has a favorable effect on metabolism. The author investigated its effect on the blood condition by experiments on dogs and rabbits, when used by hypodermic injection. For a period of eight days before the drug was injected, he made determinations of the hemoglobin and corpuscles in the blood. His conclusions are as follows: 1. In small doses the drug has a beneficial effect on the blood, increasing the number of corpuscles, and the amount of hemoglobin. 2. In large doses, up to a certain point, this effect goes on; after that the hemolytic action ceases and there is a diminution of the hemoglobin.—*Giornale Internazionale delle Scienze Mediche*, September, 1905.

**Action of Caffeine on Blood Pressure.**—Gaetano Carlo Mirano has made careful observations of a number of cases after the administration of citrate of caffeine by hypodermic injection. He desired to settle the question as to whether the drug produced a rise or a fall of arterial pressure. The cases were of various kinds, heart diseases, compensated or the reverse, arteriosclerosis, fever with mental symptoms, etc. Neglecting the action of caffeine on the nervous and muscular systems, it has a powerful action on the circulation, through the vessels themselves, as well as a direct action on the heart. It produces vasodilation when the vessels are normal. The author concludes his observations as follows: 1. Caffeine, through its vasodilation, produces a marked diminution of arterial pressure. 2. It excites the heart to stronger contraction, and regulates its movements, partially counteracting the fall of pressure due to vasodilation; in arteriosclerotic cases, in which vasodilation is impossible it increases arterial pressure. 3. There is usually a slowing of the pulse, due to the forcible heart action produced.—*La Riforma Medica*, September 23, 1905.

# Book Reviews.

THE NATIONAL STANDARD DISPENSATORY. Containing the Natural History, Chemistry, Pharmacy, Actions, and Uses of Medicines, including those recognized in the Pharmacopeias of the United States, Great Britain, and Germany, with numerous references to other Foreign Pharmacopeias. In accordance with the United States Pharmacopeia, eighth decennial revision of 1905, by authorization of the Convention. By HOBART AMORY HARE, B.Sc., M.D., Professor of Therapeutics in the Jefferson Medical College, Philadelphia; Member of the Committee of Revision of the U. S. P.; CHARLES CASPARI, Jr., Ph.G., Phar. D., Professor of Pharmacy in the Maryland College of Pharmacy, Baltimore; Member of the Committee of Revision of the U. S. P.; HENRY H. RUSBY, M.D., Professor of Botany and Materia Medica in the College of Pharmacy of the City of New York; Member of the Committee of Revision of the U. S. P.; JOSEPH F. GEISLER, Ph.C., Chemist New York State Dept. of Agriculture; EDWARD KREMERS, Ph.D., Professor of Chemistry University of Wisconsin, and DANIEL BASE, Ph.D., Professor of Inorganic and Analytical Chemistry, University of Maryland. Philadelphia and New York: Lea Brothers & Co., 1905.

THIS important work is the legitimate successor of the old National Dispensatory of Stillé and Maisch—the standard book of reference in the fields of materia medica, pharmacy, and therapeutics for a quarter of a century. Of the three chief authors Dr. Hare has written the sections on medical actions and uses, Dr. Rusby those on pharmacognosy, and Dr. Caspari those on pharmacy. Of the other authors Geisler assisted in the preparation of the section on the organic chemical substances, Base of those on the inorganic chemicals, and Kremers of those on the volatile oils and their constituents. The subjects treated of include not only the drugs contained in the newly revised United States Pharmacopeia, but also those sanctioned by the British and German Pharmacopeias, as well as many (not all) of the medicaments in more or less common use which have not as yet been admitted to any pharmacopeia.

The drugs are treated of in alphabetical order, and under each title full details are given of the pharmacognosy, the pharmaceutical methods and preparations, and the therapeutic applications. An appendix contains a great number of formulas, tests, tables of comparative weights and measures, and much other useful information. There are also two copious indexes—the usual therapeutic index and a general index, in which is to be found every drug treated of in the work under its official name, its botanical or chemical name, and its popular name, with the same also in the French and German equivalents.

The work is of equal utility to the physician and the pharmacist, and no member of either profession can well afford to be without it. Its 1,858 pages contain information which one could glean otherwise only in searching through an entire library. A valuable feature is the illustrations, 478 in number, of the crude drugs and the plants from which they are derived.

ABDOMINAL OPERATIONS. By B. G. A. MOYNIHAN, M.S., F.R.C.S. Philadelphia and London: W. B. Saunders & Co., 1905.

THE large amount of successful abdominal surgery done by the author will lend interest to a work in which the operations are described as practised by himself. In this volume he includes only operations which are common to both sexes, on the stomach, intestines, liver, pancreas, and spleen, omitting those on the kidney and bladder and hernia operations. The book also contains an introductory section on bacteriology, preparations for operation, complications, and after-treatment, and a discussion on peritonitis and visceral prolapse. The technique of the preliminaries to a operation is that in general use here, but the details of after-treatment vary somewhat from those to which we are accustomed. The chapers on the specific operations are each very complete, particular attention being given to the subjects of appendicitis, peritonitis, gastric ulcers, and diseases of the pancreas. Those operations which have proved of value, he includes in addition to the numerous methods devised by himself, all of which are described in great detail and fully illustrated by appropriate drawings and case histories. The various methods of intestinal suture are carefully described and criticised, and in asserting that all mechanical aids to anastomosis are unnecessary, Moynihan practically abandons the Murphy button and similar devices are being dangerous and as having served their day. The remaining chapters are very complete, that on the liver and gall-bladder deriving especial interest from the author's extensive experience in this field of surgery. The book is well printed and the illustrations, though not very numerous, are new, pertinent, and well executed.

ATLAS AND EPITOME OF DISEASES OF THE SKIN. By Dr. FRANZ MRÁCEK, Professor of Dermatology in the University of Vienna. Authorized Translation from the German. Second Edition, revised and enlarged. Edited by HENRY W. STELWAGON, M.D., Ph.D., Professor of Dermatology, Jefferson Medical College, Philadelphia, Etc. With 77 colored plates by the Artists J. FINK and A. SCHMITSON, and 50 half-tone illustrations. Philadelphia and London: W. B. Saunders & Co., 1905.

IN its original form this atlas was one of the most satisfactory of the series of which it forms a part, and this enlarged edition should prove still more useful. The added plates are quite numerous and have been well selected with the view of completing the series of the commoner lesions the practitioner is likely to encounter. The list of diseases chosen for depiction is a thoroughly practical one, and the text is concise and useful, so that the volume may be commended as a serviceable guide for frequent reference. The editorial comments interspersed throughout the work bear evidence to the care with which the American edition has been prepared.

A TEXT-BOOK OF CHEMISTRY for the use of Students and Practitioners of Medicine, Dentistry, and Pharmacy. By WILLIAM RUSSELL JONES, M.D., Ph.G., Professor of Medical Chemistry and Toxicology, and Lecturer on Medical Diagnosis in the University College of Medicine; Visiting Physician to the Virginia Hospital, Richmond, Va. Illustrated. Philadelphia: P. Blakiston's Son & Co., 1905.

THIS volume is intended specially for students, and consists of six parts, dealing with physics, chemical philosophy, inorganic chemistry, organic chemistry, quantitative analysis, and physiological chemistry. The first part consists of a brief sketch of such parts of physical science as are necessary to an understanding of general chemical methods. The sections dealing with inorganic and organic chemistry compose the bulk of the book, and contain a fairly full account of such portions of the subject as appeal to the class of readers for whom the book is written. A few pages are devoted to methods of quantitative analysis; and the volume closes with a section on physiological chemistry. The book is well and clearly written, but the amount of chemistry contained in it is certainly the irreducible minimum that any college can demand. As an introduction to the subject, this volume will serve a good purpose, being both accurate and easily understood; but the medical student of to-day will find it necessary to supplement the knowledge here obtained by reference to a more complete text-book.

FERIDAS E RUPTURAS TRAUMATICAS DO CORAÇAO (Cardiorrhaphia). A proposito des tres cacos pessoaes de cardiorrhaphia. By FRANCESCO SOARES BRANCO GENTIL. Lisbon: Libanio da Silva, 1905.

GENTIL, in this brief treatise, considers the traumatic lesions of the myocardium and their surgical treatment, especially by suture. He reports in detail three cases of cardiorrhaphia, in two of which the patients died, and in the third recovery took place. In view of the fact that only 77 cases of this kind are on record from 1896 to 1904, the present set of three cases is certainly an addition to our knowledge of the operation of cardiorrhaphy. The rest of the work is occupied by a systematic account of the causes, pathology, symptoms, and operative treatment of wounds of the heart. The work of Ricketts on the Surgery of the Heart" has evidently not been consulted, as it does not appear in the list of references, which is up to date, and includes titles up to the present year. The list of periodicals used includes ten titles, embracing the MEDICAL RECORD, and the year book edited by Gould, as the two American publications consulted.

METHODS OF ORGANIC ANALYSIS. By HENRY C. SHERMAN, Ph.D., Adjunct Professor of Analytical Chemistry in Columbia University. New York: The Macmillan Company, 1905.

WHILE this book is not primarily intended for medical students or physicians, it presents a concise, yet complete, treatment of the subject of organic analysis, including the analysis of food products such as milk, cereals, butter, etc. It will be especially useful to students in advanced courses or in postgraduate work who are fitting themselves for the position of food experts, or as agricultural chemists. An important feature is the references to the original sources of the methods described, which are given in almost every instance. The book presupposes a considerable knowledge of general and analytical chemistry, and is not recommended to any but the more advanced students. It is carefully put together, and contains a great deal of information in a very condensed form.

# Society Reports.

## AMERICAN ACADEMY OF MEDICINE.

*Thirtieth Annual Meeting, Held in Chicago, November 9 and 10, 1905.*

DR. WINFIELD S. HALL OF CHICAGO, PRESIDENT, IN THE CHAIR.

**Report of the Committee on Laws Regulating the Practice of Medicine.**—The Secretary, Dr. CHARLES MCINTYRE of Easton, Pa., read this report. The Academy began the study of laws relating to the practice of medicine in 1880, and the report gave some of the results of this twenty-five years' investigation. Some of the imperfections of the laws were considered: (1) The lack of uniformity in common with most legislation. In time this might be corrected. (2) The relation of wandering practitioners. Each State by special legislation, by exemption in general legislation, or by sufferance, permitted certain classes of people to perform the office of a physician without the tests required by the State for doctors in medicine. The report suggested that the general practice acts should recognize this by providing for two classes, one to be known as "Limited Licentiates in Medicine," who would be examined only on the elementary subjects. As these laws were to protect the people, they should not take cognizance of any special system. Each one should have liberty to treat disease after his own sweet will, but only after he had demonstrated to the State officials that he possessed such knowledge of the human frame as the legislature had decided was necessary for the proper protection of the citizens. (3) Another imperfection of the laws of to-day was that they did not accept the statement of the medical college as final. This had been thought to have been necessary because some medical schools had been found not to have acted in good faith. The result was a somewhat mechanical statement of requirements. Time would right this, and the future laws would accept a diploma without going behind the returns. (4) Another weakness was the provisions for the transfer of a legal practitioner from one State to another. The report suggested that authority be given to each board to accept the license of another State at its value, and to make such additional tests as might be required. (5) The laws too frequently failed to protect those who were licensed. They should provide for some official whose duty it was to search out and prosecute the unlicensed and those who were abusing their licenses. The report favored having osteopaths represented on State medical examining boards.

Dr. CARL H. VON KLEIN of Chicago referred to the gradual evolution that was taking place toward higher medical education, and said he had always been an earnest advocate of it. America was not behind in this progressive movement. In some medical schools the courses of instruction were equal to those established in foreign countries, but the preliminary education of medical students had not reached as high a standard in this as it had in foreign countries.

Dr. LEARTUS CONNOR of Detroit called attention to the origin of the medical laws, who originated them, and for what purpose. He said there were two parties involved: (1) the people, and (2) the doctors themselves. Doctors could not enact laws themselves, but they had to join with the people in accomplishing this. Doctors, however, had been the prime factors in establishing these laws, sometimes with a selfish purpose in view, he regretted to say. He thought that if doctors had looked first after the interests of the people rather than their own interests, there would have been no need for any medical laws. While this was a strong statement, it was absolutely true. Physicians should work for the good of the community first, and for themselves secondarily.

Dr. B. D. HARISON of Sault Sainte Marie, Mich., said he could not agree with the recommendation in the report that osteopaths should be admitted as members of State medical examining boards. He gave the following legal interpretation of qualifications numbers one and two in the report: "If an applicant for the reciprocal endorsement of a certificate of medical registration or license has acquired such certificate or license in another State, territory, district, or province of the United States in medical reciprocity with Michigan, under conditions and requirements equivalent at the date of issue to those with which he would have to comply subsequent to September 22, 1883, in order to have then obtained the legal right to practise medicine and surgery in Michigan, such certificate or license may be recognized and endorsed by this board as a sufficient qualification for reciprocity under section 3, subdivision 3, of act 191 of the Public Acts of 1903, provided such applicant shall further comply with the rules and regulations of this board relative to the recognition and exchange of certificates or licenses between States."

Dr. R. O. BEARD of Minneapolis, Minn., believed that if the standard of the medical profession was raised there would be less need for medical legislation.

Dr. JOHN M. DODSON of Chicago said that, urged by the medical profession, some institutions of general learning were now pursuing the plan of supplying courses in chemistry, physics, and general biology, and others in human anatomy, especially microscopical anatomy, bacteriology, and embryology.

**Report of the Committee to Tabulate the Value of the First Degree.**—This report was read by Dr. DONLY C. HAWLEY of Burlington, Vt. The committee found it necessary to make a prefatory study before attempting the definite work assigned to it. This study included two questions: (1) What is a college course intended to do? (2) What are the elements which, when compounded, make the physician? 1. A college was a factory where the value of the finished product depended upon the character of the raw material furnished. It also depended upon the process employed; but no process could cause a transmutation of metals. Unless the gold be in the ore, none could be found in the end products. 2. To obtain material upon which to base the answer to this question, a circular letter was sent to a large number of physicians, medical and other teachers, and college presidents. The replies received were studied by the committee and were also included in the report as an appendix. The questions were (1) What is the character to be desired of the neophyte in medicine? To what extent can it be developed by educational processes? And what class of studies is adapted to bring it about? (2) What mental discipline is essential that a student may profitably benefit by a medical course? (3) What facts should be in possession of the intending medical student before he enters upon his medical studies? Can the acquisition of these facts be used to train the character and the mind? The report discussed each of these topics in turn. It was admitted that sometimes the man with a limited training outstripped his fellow with greater scholastic advantage. There must be something underlying which educational processes could not supply. The boy or girl must belong to that type designated as "fact seeker" by President Hadley of Yale. He must also be self-reliant, able to arrive at fair conclusions on accurate observation, and to follow such conclusions with confidence. He must also have a bulldog tenacity, a love of seeking scientific facts apart from preconceived theories, and sympathy with mankind. These were foundations, and every trait which would make an honorable man and a cultured gentleman would be helpful. Having boys and girls of this type, what should be the mental discipline to produce the best result? The pupil should be taught to observe accurately and to interpret honestly the results of observation, to know how to study, to think logically, and train his memory to be of ready service. He should be educated first for the man, then for the physician. And, on the whole, the course in colleges leading to the A.B. degree seemed to be fitted for this better than any other course. Besides, the mind so

furnished should be in possession of certain facts to be used directly in his medical studies. These included a knowledge of elementary physics, that he might understand its application in physiology and elsewhere; such a knowledge of chemistry as to make it necessary to teach only medical chemistry in a medical course; and general biology that the student could undertake the study of life processes in man in an intelligent manner.

Prof. Losey of Northwestern University, Chicago, emphasized that part of the report that students preparing for medicine should be advised to elect or to select studies in their college course, so that they might have two or three years of work in chemistry, biology, etc., and that they be advised to take up such subjects as histology, embryology, and comparative anatomy. Some institutions were pursuing such a course at present.

Dr. Leartus Connor of Detroit said a four-year course of study in medicine would give a man a broader outlook; it would give him imagination to look forward to what he ought to become; to have a broad, sympathetic outlook for those with whom he had to do. The practice of medicine required a vigorous body, and a college course ought to give chance to know what sort of body a man had; whether he could endure the long strain of days and nights and of anxious thoughts about critical cases, etc.

Dr. Carl H. von Klein of Chicago emphasized the value of an academic training preliminary to entering upon the study of medicine. The man who was academically well trained, other things being equal, made a good physician.

Prof. H. B. Ward of the University of Nebraska said that those who had not followed carefully the development of modern college education were not aware of the extent to which even in small colleges the elective system had been introduced. Formerly, a college course meant more or less the same training; not only four years, but four years applied to similar lines. The modern college had made a departure from this. Even the most conservative had introduced different courses which went under different names, but which in many, if not in all, cases led to the same degree. He deplored the fact that there was not a series of recognized studies toward the professional line of medicine as there was in the mind of the college teacher with reference to theology, to law, or to some other vocation.

Prof. James G. Needham of Lake Forest University favored teaching general biology in colleges, leaving to the medical schools to teach it as it applied to the human body. He would favor the colleges teaching general embryology, vertebrate embryology, but would let the medical schools teach those phases of it that applied to the human being and to the practice of medicine. The same with reference to other subjects. General colleges or universities could teach these branches to greater advantage than they were now being taught in medical schools.

Dr. Burton D. Meyers of the University of Indiana said he had been studying seriously in connection with the medical department of the Indiana University the best means of developing and furnishing a preliminary education. The aim of those in authority was not to establish another medical school, but a medical department of the better kind, and they were ready to require four years of collegiate work if they were convinced that this was essential. A man who entered upon the practice of medicine ought to be able to use the English language correctly, to express himself clearly and concisely. He ought also to be able to read French and German.

The report was further discussed by Drs. Daniel T. Nelson, John M. Dodson, R. O. Beard, B. D. Harison, and Prof. Halsey.

**Report of the Committee on Teaching Hygiene in the Public Schools.**—This report was read by Dr. Helen C. Putnam of Providence, R. I., the other two members of the committee being Dr. Edward Jackson, Colorado, and Dr. Geo. G. Groff, Pennsylvania. Over seventy classes in domestic science in eighteen different cities were visited, and about as many in nature study, in elementary, high, normal and special public schools. Last year, in its report on the laws and on nearly one hundred text-books in physiology and hygiene, written for children since 1882, the committee selected the latest and best books for special examination, to learn the possibilities and aims of these books. For the same reasons, in reporting the teaching of hygiene through domestic science and science teaching, the best programs of work were outlined, with brief details of the differences between these and the larger number of less efficient programs. The actual practice of principles of hygiene in domestic science and in the actual observation of biologic details and physical phenomena in the teaching of the sciences—called nature study in elementary schools—were briefly compared with the method of memorizing from books and talks. The larger range of work covered in the former classes was also noted. The committee reserved its recommendations until it had reported on the other direct methods of teaching hygiene in the public schools.

**Altruism in the Medical Profession.**—Dr. Winfield S. Hall of Chicago took this as the title of his president's address. The higher the order of altruism, the fewer there were who attained to it. Voluntary sacrifice of life in order that other lives might be saved was the highest order of altruism. This height had been attained by a comparatively small number only; a number, however, that should include many unknown heroes who had gone to their deaths while ministering to the sick in plague-stricken places, leaving no record of their heroism. The speaker cited examples from the ranks of the medical profession, covering a period from the founding of the profession to the present time. Enduring fame in the medical profession could be won through altruism only. Organized for the purpose of advancing the standards of medical education, of advancing the boundaries of medical science, of elevating the profession, and of preventing disease, the work of the American Academy of Medicine had been altruistic from the time of its organization to the present. The field of its activities was ever-widening, and always along altruistic lines. If he were asked to make a general recommendation, it would be that the Academy accept as its field of endeavor the altruistic responsibilities and activities of the medical profession, definitely outlining a program of research to be prosecuted along various lines, as education, school hygiene, State medicine, ethics, etc. This research could be followed by carefully directed and persistent efforts to accomplish that which the research revealed to be advantageous to society.

**Recreation In Its Effects Upon the Nervous System.**—Dr. William James Herdman of Ann Arbor, Mich., stated that the practical methods by which suitable recreation was to be selected to meet the requirements of special classes or individuals would vary as taste, occupation, and opportunity varied. From the complexity of occupations in which people engaged there resulted the greatest variety of channels through which the store of nervous energy was depleted. Outdoor plays and games requiring some skill, such as boating, fishing, swimming, skating, horseback riding, gardening, tool work, and the like, were of much more recreative value than any of the artificial gymnastics which had no purpose nor incentive beyond the movement itself. For the brain worker the way was open to innumerable recreations, and the opportunity for choice and the possibility of varying their character, at will, would make the problem of healthful living an easy one if any man would but cultivate a sufficient variety of interests, so that when one channel of activity was for any reason closed to him, as a relief from necessary work, he had but to choose another. The practical result in this was seen when the statistics of health and longevity of the brain worker and of the muscle worker were compared. The researches of Dr. Beard and others had shown that brain workers not

only lived from fourteen to twenty years longer than muscle workers, but that their health was more uniformly good and their stature of larger average. When mankind was once emancipated from the conception that honest work was contemptible drudgery, and learned to recognize the pleasures and recompense it had in store when rightly apprehended, which meant that the work selected must be suited to individual capacities and tastes, and when greed and selfishness gave place to a spirit of mutual helpfulness, the problem of recreation would be solved.

**The Physiology of Recreation.**—Dr. Geo. W. McCaskey of Fort Wayne, Ind., said that the primary and predominant factor in practically all forms of recreation was the psychical one. Although the influences of the mind over the body were recognized in a general way, it was fully comprehended by few, if any. The sudden change from a state of extreme depression and misery, with perfectly distinct physical suffering, to one of buoyancy and exultation, with entire forgetfulness of self as a result of a change of emotion was a not unfamiliar experience in the lives of most people. As an illustration of the broad effects of mental impression in general, he mentioned the case of an attorney under his observation, whose digestion, after considerable improvement, remained more or less distressing in spite of all he could do for his relief, which included the treatment of a local stomach disease by suitable methods, careful regulation of diet, gymnastics, and a liberal amount of outdoor exercise. This gentleman would go to a little lake forty miles away, and the very first meal that he would eat there, long before there could be any possible effect of exercise, atmospheric change, etc., would be digested without the slightest disturbance or even consciousness on his part, and this would continue until his return to the city, when the old conditions would be immediately resumed. If the various forms of recreation were closely scrutinized, it would, he thought, be found that those diversions and amusements which produced the promptest and most brilliant effects upon both the mental and physical states of those who participated were precisely those in which the physical impression was the strongest. The first requisite in what might be termed successful recreation was a complete diversion from self, a complete submergence of self-consciousness, which inhibited that everlasting introspection of our physical selves which was the foundation of half the morbidity of the world. How this could best be done was a problem for the individual, and depended upon his age, sex, social status, intellectual development, and other factors which went to make up the complete ego. He next invited attention to the purely physical or mechanical aspects of many forms of recreation, in other words, the factor of muscular exercise, and said that the systematic introduction into our lives of such recreation as was suited to individual needs should be the rational aim of all, and a proper understanding of the physiological laws and facts which underlay the whole subject could not be otherwise than helpful. He concluded with the admonition of Virgil, that "rural recreations abroad, and books at home, are the innocent pleasures of a man who is early wise."

**Recreation As a Sociological Factor.**—Dr. Donly C. Hawley of Burlington, Vt., said that while work was necessary and ennobling, refreshment of the strength and spirits after toil was likewise a necessity, which found expression in the natural cravings of the social instinct and in the general desire for diversion and amusement. The social instinct demanded satisfaction, and would find it in recreation and amusement, which was either beneficial and uplifting, or injurious and degrading. Teachers should realize the importance of recreation and use the opportunities which their positions afforded in influencing the children under their care to seek recreation which recreates and amusements which would bring the most perfect joy.

**The Relation of Recreation to Education.**—Mr. R. K. Row, Superintendent of Schools of Berwyn, Ill., presented a brief statement of the recognized psychophysical theories of play, and then discussed the special educative functions of recreative activities. Out-of-door games, plays, and recreations were the best means of physical education. He referred to the forms of recreation which involved considerable intellectual activity, and said cooperative games promoted social education. They developed the qualities of leadership, self-reliance, self-control, and the spirit of cooperation in social groups. Recreation was a very large and vital factor in esthetic education. Recreative activities had also important ethical functions.

**Ceremonials and Festa in the Recreation of Larger Groups of Individuals.**—Dr. Bayard Holmes of Chicago said that the value of the pageant had been well recognized by every organization which had aimed to secure a control over public opinion and public life. The educational and social functions of the pageant could not be confined to any one class or age. It had a use for every class and for every member of society. For the youth, the occasion was one of unequal liberty and freedom from restraint. For the young adult it furnished the occasion for prenuptial amenities. For those in the prime of life abundant opportunity was given for the display of success in any and every activity of life. The social, the economic, and the political success could be ostentatiously exhibited without the odium of effrontery or vulgarity. Even the aged might receive the scanty satisfaction of an honorable decline. But the extension of the influence of the pageant and the communal festivity reached farther and cultivated and encouraged every joy-giving activity of life.

**Medical Features of the Papyrus Ebers.**—Dr. Carl H. von Klein of Chicago presented an exhaustive paper on this subject. The author described the papyrus, the style of writing, mentioned its age, the date of transcription, its contents, and gave a description of the diseases mentioned in it and their treatment. He likewise mentioned the transcription of the papyrus from hieratic to hieroglyphics, and from the latter into a Latin glossary. He called attention to the various medical papyri now in existence, and referred to the similarity of ancient Egyptian medicine to the Mosaic. He discussed post-Biblical medicine in its relation to the time of Hippocrates, following up with the Mishna and Homer, giving a complete history of prehistoric medicine from about five thousand years before the Christian era down to the time of Hippocrates, with a translation of the same into English by the author.

**Officers.**—The following officers were elected for the ensuing year: *President,* Dr. Donly C. Hawley of Burlington, Vt.; *Vice-Presidents,* Drs. Helen C. Putnam of Providence, R. I., G. W. McCaskey of Fort Wayne, Ind., Henry B. Favill of Chicago, and James T. Searcy of Tuskaloosa, Ala.; *Secretary-Treasurer,* Dr. Chas. McIntire of Easton, Pa.; *Assistant Secretary,* Dr. Samuel C. Stanton of Chicago. Boston, Mass., was selected as the place for holding the next annual meeting; time, June 2 and 4, 1906.

## NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS.

*Stated Meeting, Held October 26, 1905.*

Dr. Charles F. Adams in the Chair.

**Specimens of Uterine Fibroids.**— Dr. Augustin H. Goelet presented these specimens with the object of showing the necessity of removing the uterus in certain cases rather than attempt to retain it by doing a myomectomy. Since many authorities were at variance as to when to remove the uterus and when to save it when there were fibroids imbedded in its walls, and since the course adopted must be decided by the experience of the operator and the condition found in individual cases, made this a question which might come up from time to time as our experience ripened and we might be able to throw more light upon the subject. He believed that it was better to save the uterus whenever

it was possible without jeopardizing the health of the patient, if she was removed five or more years from the menopause. If a patient was presumably nearer than five years and the fibroids could be readily removed without mutilation and there seemed to be no smaller nodules in the walls, the uterus then should certainly not be removed. If, on the other hand, there were small nodules distributed throughout the walls of the uterus in a patient further than five years removed from the menopause it would be better surgery to remove the uterus, because future developments would necessitate a second operation. He would not hold to the last rule if the patient was under 35 years. In all cases the ovaries should be preserved and only the diseased portions removed and some healthy structure in one or both ovaries should be left. He cited the case of a patient from whose uterus he had removed nine fibroids, some of them encroaching so much on the interior of the uterus that it was opened into several times. That was six years ago and the patient was enjoying excellent health at the present time. Two cases were reported in detail, and specimens shown, illustrating his remarks. If patients could be made to understand that, in many instances, these tumors could be removed without removing the uterus, and that in any event one or both ovaries, or a portion of an ovary, might be preserved if the operation was not too long delayed, and if patients were assured that the risk was really not great and that they would regain their health, operation would be more often consented to and fewer women would suffer unnecessarily from these conditions.

**Specimens of Ectopic Gestation.**—Dr. S. M. Brickner presented five specimens of ectopic gestation which he said were of peculiar interest. The specimens were selected with reference to the remarks he expected to make later. 1. The woman from whom this specimen was removed entered the hospital immediately following a rupture of a tubal ectopic pregnancy. The interest centered largely in the fact that there was presented simultaneously an ovarian cyst. 2. This specimen was removed from a woman who entered the hospital with a diagnosis of tubal pregnancy, with a pulse of 80, and general condition very good. One hour after admission she began to show signs of internal hemorrhage and, without waiting for permission to operate, the condition being so alarming, she was operated upon. The site of the rupture was shown together with the remnants of the sac in the tube and a few blood clots. The fetus had escaped. The patient made a good recovery. 3. The history of this case was rather dramatic because of the anatomical features. This patient was admitted to the hospital as a private patient and because of the presence of infection in the institution operation was postponed for twenty-four hours. On the same evening he saw one of the ward patients and, as a matter of courtesy, he visited this patient and discovered that she was almost moribund, pulseless and in a condition of collapse. She was hastened to the operating room, an abdominal incision was made, the abdomen was found to be filled with blood as a result of a ruptured ectopic pregnancy, and the time consumed in all was twelve minutes. The patient had been ringing the bell for some time for the nurse who refused to respond, thinking she was simply nervous; had he not entered the room when he did no doubt she would have died. The specimen showed a rupture in the center of the tube. She recovered. 4. The patient from whom this specimen was removed was operated upon by Dr. Brettauer. It showed a particularly tortuous tube which was the site of an abortion, the aborted ovum being seen outside the fimbriated extremity. 5. This specimen showed because of a simultaneous intra- and extrauterine pregnancy. Abortion occurred apparently at two and a half or three months. Nothing whatever was found in the appendages when the patient was curretted. Three weeks after this was done the patient complained of pain in the right side with a continuation of the flow and a diagnosis of tubal pregnancy was made. At the time of operation the fetus was found lying in the abdominal cavity. The tube itself was the seat of a mole.

Dr. Egbert H. Grandin presented the following specimens: 1. The first was a double ectopic pregnancy, one of three that he had in his series of ectopic pregnancies. The ovum was shown on one side, approximately of six weeks' life. In the other tube abortion had just taken place. He left the ovary behind. The history was atypical. 2. This specimen was interesting in that it demonstrated the reparative efforts of Nature. When the patient entered the service she was in a condition of collapse. The abdomen was opened, the fetus removed; it was developed about to the twelfth week. The abdomen was filled with blood and clots extending as high as the ensiform. The patient made a good recovery. The tube and ovary left *in situ* on one side but, on the other, being of no use to the woman and having ruptured, it was removed. 3. This specimen was removed from a patient who gave history of repeated ectopic pregnancies, the diagnosis being made each time in the office; it was not a presumptive diagnosis. Sometime in 1902 he removed a ten-weeks' fetus in an unruptured tube; three years after, in 1905, he removed the left unruptured tube containing a fetus about six-weeks development. In this case both ovaries were left *in situ* and the patient menstruated. The tubes which were distended with blood, clots, epithelia, etc., if left behind would no doubt have proved a great source of discomfort to the patient and possibly have made her an invalid. Both were unruptured. 4. This was a specimen of right ectopic gestation with atypical history, one not at all in accord with the histories laid down in the text-books. She entered the hospital with a pulse of 160, temperature 101 and respirations 35. The diagnosis of a presumptive ectopic gestation was made and the abdomen opened. A right salpingo-oorphorectomy was performed which was followed by an uneventful convalescence. The same operation was performed on the left side at the same time. 5. This was another specimen of a right ectopic gestation with atypical history, the diagnosis being only presumptive. A right ectopic of six weeks was removed, the right ovary and tube being removed as well. 6. This was another specimen of an ectopic, the abdomen being filled with blood and clots as, in fact, all the cases had. All the cases recovered. Dr. Grandin said that his experience with a large number of cases of extrauterine pregnancy had led him to the following conclusions: (1) The symptomatology was rarely typical; (2) if he regretted one thing more than another it was in extrauterine pregnancies when the other side seemed to be not quite normal, not removing that tube. He said he could recall four cases at least of repeated ectopics. While the woman got well they felt that one was not doing their full duty at the first operation in not removing the tube apparently diseased, and saving them the risks of a second abdominal section. (3) He was satisfied that except in hematocele formation the only surgical way of operating was by the abdominal route.

Dr. Hermann J. Boldt presented a specimen of double tubal pregnancy which he removed from a patient, 35 years old, married 15 years, who had had two children, the last fourteen years ago. Four months ago she was sent for advice because of the presence of almost constant bleeding for a few weeks, and it was assumed by both the patient and the doctor that she was pregnant about four and a half or five months. The uterus was found to be somewhat enlarged and relaxed, boggy, and could be pushed forwards and was practically immobile. Behind the uterus was a mass, globular in shape, very sensitive to the touch, and about the size corresponding to a tumor three inches in diameter. In close connection and inseparable from the mass, and in direct connection with the uterus, was an elastic tumor having the size and shape of a gravid uterus about the fifth month of gestation, and was felt in the lower abdomen. It had not, however, the same definite outline as a pregnant uterus, and the uterus could be mapped out independently of the tumor, and was a little to the left of the median line and pushed well forward. The uterus and the tumor formed an intimately blended

mass. Feeling confident that the uterus did not contain a fetus, a sound was introduced and its depth was found to be three and a half inches. The patient had had a severe attack of pain some time previous, its site being in the lower abdomen and more towards the right iliac fossa. At present more pain was complained of in the left side. The patient was anemic. The diagnosis of secondary abdominal pregnancy was made, with the presumption that the primary rupture had occurred some time previous when she had her severe pain. On operation the omentum and intestines were found to be intimately adherent and there was a mass attached to a tumor which felt to be cystic in some parts, and solid in others. This tumor lay in the median line and extended to the right, and was attached to the right broad ligament and to the intestines. It was also adherent to the uterus, which was not increased in size to any marked extent. Behind the uterus, on the posterior surface of the fundus, was a hard tumor, which was recognized as probably a fetal head. The capsule of this tumor was accidentally opened and a thick creamy fluid escaped which first impressed him as being pus. There was no odor, and later it was found to be broken down brain tissue. All the skeleton bones were encapsulated in what seemed to be the skull, and apparently arranged on top of each other like cordwood. The large intestines were extensively injured during the separation of the adhesions, but were sutured without requiring resection. This fetus was the product of a left tubal gestation. Both ovaries were retained and attached to the cornuæ of the uterus, although both glands were enlarged and inflamed. The patient made a slow recovery. The semisolid tumor on the right side proved to be another extrauterine pregnancy about two and a half months' gestation. This was the second double ectopic gestation that he had had the opportunity to operate upon this year.

Dr. L. J. Ladinski presented a specimen which had been removed from a patient, 23 years old, who two days before admission to the hospital had been taken with violent abdominal pains and vomiting. There was no blood in the vomitus. The doctor who was called in consultation made a diagnosis of gastric ulcer while her own physician made a diagnosis of either "appendicitis, ectopic gestation, or pyosalpinx." Immediate operation was performed and a ruptured ectopic gestation found.

**Case of Toxemia of Early Pregnancy.**—Dr. Bandler reported the case of a woman, 42 years old, who had passed her menstrual period two weeks and two days. Four or five days prior to admission to the hospital she had pain in the abdomen, and on the day following began to vomit which continued until day of admission. A diagnosis of appendicitis was made. The house staff diagnosed ectopic gestation. There was a tremendous hematoma and more fluid blood than he had ever seen in similar cases; the blood was unclotted. When admitted the patient still vomited and was delirious. Nothing was noted on operation. The case was supposed to be one of toxemia occurring in early pregnancy.

**Etiology of Ectopic Gestation.**—Dr. S. M. Brickner said that the theory which held apparently the greatest number of supporters was that this resulted from some inflammatory action about the tube, *i.e.* a deep seated salpingitis or adhesions about the tube which interfered with the progress of the impregnated ovum to the uterus. Yet in one of the cases presented there were no signs of any inflammatory action. He felt confident that all of those present had encountered instances in which there was no inflammatory condition present and in which none could even be revealed by the pathological examination. German writers held that extreme torsion of the tube was a cause of ectopic gestation, but that was to be doubted. Perhaps the suggestion which took the greatest hold upon the scientific mind was that of Webster, in which he considered ectopic gestation as a reversion to lower type. The fact that some women had intrauterine pregnancy and then ectopic, or ectopic pregnancy and later intrauterine pregnancy, or repeated extrauterine pregnancies was significant, and seemed to interfere with the correctness of this theory as a cause alone. Webster's assertion was that any part of Müller's tract might become the seat of pregnancy; if it occurred in the tube he assumed reversion to a lower type. Of course that which would overthrow this theory would be the anatomical demonstration of a case of primary pregnancy on other than Müller's tissue, and such an unquestioned case had been reported. That alone was enough to make Webster's theory as the sole cause of tubal or ectopic pregnancy untenable. One year ago in Vienna Miholitsch made out a good case for accessory lumina in the tube as a cause, but he did not believe that could be cause alone on account of untold instances in which accessory lumina were not present. It was entirely possible that in some instances we had combined elements working to produce ectopic gestation. Thus a woman might have a salpingitis and also have accessory lumina. It was possible for these or any other two elements to be combined in the production of ectopic pregnancy. With regard to lesions in the tube itself, first there were to be considered neoplasms. Polyp of the tube had been supposed to be a cause of ectopic gestation because such a condition interfered with the passage of the ovum from the fimbriæ to the uterus. Dr. Vineberg had such an instance last summer. There were untold instances in which one found no deviation from the normal, no part apparently being involved in any neoplasm. With neoplasm of the ovary the same conditions might exist. Dr. Brinkner said that, summing up all that was known concerning the etiology of ectopic gestation, any factor, or combination of factors, which interfered with the proper migration of the ovum to the uterus must be regarded as a causative factor. That was tantamount to saying that we knew almost nothing about etiology.

**The Indications Requiring the Abdominal Operation.**—Dr. C. C. Barrows said there was general consensus of opinion on the part of all obstetricians that whenever the fetus was alive median laparotomy should be employed in cases of ectopic gestation. He believed that one might safely say that almost all cases of ectopic gestation that came to the hands of the operator were in that period of fetal life that ranged between the eighth and twelfth week of pregnancy, about 90 per cent. of them being tubal. A careful study of the best authorities showed that there was an enormous preponderance in favor of the abdominal method. He said he was free to confess that after some experience with both routes of approach he was quite satisfied that in his hands the prospects of the patient's recovery were far better when the abdominal route was chosen. His operative experience in ectopic gestation was based on 79 cases, not including several others of old so-called pelvic hematocele operated upon per vaginam. Of these two were operated on by the vaginal route and 77 by the median abdominal incision. In two of his cases he had the good fortune to open the abdomen almost immediately after rupture had taken place, when the arteries were seen spurting vigorously. When one opened the abdomen in cases of ruptured ectopic gestation he was impressed with what seemed to be the enormous quantity of blood in fluid form in the peritoneal cavity. Clots were to be found everywhere as well. There was softening and maceration of the structures within the cavity. The technique which he said he would adhere to was to open the abdomen by a median incision, large enough to admit the hand if necessary. The fingers were carried deep into the pelvis behind the broad ligament. The mass should be quickly brought out into the adbominal incision and the adnexa removed. Dry mopping of blood and removal of clots which could be detached without injury or excessive handling should be followed by closure of the abdomen without drainage. This was an abdominal and not a pelvic condition. There had been no deaths among his 79 cases, and convalescence had, as a rule, been satisfactory. In many of these cases he had noticed a decided rise in tem-

perature, beginning within a few hours after operation, and continuing for several days without other unusual symptoms.

**The Indications Requiring the Vaginal Operation.**—Dr. J. Riddle Goffe said that the conditions requiring vaginal section would be limited to old ectopic pregnancies in which one met with hematocele and, perhaps, decomposing fetus. Under such circumstances frequently infection had already occurred, but whether infected or not the indications demanded vaginal section. That of course limited the indications to those that existed in cases of pelvic abscess. Pelvic abscesses were better treated through the vagina than through the abdomen. In the two classes referred to by Dr. Barrows first where there was a living child the indications called for abdominal incision; secondly, where the woman was *in extremis* from an active hemorrhage the abdominal incision undoubtedly brought one more promptly in contact with the condition and enabled one to stop the hemorrhage with more celerity than if the vaginal route was selected. These two conditions then would require the abdominal incision, but all other conditions could be better treated through the vaginal incision, and he made this statement in spite of the fact that he knew it would bring down upon him much criticism. He said he was not present to apologize advocating the vaginal route of attack, but to aggressively assert its claims. He believed the vaginal to be the true route of attack, that it was safer, more logical, and more direct than the abdominal. Dr. Goffe had had experiences with both routes and, in his hands, the vaginal was more satisfactory than the abdominal incision. In dealing with ectopic gestation, so far as difficulty of procedure was concerned, it did not compare with operating for salpingitis with adhesions, and in dealing with the latter the original route was used. In a tubal pregnancy with no adhesions and no sepsis, the parts being as a rule, freely movable, the organs could be brought into sight in the vagina and the field of hemorrhage readily controlled. By vaginal section was not meant simply puncturing the cul-de-sac of Douglas. The work was done through the anterior vaginal fornix. In many instances the posterior vaginal incision was also used. Dr. Goffe then demonstrated his technique by means of charts and drawings. With his technique the operation by way of the vagina was a very simple and easy one. He said objections had been made to this method because of the likelihood of scar tissue formation and consequent difficult labors, and he reported instances to prove that this was not the case, and that labor following vaginal work was gone through with ease and without special discomfort. The objections raised that after vaginal section cicatricial tissue in the vagina interfered with delivery he said was nonsense.

**The Differential Diagnosis of Ectopic Pregnancy.**—Dr. Brooks H. Wells read this paper (see page 845).

Dr. H. N. Vineberg, referring to Dr. Bandler's specimen, did not believe that such an intoxication could occur at such an early period of extrauterine pregnancy, and that in all probability it was a case of peritonitis. About 75 per cent. of the cases of ectopic gestation coming to the hospital were diagnosed properly by the house staff, whilst outside the hospital seldom was a correct diagnosis made. One of the misleading features in making a differential diagnosis was the amenorrhea, because in a fair percentage of these cases there was none. Dr. Vineberg had had four or five cases that he remembered in which there was a ruptured extrauterine pregnancy 16 or 17 days after a perfectly normal menstruation. When a diagnosis of extrauterine pregnancy was made one should operate at once and by the abdominal route. In cases of hematocele a better recovery would follow an incision through the vagina. Sometimes in opening the abdomen the intestines would be found closely adherent, or matted together by adhesions, with the peritoneum highly injected, and in such cases the vaginal incision was to be preferred. Very often great difficulty was experienced in finding the tube that was the seat of rupture and of hemorrhage.

Dr. Herman J. Boldt asked Dr. Brickner his reasons for assuming the existence of an extra- and intrauterine pregnancy simultaneously.

Dr. Brickner replied that the patient had been curetted for an incomplete abortion and chorion was found on microscopical examination.

Dr. Boldt said that he had seen a number of instances of curretting for a supposed abortion when, as a matter of fact, there was an extrauterine pregnancy. So far as the etiology was concerned his own observation, covering about 150 cases of ectopic gestation, showed that in the majority of the cases there was some inflammatory condition of the Fallopian tube as an etiological factor, and this should be borne in mind. He had had instances of repeated ectopic gestation; at the time of first operation he had found the other tube, the one not involved by pregnancy, to be the seat of inflammation which suggested to him at the time that this other tube might become the seat of an ectopic pregnancy at some future time. And this had really occurred in several instances. Therefore, in doing an operation for ectopic gestation, if one saw the other tube the seat of inflammation he thought that the operator should not be adversely criticised if he also removed it, although he himself did not follow this course, believing that the salpingitis would become spontaneously cured in the course of time.

Dr. William S. Stone believed that Dr. Bandler's case was one of toxemia of pregnancy, and in affirmation of this he reported a case seen in the literature. Such an intoxication might occur with a hydatiform mole.

Dr. Joseph Brettauer believed that a choice of the vaginal or the abdominal route of attack in cases of ectopic gestation was a matter of preference and experience and that one was as easy to do as the other if one knew how. Many cases he had seen did not require any operation. By the time one operated in cases of ruptured ectopic gestation often it was found that no actual hemorrhage was present and that the ovum had been expressed from the tube and the patient on the way to recovery.

Dr. John O. Polak of Brooklyn said that there were many cases of primary rupture that were followed by secondary rupture; often the primary rupture was unrecognized. The hemorrhage in tubal abortions would stop of itself in about 75 per cent. of the cases, and the peritoneal cavity seemed to be able to care for its contents. Yet all who were doing abdominal sections knew what the results of such a condition were and the peritonitis which followed. The proximity of the colon bacilli and other bacteria should be remembered and the facility with which they gained entrance to blood clots and the resulting state of invalidism. He agreed with the principle laid down by Dr. Barrows, "when a diagnosis of ruptured ectopic gestation had been made, operate." Dr. Polak reported an interested case in which there coexisted an extra- and intrauterine pregnancy.

Dr. Bandler wondered that ectopic gestation did not occure more often, and said that the only way the ovum could pass through the tube was by means of the ciliated epithelium, and the cilated epithelium at the outer end of the tube must be normal in order to transfer the ovum to the uterus.

Dr. Gallant reported two cases in which a mistake in diagnosis was made. One was a hematocele and the other a cyst of the ovary, both being thought to be cases of ectopic gestation on both sides.

Dr. Wells believed that in every case of early tubal pregnancy a certain amount of bleeding occurred before the rupture. The opposite tube should not be removed unless there were evidences of inflammatory involvement. The percentage of recurrences were small. The abdominal route was to be preferred in every case of ectopic gestation, or even where there were strong presumptive evidences of such a condition.

Dr. Goffe said that if the patient was *in extremis* the abdominal route was to be preferred, because it was the

quicker. In the majority of the cases that came to operation hemorrhage had ceased and undoubtedly many patients recovered without operative interference. It was quite possible that as many patients suffered from ectopic gestation in whom the condition was never diagnosticated and recovered without operation as were subjected to operative procedure. With more experience in ectopic cases the more inclined was he to keep the patients in bed and under careful observation in the hospital, where prompt operation could be done if necessary.

### Philadelphia County Medical Society.

At a stated meeting held October 11 Dr. David L. Edsall presented a communication, entitled "The Physiology of Glycolysis." He traced the successive steps by which carbohydrates taken as food were transformed into the final products carbon dioxide and water. As a result of some failure in the metabolic processes, the transformation might not be carried beyond the stage of sugar formation, and the sugar circulated in the blood and was eliminated through the kidneys. The condition might be transitory or permanent, in accordance with a variety of factors. The lesion most commonly found associated with true diabetes mellitus was some disease of the pancreas affecting especially the islands of Langerhans. Such a connection had been observed clinically, as well as experimentally. The coma that not rarely terminated life in cases of diabetes mellitus was due to an accumulation of acids in the blood, diacetic and oxybutyric especially, and was to be attributed to a deficiency of carbohydrates in the food. It could be averted by the administration of carbohydrates or of generous amounts of alkali. Dr. L. Napoleon Boston read a paper entitled "Varieties of Glycosuria." He considered briefly the appearance of glucose in the urine in connection with emotional influences, excessive ingestion of carbohydrates, traumatism, especially involving the brain, cerebral lesions of one sort or another, intoxications whether by drugs or other agents, and pregnancy, and that occurring in early life. Dr. Aller G. Ellis read a paper entitled "The Relations Between Diabetes Insipidus and Diabetes Mellitus." He pointed out that while the two conditions might not be related genetically, still well-known symptoms were common to both, and in some cases of each the pathology was similar. He made a comparison of the two, with the object of determining whether any interrelation existed. The resemblances and the differences were clinical, or symptomatic, and pathological. Diabetes insipidus occurred in younger persons and was not so fatal as diabetes mellitus. The latter was the more common, the former being rare. Emaciation was pronounced in some cases of symptomatic diabetes insipidus, but usually the weight and general condition was much better than in cases of diabetes mellitus. Complications, such as eczema, furunculosis, pneumonia, pulmonary tuberculosis, not uncommon during the course of the latter, were almost unknown in the course of the former. Coma rarely or never attended diabetes insipidus. Polyuria and thirst were usually more marked in cases of diabetes insipidus. In the one condition the urine had a high specific gravity, in the other a low specific gravity. Glucose, acetone, diacetic acid, and oxybutyric acid occurred in the urine in the one condition and not in the other. Diabetes mellitus was a disorder of metabolism affecting the glycogenic or glycolytic function of the body, and through it the sugar-regulating mechanism. Diabetes insipidus, on the other hand, was a disorder of innervation resulting in an altered filtration or secretion on the part of the kidney. Occasionally the one condition had been known to be transformed into the other. Although such a transition would appear to be indicative of some connection between the two disorders, it might occur in the absence of a common underlying ground. Dr. James Tyson presented a communication entitled "The Management of Cases of Diabetes Mellitus." He emphasized the fact that the dietetic treatment was far more important than the medicinal treatment. It was necessary to determine the patient's power of assimilating carbohydrates, and this could best be done by administration of a suitable test diet, and then making a careful study of the urine. Then carbohydrates should be withdrawn from the food until the sugar in the urine grew less or disappeared entirely. From time to time all carbohydrates should be omitted for a brief period. The protracted omission of all carbohydrates was attended with the danger of acid intoxication and fatal coma. Only second in importance to the dietetic treatment was the hygienic management. Various forms of muscular exercise were to be commended, together with bathing and friction of the skin. Cheerful surroundings and mental occupation were also of importance. The only drug capable of effecting a reduction in the amount of sugar in the urine was opium in some form. Gum opium was probably the most efficient preparation. Codeine was also useful. The continuous use of arsenic exerted a favorable influence on the course of diabetes mellitus. The alkalies were serviceable, especially for the purpose of averting acid intoxication. The waters of various mineral springs induced good results, partly because of their laxative effects, partly because of their alkalinity.

### College of Physicians of Philadelphia; Section on General Medicine.

At a stated meeting held October 9 Dr. Joseph Sailer exhibited "A Patient with Obliterative Endocarditis." Dr. James C. Wilson read a paper entitled "Some Observations on the Diagnosis of Acute Pancreatitis," in the course of which he discussed the etiology, the pathology, the symptomatology, the differential diagnosis, and the treatment. Dr. Alfred Stengel reported "A Case of Stokes-Adams Disease." The patient presented the characteristic features of this disorder, namely, attacks attended with cyanosis and great slowness of heart action. Ordinarily in the attacks the pulse would fall to eighteen and twenty beats in the minute, while on one occasion no beat could be distinguished for more than two minutes. Cardiographic tracings showed that while the number of ventricular beats was diminished the number of auricular contractions continued as before. After death the heart was found greatly enlarged, and the only lesion discoverable was a small patch of atheroma on the interventricular wall, near the base of the anterior mitral leaflet, corresponding to the situation of the so-called bundle of His, disorder of which has been shown experimentally to be capable of giving rise to the kind of heart action observed in cases of Stokes-Adams disease. Dr. M. Howard Fussell read a paper entitled "The Position and Size of the Heart in Advanced Cases of Mitral Stenosis." He reported a case in which the anterior aspect of the heart consisted of the right auricle and ventricle, the right border being constituted by the right auricle and the left border by the right ventricle. Dr. J. Dutton Steele read a paper entitled "The Clinical Examination of the Feces." He pointed out the advantage of studying the intestinal discharges and the indications to be derived from detection of various undigested matters in the stools, such as fat, meat fiber, etc. The examination might, with advantage, be preceded by a test meal of suitable composition. Dr. Joseph Sailer presented a communication entitled "Tuberculosis of the Liver," referring to several cases of this disorder that had come under his observation. The distinctive symptoms are pain in the right hypochondrium and enlargement of the liver, with irregular elevation of temperature. The affection is most invariably associated with tubercidosis of other viscera.

**Disease Caused by Stored Game.**—The New York and New England Association of Railway Surgeons, at the annual meeting recently held, adopted resolutions against the practice of game dealers of storing game and poultry without drawing, dressing, or otherwise preparing it. The resolutions affirm that this is the cause of most of the cases of exogenous toxicosis, or toxinfection.

### Pathological Society of Philadelphia.

At a stated meeting held September 28 Dr. V. Nisbit exhibited "Sections from Washings from the Stomach." In one instance the histological appearances confirmed the diagnosis of carcinoma, and the accuracy of this was demonstrated after death. In another a bit of tissue was caught in the mouth of the stomach-tube, and the microscopic appearances were indicative of malignant disease. Shreds of tissue may be found in the vomited matters or in the fluid removed on lavage or finally obtained by means of special apparatus. Dr. Giffin of Baltimore exhibited a section of malignant tissue found in the gastric contents of a patient in the Johns Hopkins Hospital. In only two other cases was there a record of a similar observation among nearly two hundred cases of neoplasm of the stomach. Dr. Allen J. Smith demonstrated "Specimens from a Case Presenting Multiple Tumors." The patient exhibited during life symptoms indicative of mediastinal growth, but post-mortem examination disclosed the presence of epithelioma of the larynx, adenoma of the thyroid gland, and cavernous angioma and spindle-cell sarcoma of the liver. Dr. Alfred Stengel presented "Specimens of Cirrhosis of the Liver." The sections were prepared from the livers of two men who had been addicted to alcoholic excess, and who, during life, presented at first enlargement and subsequently diminution in the size of the liver. After death characteristic atrophic cirrhosis of the liver was found, and the marked increase of the interstitial connective tissue was apparent in sections. Dr. Stengel exhibited also "Specimens of Chronic Fibrous Myocarditis." In one case the patient exhibited no physical signs of disease of the heart, although subsequently it was recalled that at times he became livid and manifested other indications of cardiac weakness. Death ensued during recovery from an operation for appendicitis, and post-mortem examination disclosed an extraordinary attenuation of the walls of the heart, especially of those of the auricles. On histological examination marked fibroid change was found in the myocardium. In another case presenting during life the Adams-Stokes syndrome, with paroxysms of lividity, dyspnea, and marked slowing of the pulse, a small area of endocarditis was discovered near the attachment of the anterior mitral leaflet extending into and involving the muscular bundle of His, and thus giving rise to so-called heart-block. The pulse often descended to eighteen in the minute, and on one occasion it fell to 16, although the auricles were found to be contracting with greater frequency. Dr. Courtland Y. White presented "A Specimen of Pyopneumothorax" in which the pleura was thickened in extraordinary degree and the lung was compressed into a small area in the posterior mediastinum. The heart was displaced to the right, and the right lung was in fairly good condition. There was a history indicative of multiple perforation of the lung.

### Chicago Medical Society.

At a regular meeting of this society, held October 4, 1905, Dr. Max Reichmann reported a case of "Tumor of the Brain, Diagnosed by Roentgenogram," and exhibited the patient. Dr. Sanger Brown, in the discussion, said that he had never seen a skiagram in which the convolutions were so plainly shown. His experience had led him to believe that skiagraphs were misleading in brain tumors. Dr. Charles P. Donelson was much interested in the case, and referred to the difficulty of localizing disease or tumors of the brain. He believed that the *x*-ray had opened a new era in this class of diseases. Dr. Julius Grinker referred to the value of the x-ray in the diagnosis of tumors of the brain. He thought that Dr. Reichmann laid too much stress on the *x*-ray in diagnosing these growths. He was of the opinion that in the very cases in which we needed the *x*-ray, as an aid in diagnosis, it failed to be of any assistance. Dr. L. Harrison Mettler agreed with Dr. Grinker. His experience in the use of skiagrams in the diagnosis of intracranial neoplasms, though limited, had been disappointing. He thought too much reliance should not be placed on the *x*-ray in these cases, but upon those well-known, established clinical findings of intracranial growths of all kinds. Skiagrams were simply confirmatory. Dr. Reichmann, in closing, said that it was possible to skiagraph the convolutions of the brain and bring them out clearly, and that in the case presented there was positive evidence of the presence of brain tumor. Dr. Harold N. Moyer presented a case of "Incipient Acromegaly," in a woman, 23 years of age, in whom the cardinal symptoms of this disease were present. He suggested the removal of the pituitary gland, if such an operation were possible, and thought there ought to be some advance in surgery of late years along this line. It seemed to him that surgery offered the only chance, and referred to a case reported some time ago where an operation had been attempted, but he did not know how well the surgeon had succeeded. Dr. Henry Gradle said that hemianopsia might be divided into those cases which were clearly due to acromegaly and those which were not. There was a large proportion of cases of hemianopsia positively not due to acromegaly. Dr. Hugh T. Patrick said that every tumor of the pituitary body did not mean acromegaly, by any means. Some of these tumors were benign, and he had had at least one case in which total amblyopia supervened, but otherwise the individual was well and strong, and, of course, that would bear upon the question of surgical intervention. He was of the opinion that the removal of the enlarged pituitary gland would be something of an undertaking, even for the most experienced surgeon. Dr. Julius Grinker spoke of the separation of the teeth as a diagnostic point of value. Dr. Moyer, in closing, said that if he had not been confident the case was one of incipient acromegaly, he would not have presented the patient. Dr. Hugh T. Patrick showed a colored woman, 41 years of age, who had the typical symptoms of tabes. Tabes in a colored patient, he said, was quite rare, this being the sixth case he had seen, and of those it was the only typical one. Regarding treatment, Dr. Patrick advised the rest cure, with nutritious food, when he thought the symptoms would be greatly improved. Dr. Patrick also showed a patient with palsy caused by pressure on the arm during sleep.

---

**The Relation of Pleurisy to Tuberculosis.**—Silvio von Ruck collates the opinion on this subject from the writings of a large number of authors. From this mass of material he makes the following practical deductions: (1) The pleural cavities are readily accessible to bacterial invasion. (2) The great majority of pleurisies with effusion which occur in otherwise healthy individuals are due to infection with tubercle bacillus. This is proved by autopsy findings, by methods of exact diagnosis, and by the subsequent clinical histories of the majority of persons who have been the subjects of such attacks. (3) There is ample evidence to indicate that the so-called idiopathic, dry pleurisies are likewise usually tuberculous. (4) The subjective symptoms of inflammation of the pleural apices often simulate those of myalgia or rheumatism. (5) In every case of pleurisy, or of persistent pain in the chest or shoulder, which cannot be satisfactorily ascribed to other causes, tuberculosis should be suspected and a careful physical examination should be instituted to determine, if possible, the existence of a tuberculous process in the lungs, or elsewhere. (6) Even if physical examination in such cases proves negative, the patient should be regarded as tuberculous until the contrary is proved, and should at least be kept under prolonged observation and re-examined from time to time. (7) The tuberculin test may be relied upon to confirm or exclude the tuberculous nature of pleurisy in case of doubt. (8) The application of these principles will always lead to an earlier recognition of tuberculous disease of the lungs, especially, and to the institution of treatment at a period which will, in many cases, secure to the patient most important advantages in his prospects for recovery—*New York Medical Journal.*

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 18, 1905:

| | Cases | Deaths |
|---|---|---|
| Measles | 253 | 6 |
| Diphtheria and Croup | 286 | 17 |
| Scarlet Fever | 132 | 4 |
| Smallpox | .... | .. |
| Chickenpox | 137 | ..... |
| Tuberculosis | 419 | 174 |
| Typhoid Fever | 84 | 16 |
| Cerebrospinal Meningitis | 10 | 9 |
| Typhus Fever | .... | .... |
| Yellow Fever | ..... | ..... |
| Cholera | ..... | ... |
| Totals | 1,321 | 226 |

**Uterine Fibroma and Carcinomata.**—G. Piquand believes that the coexistence of fibroma and carcinoma of the uterus is not rare. He has collected three hundred and sixty cases. An epithelioma may develop in a fibromyoma; there may be coexistence of a fibroma and carcinoma of the body, or of a fibroma and carcinoma of the cervix. The development of an epithelioma in a fibromyoma is exceptional; nevertheless, it is possible, the writer having collected forty-four cases. Generally in these cases the epithelioma is secondary, the fibroma being invaded by a neighboring cancer, almost always by a cancer of the uterine mucosa, rarely by a cancer of a neighboring organ, especially of the ovary. In extremely rare cases neoplastic bits may migrate to a fibroma by means of the lymphatics from a distant carcinoma. The development of a primary epithelioma in a fibromyoma of the uterus has been observed. Such a condition is denied by many authorities, but the writer has collected twenty-four cases, a number of which appear to be absolutely indisputable. The coexistence of fibroma and carcinoma of the body of the uterus is quite frequent. The writer has collected one hundred and seventy-nine such cases. The appearance of carcinoma of the body consecutive to a fibroma has been observed especially in nulliparous women between fifty and sixty years of age. The relations between fibroma and carcinoma of the cervix are less clear. Nevertheless, it is certain that carcinoma of the cervix has been observed more often in patients with fibromata than in other women. The writer has collected one hundred and thirty-six cases of the coexistence of fibroma and carcinoma of the cervix. Fibroma appears to predispose to carcinoma by causing disturbances in nutrition and alteration in the mucosa of the cervix. Total abdominal hysterectomy constitutes the only advisable intervention in the case of fibroma complicated by carcinoma. This operation is attended by a high mortality and is often followed by rapid recurrence. The writer believes that the frequency with which uterine fibroma is complicated by carcinoma offers a most powerful argument in favor of immediate operation in the case of all fibromata even when these tumors are not very troublesome and when the patients are approaching the menopause.—*Annales de Gynécologie et d'Obstetrique.*

**Typhoid Fever Limited.**—Alexander G. Brown believes that to understand the problem of the limitation of typhoid fever, it must be known by what route the typhoid bacilli leave the body and by what means they gain access to the body. The microorganism is most often found in the fecal discharge and urine. The stools offer the most fertile source of infection in typhoid fever. It is acceded that the digestive tract is the channel of entrance in the vast majority of cases. Of the carriers of the germs, water is preeminent in importance. Milk is also another mode of infection. Other sources are articles of food, such as butter, tea, vegetables, oysters, and clams. It has also been shown that flies, after coming in contact with typhoid infected feces, may carry the germs and infect food. The writer believes that the public should be educated as to the nature and processes and dangers of the disease. Strict laws should be made and should be observed in all cases of typhoid fever. These laws should require the report of all cases of typhoid by the physician in attendance. All cases should be closely scrutinized by the City, County, or State Board of Health. In the Health Department general measures for the appropriate regulation of sewage regulations should be instituted. The water supply should be carefully supervised; it should be kept pure. Individual prophylaxis is of the greatest importance. Scrupulous cleanliness of the patient dead. The hands of the nurse and physician should be used, and disinfection of stools should take place as soon as they are voided. Sputum should also be disinfected. Great care should be taken in disposing of the typhoid dead. The hands of the nurse and physician should be surgically cleansed on entering and retiring from the room. In closing, the writer mentions preventive inoculation, which has been lately introduced.—*Virginia Medical Semi-Monthly.*

**Some Remarks on the Clinical Aspect of Cavite Fever.**—Remus Charles Persons says that this affection, which he observed in the Philippines, was generally called an acclimatizing fever by the laity, and its nature was regarded differently by various medical officers. Most newcomers were attacked within the first few days. In many cases this fever recurred at intervals of a few weeks. The attack, which was generally sudden, seemed to have no connection with the previous health of the patient. Headache, pain of a rheumatic character in the deep muscles of the back, and soreness of the muscles of the arms and legs with severe involvement of the joints, sometimes preceded the attack, but always accompanied it. As a rule there was nausea, and anorexia was invariably present. Acuteness of hearing was very irritating, and pain about the eyes was characteristic. The bodily functions were always interfered with. An erythematous eruption on the skin was sometimes present and sometimes absent; itching was severe in certain cases. The usual rate of the pulse was about one hundred and twenty, and rarely exceeded this. The temperature varied, sometimes rising as high as 104.5°. Respiration quickened with the increase in pulse rate. A few patients were delirious. Great depression accompanied a severe attack. The duration was from three days to a fortnight. Prognosis was favorable. The writer does not regard this fever as contagious, although all had it, but all were exposed to the same influences. The cause of this disease has not been scientifically demonstrated. Many cases of this illness resembled remittent fever, many dengue, and many thermic fever or calentura. There was always a morning remission of the fever. The surface conditions of the soil in and about Cavité were good, with the exception of the disposal of excreta and refuse. After the place had been thoroughly cleaned by the troops, the fever continued just as before. The writer thinks that the probabilities point to the fact that this disease is a modified form of dengue rather than malaria, its symptoms being accentuated or suppressed according to unusual circumstances. Quinine did not seem to have a specific effect except when the remittent character was marked, then when combined with Dover's powder it seemed very effective. In general, treatment was symptomatic. The coal-tar preparations were soon abandoned on account of their depressing effect. Baths, freely used, were of the greatest value. Unless ice and alcohol were available for frequent sponge baths, the tub alone was used, and the sea water preferred. As a rule the tub and a good soaking were necessary to obtain the desired results. When the patient was strong enough to endure it, the salt-water shower was found to be effective and more pleasant, but the tub was more advantageous for general use.—*Journal of the Association of Military Surgeons of the United States.*

### THE SYSTEM OF AMERICAN HOSPITAL ECONOMY.*

By ARPAD G. GERSTER, M.D.,

NEW YORK.

SURGEON TO MT. SINAI HOSPITAL.

MR. PRESIDENT, LADIES, AND GENTLEMEN: When I was honored by the request to address the fellows of the Academy of Medicine and their guests, the president suggested the choice of a subject, untechnical, that would, while essentially medical, yet appeal to the interest of the public at large.

The immediate cause of the particular selection of the subject we shall deal with to-night was a meeting held last spring in the building of the Charity Organization Society, called to consider, and to remedy, if possible, the constantly recurring deficit in the budget of some, I might almost say most, of our large metropolitan hospitals. Most of those that discussed the matter were prone to devote their attention to the question of raising larger funds to defray increasing expenses, a question of considerable magnitude, if we remember that the deficits of some of our hospitals have reached the annual sums of eighty and ninety thousand dollars. Be this as it may, the fact remains that these and other hospitals lack adequate funds for maintenance. Dr. Brannan, the president of the board of management of our city hospitals, at whose immediate instance I had the pleasure of attending that meeting, struck in the discussion the most important note by stating, that funds would probably be adequate enough if the management of the food and linen, the medical and surgical supplies, were less wasteful and more economical. From his remarks it may be concluded that, whatever the reason may be, collecting larger funds for maintenance is a matter of increasing difficulty; hence it is incumbent upon the management of these institutions to see whether the funds actually at their disposition could not be made to reach further than they do at present.

It was curious to see how coldly Dr. Brannan's suggestions were received by those who were frankly enthusiastic to impose further burdens on the benevolent. Consider, that with a few exceptions, the money contributed to the maintenance of our hospitals is drawn from the pockets, not of the generality of the public, but of a comparatively few, well-known philanthropists. It seems to be unfair to burden still more those who already bear heavy burdens; this unfairness becomes still more conspicuous, if we recall the following facts:

The general public, or more particularly that vast portion of the community we designate as the well-to-do middle class, those who in modern American society represent the thews and sinews of the nation, may seldom or never require the immediate personal succor of our public hospitals, hence, in a large way consider themselves exempt from the duty of supporting them. It is very easy to show that this narrow view is erroneous for many reasons, the principal one of which is this, that the hospitals are not merely a convenience to dispose of a sick servant or needy relative, but that they form an important hygienic bulwark against infection and disease, a well-guarded and effective barrier against the importation of contagion of all forms into the intimate bosom of these millions of well-to-do and respectable families. For the sick individual, the personal curative function of the hospital is the most urgent one; on the other hand, its protective service is of the utmost moment to the general taxpayer. Hence we see that on the continent of Europe, hospitals maintained by private benevolence are few and small, and that the expenses of maintaining the large institutions are all defrayed by general taxation.

It was said before, that Dr. Brannan's words found little friendly response at the meeting mentioned at the beginning of this paper. And yet, in the judgment of all experts, he struck the very keynote of the question. Experts as well as amateurs unanimously admit that the management of our hospitals is extremely costly, quadrupling and sextupling the daily per capita cost of housing, clothing, feeding, and curing one patient, compared with what is found to be adequate abroad. To illustrate the differences obtaining here and abroad, I have collected the items of a list of hospitals, and wish to express my thanks to Dr. S. S. Goldwater, superintendent of Mt .Sinai Hospital, who has kindly aided me in obtaining the following figures.

The first thing that strikes the investigator is the circumstance that very divergent methods of computation obtain in our hospitals, the systematic uniformity of the calculation of cost rigidly observed abroad being entirely absent. Items strictly pertaining to maintenance are dropped at will in this or that institution, the selection of items dropped also lacking uniformity. Hence, on the whole, the figures referring to American institutions are not entirely reliable, especially if we remember the natural tendency to depress the figures of daily maintenance.

*New York City.*

|---|---|---|
| Bellevue Hospital ..... | 1904 | $1.30 |
| German Hospital ..... | 1904 | 1.83 |
| Mount Sinai Hospital ..... | 1891 | 1.52 |
| | 1893 | 1.65 |
| | 1905 | 2.00 |
| Roosevelt Hospital ..... | 1901 | 2.01 |
| | 1903 | 2.34 |
| Presbyterian Hospital ..... | 1901 | 2.34 |
| | 1903 | 2.50 |
| St. Luke's Hospital,* including private patients. | 1904 | 235 |

*A member of the board of trustees informs me that this figure is erroneous, the correct one being $1.97. The discrepancy is probably explainable by the different methods of computation above alluded to.

*Address delivered at the anniversary meeting of the New York Academy of Medicine, November 2, 1905.

| | | |
|---|---|---|
| *Other Cities.* | | |
| University of Pennsylvania Hospital | 1901 | $1.90 net. |
| | total | 2.12 |
| Massachusetts General Hospital | 1901 | 2.17 |
| | 1903 | 2.35 |
| | 1904 | 2.42 |
| Boston City Hospital | 1901 | 1.92 |
| | 1904 | 1.55 |
| Lakeside Hospital, Cleveland, O., excluding dispensary and pathological plant | | 2.20 |
| Kings County Hospital, Brooklyn | 1903 | 0.95 |
| | 1904 | 0.92 |
| St. Luke's Hospital, Bethlehem, Pa. | 1904 | 1.85 |
| City and County Hospital, St. Paul, Minn. | 1903 | 0.73 |

The figures of two of these hospitals deserve special attention. One is the City and County Hospital of St. Paul, Minn., with 73 cents, and the Kings County Hospital, Brooklyn, with 92 cents per day. Both are managed by paid medical superintendents. A third hospital, St. Luke's, at Bethlehem, Pa., is also in charge of a paid medical superintendent, who at the same time has the professional care of the patients, mainly surgical. Its cost, $1.85 per day, covers every form of expenditure, including the training school for nurses and dispensary. A farm is also included in the plant, and materially helps to swell the charges. Its produce costs double the amount it would cost if bought in the open market, but it is maintained by the fancy of some of the trustees, against the advice of the superintendent.

| University College Hospital | 1.85 |
| Guy's Hospital | 1.55 |
| *Paris, France.* | |
| Lariboisière Hospital | 0.50 |
| Civil Hospital | 0.67 |

Of Germany it may be said that the new hospital at Nuremberg, the most lavishly built, appointed, and managed, maintains its patients per day for 70 cents; Eppendorf at Hamburg for 30 cents, the average of all the larger hospitals being 35 cents.

Admitting in all fairness the great difference existing between the buying capacity of money here and abroad, even then the difference is most remarkable and deserves incisive study. What is the cause of this curious difference? Is it necessary in the presence of increasing financial embarrassment to accept this difference as the inevitable decree of inscrutable Providence, is it audacious and irreverent, closely to examine the methods which make the curing of the American hospital patients so disportionately costly; or, on the other hand, is this business, grown from diminutive beginnings into vast proportions, involving here in New York alone the annual expenditure of millions of dollars, is this stupendous work a form of necessary business, that demands, like any other business of its magnitude, the most careful and painstaking looking after, not of amateurs, but of real experts in the most serious meaning of the word?

Admitting the second alternative, if for no more elevated reason than that of the vast sums annually expended, we conclude that this divergence must be explained, aside from the difference in the buying capacity of money, by the difference existing between the fundamental principles that govern hospital management with us and those that prevail abroad. This difference is concisely expressed by saying, that while abroad the hospitals are governed by a comparatively few paid experts, who devote the best part of their time and energy to this specific work, with us the same work is attempted, and imperfectly done, by a vast number of lay and professional free lances, loosely banded together in gratuitous and voluntary effort. The laxity and shifting character of this organization implies the negation of that strictness of professional and business management, without which no undertaking of some magnitude can be successfully conducted.

As a matter of fact, cases of extravagant waste will occur even in Germany; but the general feeling is averse to it, and provision is made for its speedy detection and suppression. With us, the idea of economy is extremely unpopular, being too readily associated with parsimony, and no fixed apparatus exists to detect waste and to stop it promptly.

The gist of the matter is the postulate that it is not sufficient for the benevolent to spend money on hospitals, but that it is their duty likewise to see that their money should be economically spent.

Before entering upon the merits of the matter, it is necessary for me expressly to state that I do not in the least wish to discourage private benevolence expended on the maintenance of hospitals. On the contrary, I consider it the glory of our country, that it can boast of such a large number of important curative institutions as we possess, exclusively maintained by private means. The justification of this avowal lies in the fact that, in view of the increasing difficulty of providing necessary funds, some discouraged persons have insisted, that all hospitals ought to relinquish their private character and should be kept up by taxation. Much as there is to be said in favor of the plan of throwing the burden of all hospital maintenance on the taxpayer, yet by adopting it we would lose more than we would gain. The principle of independent self-help, characteristic of Anglo-Saxon pride and polity, would be exchanged for a questionable dependence on government. Furthermore, it may be said that such a sacrifice is unnecessary, as our institutions have sufficient plasticity to permit of adaptation to our conditions of what is found commendable abroad.

First of all, let us then mark this fundamental difference, that while our system is based on the principle of self-help, organized by enterprising citizens possessing a great deal of general business ability, but no expert knowledge, devoting to this work only a limited portion of their time in weekly or monthly meetings; that while this system palpably exhibits in all its details a certain laxity, and the easy-going, unbusinesslike tendencies of all amateur management, the system abroad is the outgrowth of long experience, is entirely in the hands of salaried experts who are held to the strictest financial and professional accountability, and whose main interest, whose bread and butter, so to say, depends upon satisfactory efficiency.

The limit of time does not permit us fully to enter upon the consideration of this vast subject in all its bearings. The object being rather to evoke and stimulate interest in than to give a complete exposition of this matter, I shall content myself with drawing for you a parallel sketch of the workings of the two systems.

I have studied the question of hospital government in four cities, Hamburg, Berlin, Vienna, and Budapest, involving the management of institutions that contain in the aggregate about sixteen thousand beds. As regards their supreme direction, it lies invariably with the government, in State institutions directly, in municipal institutions indirectly. Even private institutions must submit to state supervision, if for no other reason than their freedom from taxation. This involves no petty meddling with details, but consists rather in the fashioning of the higher policies, and in the strictest supervision of general expenditure. It serves as a check on extravagance in all directions, as by the frequent reports it receives from everywhere it is in a position to make comparisons, to notice unusual excess in this or that direction, to ascertain its cause, and to suggest, or, if necessary, to enforce, retrenchment. Its instruments are in state institutions, the proper bureau of the ministry, in city hospitals, a small board of lay and professional members, called either "curatorium" or "deputation," usually a committee of ten to twelve men of the common council, to whom the directors proper of each subordinated institution are held strictly responsible. "Director" means there the man who has immediate and full charge of any one institution. This supreme board of government, "curatorium," or deputation is holding monthly meetings, at which the presence of the hospital directors in an advisory capacity is obligatory. One of its members is deputed in rotation to maintain continuous contact with the director or dirigents of the hospital by means of biweekly, if necessary daily, visits to the institution.

In the form of the immediate direction of the business of the hospitals we see certain variations, which, however, do not materially influence its general character.

In Vienna, the Allgemeines Krankenhaus with over 2,000 beds, and the Rudolf Hospital with 600 beds, are each governed by a medical director, with an annual salary of from 12,000 to 15,000 crowns, quarters in the hospital, free lighting and heating, eight weeks' annual vacation, and the right to a pension. To them are subordinated all the medical and lay officers and the employees of their institutions. They are aided in the management of the domestic detail by a lay inspector and a well-organized corps of clerical and technical employees.

Budapest's six hospitals, with an aggregate of 2,500 beds, are all under the management of one medical director, whose annual salary is 11,400 crowns, the other conditions of his appointment being similar to those of Vienna.

Of Hamburg's two hospitals, the one at Eppendorf, with 1,400 beds, is managed by one medical director, aided by two subordinated lay inspectors, one for the clerical, the other for the technical department. His salary is 30,000 marks. The St. George Hospital, at Hamburg, 1,000 beds, is under a medical and a lay director, who are coordinated.

The hospitals of Berlin show a somewhat different organization. Here the management rests, in the new Virchow Hospital of 2,000 beds, with a board consisting of two medical directors, one of whom is the chief of a medical, the other of a surgical division. The third member of this board is also a medical man, but one who never did practice, whose special branch is hospital hygiene and management, and who is a man of recognized business ability. He is called the "economic director," and has an initial salary of 11,000 marks, which will be, in due course of time, augmented to 15,000 marks per annum. The salary of the two other medical directors, who, aside from the labors of management, have also the care each of a large division of the service, is 6,000 marks. They are permitted to do a consulting practice, and as regards vacation and pension, are similarly provided for as the Viennese and Budapest men. Friedrichshain of Berlin is organized in a similar manner. *Bethanien,* the hospital of the Protestant nursing order of deaconesses, with 400 beds, is managed by the two chiefs of the two departments, medical and surgical, in conjunction with the sister superior, who is the business manager. Urban, and the Charité have two directors each, one lay and one medical, in a similar manner to that of St. George's at Hamburg. All the military hospitals and insane asylums are governed by one medical head. The salaries vary from 6,000 to 12,000 marks, according to the size of the hospital. Thus we see that everywhere the medical element predominates; that, considering the value of money in Germany and Austria-Hungary, all these officers are very well paid. It is reasonable to assume that their pay must be well earned.

As hinted at before, to them are subordinated all the medical and lay officers, and to them belongs the supreme control of every branch of the service,—not, however, in an arbitrary manner. Monthly meetings of all the medical chiefs of division are obligatory, at which the important policies of the institutions are discussed, in which the medical directors participate, though they are under no obligation to accept unconditionally its suggestions. The institution of hospital superintendent, in the American acceptation of the term, does not exist abroad.

Now we shall take up that part of the hospital work which forms its "punctum saliens," its heart as it were, and upon the intelligent performance of which depends more than on anything else, both the welfare of the patients, and the proper and wise use of the material, food, liquors, linen, clothing, medicines, dressings, and surgical apparatus, the heating and lighting, the ventilation, drainage, the maintenance of cleanliness, of decency, and repose appropriate to a hospital:—I mean the ward work, done by the medical and surgical chiefs, or according to our nomenclature, by the visiting staff, together with their assistants.

The first thing that attracts attention is the large size of each service, which rarely comprises less than 200 and often includes 350 beds. Schede's department of surgery at Hamburg contained over 400 beds. The second thing that favorably impresses the visitor is the undivided unity, responsibility, and permanency of each service, both in its chief and his salaried assistants. The duties of the chief are manifold and onerous. He holds morning rounds in person every day, Sundays and holidays not excepted. During his vacation of from six to eight weeks, he is substituted by his first assistant, usually a person of maturer character, who is fully conversant with the exigencies of the service, and must be, in every sense, competent. The chief, however, remains responsible for the conduct of his service even during an absence. At morning rounds he must pay personal attention to every patient under his care, must personally examine him, dictate the history, state the leading facts to the assistants, and himself order the remedies and diet from day to day, have them inscribed into the medicinal and diet list as they come up, which he must sign in person every day *after,* never before they are fully made out. He is absolute master in his service, and is responsible for its proper cleanliness, ventilation, lighting, and heating, and bedding, clothing, apparatus, or dressing materials cannot be procured without his written order. All the materials thus received are properly

booked under the supervision of the first assistant by one of the orderlies, and monthly reports must be sent in to the directory on everything that has been received, that is being and was used, and what remains in stock. The distribution tmong the assistants, and a vigilant and continuous personal control of their work is another one of his duties, the complement of which is a specific report to the director on their usefulness and fitness.

After the visit comes the daily operative activity of the surgeons, and the necessary laboratory work of the internists. Weekly examination of the quality of the food, of the water closets, drains, etc., are prescribed. The constant supervision of the assistants, aside from its immediately practical utility, has a high educational value also, inasmuch as each hospital, besides its regularly salaried assistants, admits and appoints a liberal number of graduates under the title of *volunteers*. They are unpaid assistants, who join the service for the sake of learning, and who, under the direction of their older colleagues, perform all the duties of an assistant during the term of from one to two years. Finally, whenever there are medical schools, the law makes it obligatory for the undergraduates to attend, at a designated division of a hospital during a term of weeks, where a certain number of patients are assigned to each of them, and for whom, under proper supervision and control, they perform the services of a younger assistant. To extend this privilege is obligatory on all hospitals, and its enormous importance and utility to the general public cannot be emphasized too strongly. This is a point hitherto vainly urged by medical educators on American hospital managers, a point which has recently been energetically dwelt upon by Osler in his parting speeches. The daily personal contact of the chief, with all his assistants and students at the bedside, is a wonderful stimulus to all concerned. The one who derives the greatest benefit from this continuous and mutual critique is the patient.

Add to this that each hospital expects all its medical servants to be progressive and alert to every improvement of their art; that original research is encouraged, aided, and rewarded in a most liberal manner; that monthly business and annual scientific reports must be rendered, and the latter prepared for publication, that this work demands the undivided attention of the chief during from three to six hours daily, and you will become convinced that the high salaries of the medical chiefs are honestly and well earned. The return for the outlay is expressed by these terms: that the individual patient receives the possible maximum of daily and personal expert care of the highest order, and, further, that the interests of proper economy are continuously and scrupulously guarded. This explains the low cost of the maintenance of these institutions as compared with ours, notwithstanding the fact that all the employees, medical and lay, receive liberal, or at least adequate compensation.

Little has to be said of the assistants, as their status is very much the same all over Germany and Austro-Hungary. According to the acuteness of the service, there is generally provided one paid assistant for from 35 to 50 patients. Accordingly a service of 200 beds would have from four to five assistants. Their pay varies from one thousand to twelve hundred marks per annum, together with free quarters and board and a vacation of four weeks. Their term of service is indefinite, and they are not permitted to practise. They are appointed by the chief of the service with the approval of the medical directors, and can be dismissed by their chief. Usually they are picked out of the number of the volunteers, general merit and utility determining the choice. The oldest and most reliable one of them is the first assistant, and serves, when needed, in the capacity of substitute for his chief. On an average, the length of service of an assistant is three years. Ambitious men of means have served as long as ten years, that is, until they were appointed to a vacant chiefship.

Now let us compare and see how things work in our hospitals.

Before drawing this parallel, the question may occur to the curious student of human institutions, How is it possible that we, progressive Americans, have not hitherto grasped the advantages of this system? The explanation is historical. History shows that Europe has passed, several centuries ago, the stage of organic development in which we still find our hospitals; it shows, further, that the laws of evolution will inevitably lead us to the acceptance, with local modifications, of the principles here illustrated.

To study the history of hospital benevolence and organization abroad, we must turn back to the middle ages. We shall thus see that, with due allowance for changed external conditions, the process of internal development in their hospitals bears a strange and striking resemblance to that of our own institutions as they exist to-day.

There, too, institutions founded and maintained by voluntary effort were the first ones to appear, and medical attendance and nursing were gratuitous, having a more or less ecclesiastical character. For obvious reasons there, as well as here, the difficulty lay not so much in getting gratuitous medical service, as in securing unpaid nursing. This difficulty was so great and prohibitive, that we do not see large hospitals, in the modern sense of the word, appear, until this question of nursing was properly solved in the organization of the Order of Franciscan Sisters of Charity through Saint Francis of Sales, in 1610, by Madame de Chantal of Dijon in France. For a long time medical attendance at those hospitals remained really unpaid; that is, was considered only the subsidiary and secondary function of the "physics" or health officers of the city, or town, or province, or that of the professors of the medical faculties of universities. While these houses were small, the waste and abuses inseparable from such a régime did not attract sufficient attention to lead to reforms. As soon, however, as they assumed important proportions, it became evident that the happy-go-lucky ways of ordinary 'charity" could not further be trusted with the conduct of their increasing business. At the end of the seventeenth and the beginning of the eighteenth centuries the first large hospitals are seen to arise, with salaried medical officers paid to do hospital work, who also appear more and more frequently in the rôle of hospital managers. The remnants of this primitive form of hospital organization still survived, here and there, in small country hospitals of Europe, my own native town exhibiting such an example up to the year 1874 or 1875. To-day on the continent of Europe I believe it to be practically extinct.

The dogged conservatism of England has preserved this medieval phenomenon almost intact to this day, but its maintenance there, too, is becoming a matter of increasing difficulty.

We here in America have received this ancient form of hospital management from England, and in the primitive conditions of our colonial period this form, which had become obsolescent abroad, was the very thing we needed. It found here the rich pabulum of a newly broken soil, the rough-and-ready, resourceful spirit of a pioneer community, where general expediency was the determining factor, and where economic precision, perfection, and complete-

ness of results were not known and could not reasonably be expected. The conditions of existence in newly settled parts of our country are necessarily primitive, hence offer in many respects, curious parallels to, and resemblance with, the status of pioneer communities in medieval Europe. It is but natural that this form of hospital system, evanescent in settled conditions such as Europe now presents, should have had a late and remarkable revival in the United States. Hundreds, perhaps thousands, of flourishing institutions of this type have sprung up all through the union, and, where the conditions are and remain primitive, are doing excellent work. The drawbacks of this system, however, cannot but appear, and become glaring, where a primitive status passes over into a more highly specialized and comcomplicately organized form of communal life. Nowhere else on this continent has such a change become more apparent than just here in New York.

Let us now see how the work of our own hospitals is conducted. The city hospitals are governed by a board, nominated by, and responsible to, the Mayor. In the German and Mt. Sinai hospitals the basis of organization is a paying and voting membership, that, should abuse occur, may potentially any day demand strict account of its managers. As a matter of fact, however, all the business of the annual meetings is cut and dried beforehand, according to the will of the majority of the board.

The other hospitals are governed by boards that fill their own vacancies, and are thus practically responsible to nobody but themselves. In spite of the fact that all of them enjoy exemption from taxation, none tolerates supervision by the State. In all of them we miss an adequate representation of the medical element, a circumstance that is unnatural and vicious, and is the cause of many blunders. Some of them have carried their disdain of medical cooperation in their councils to an incredible extent. So, for instance, a large hospital had been planned and built, at great cost, on one of the most prominent sites of this city, and not once had the opinions of the medical men connected with that institution been asked for by their board of directors. As a matter of course, the building may serve as an example of how a modern hospital ought not to be built. This lack of mutual cooperation of the lay and medical elements is the rule, rather than the exception with us, and constitutes a great weakness of the system.

I take great pleasure in contrasting with this hidebound attitude the enlightened and wise policy observed by the trustees of Mt. Sinai Hospital, with which I have the honor to be connected. From the very first beginning of the undertaking of erecting their new hospital, a carefully planned and well organized form of cooperation was established between the medical officers, the architects, and the trustees. All fundamentals, such as the allotment of space, the location and shape of each building, the lighting, heating, and ventilation, were only disposed of after thorough discussion by lay and professional officers. The requirements of each of the medical, surgical, and special services were likewise agreed upon in common, the greatest consideration and liberality towards the professional standpoint being the invariable attitude of the trustees. The quality of the establishment is the highest form of testimony to their wisdom.

In many instances the real executive officer of the board is a poorly-paid lay superintendent, taken fortuitously from any walk of life, and lacking that amount of general and specific knowledge, and that suppleness and tact, that compel respect from above and give authority below. Deplorable conflicts between lay superintendents and medical men are therefore too numerous, and unfortunately deteriorate the common work to a very great extent. Commendable exceptions to this are to be noted in a few institutions where the superintendent is a medical man, and where domestic peace is the prevailing rule. The leading fact to be noted, therefore, in most of our hospitals is that the medical men, those who do the most essential work of the institutions, have no voice whatever in their government.

Let us now see how the work is done in the wards. The services of the visiting men and of the house-staff—excepting in some instances those of the pathologist—are gratuitous, and being a free gift, cannot be controlled with that strictness that is possible only under a contract with clearly defined duties counterbalanced by adequate pay. The managers are eager to secure the services of the most prominent men, that is men of an independent position. In return therefor they must accept what these prominent men are willing to give, the amount of actual services rendered diminishing in inverse ratio with the weight and caliber of the medical incumbent. A strict regulation of the visiting hours, a control of the amount of attention given to each individual patient by the visiting men are utterly impossible, the result being that the visiting men are virtually the consultants only of the house-staff, to whose immature knowledge and care is relegated the immediate and most important part of the ward-work. The visiting man rarely, if ever, pays the slightest attention to the making out of the diet-lists, the control of alcoholics, of costly medicines, dressing materials, apparatus, or surgical instruments, hence the utmost waste may go on, and often does go on, unnoticed, intermittently or permanently, and without effective remedy. The house-staff are there to learn medicine and surgery, not to learn to be economical, and to enforce continuously and successfully the desired degree of economy is a labor of such magnitude, involving so much loss of time, that nobody as yet has had sufficient hardihood to demand this additional service of the unpaid visiting men.

This lack of businesslike order and method is augmented to an incredible degree by the circumstance that many hospitals still tolerate an alternating service of the visiting men,—that is, that every three, four, or six months, one or more of the visiting men step out and are replaced by another set of men. Thus the system introduced by one is changed or totally abrogated by his successor. Comparatively small hospitals, containing not more than 200 or 300 beds, must therefore appoint a disproportionately large staff of visiting men, between whom the service is parceled out in weekly or monthly doles. Laudable exceptions to this are found at Mt. Sinai and Roosevelt. Add to this finally the perpetual change in the house-staff, every six months bringing in a new house-surgeon and physician, a new set of nurses, and you can only wonder that chaos and waste are no greater than they actually are.

But large as the waste is, much larger and graver is the detriment to the service proper by this universal unrest and lack of system,—a detriment that is most injurious to the patient. Surely the patient who trustfully enters our palatial hospitals is entitled to expect the very best that the century affords in medical and surgical achievement. Professional talent and good will we certainly have in great abundance but the system is such, that the patient cannot and does not get so much of the daily personal attention of the illustrious man, whose name attracts him to this or that institution, as he would get under similar circumstances in a well organized and salaried service.

It is only fair to state, and I fulfil a pleasant duty to my colleagues by saying, that most of them do the utmost that fairness can expect, many of them frequently sacrificing lucrative opportunities to their hospital work. But even so, the work they do is inadequate, because too much of what is the chief's work must inevitably be entrusted to an inexperienced, however zealous and clever, house-staff. Our house-staff bears, in these days of heroic and extremely active surgery, a burden of responsibility altogether too great for its young shoulders, and it is a great wonder that fatal blunders and mistakes are not of daily occurrence.

If they do occur, the overworked and inexperienced men of the house-staff cannot be justly held responsible; the visiting men cannot be held responsible either, for the acts of assistants over whom they have only a shadowy and brief authority. The real responsibility rests mainly on those men in the boards of directors who do not wake up to the necessities of the changed times and conditions.

It may seem harsh to throw most of the responsibility for existing mischief upon these men, who certainly have not created the prevailing system, but only have found and accepted it, and who, moreover, undeniably spend much money, time, and labor in forwarding the cause of hospital charity. But on closer inspection of the facts bearing upon the case it will become plain that this conclusion, though harsh, is at the same time just. First of all, it must be said that those who jealously reserve all power to themselves, must also be ready to bear all the responsibility; consequently they must not wince at just criticism when the system upheld by them proves to be faulty. And if the system is a faulty one, then it is their duty to recognize the fact, and to bestir themselves towards the right way. As they possess exclusive power, we must look to them, and to them alone, for relief.

It would be easy for any one of us old hospital men to go on for hours illustrating by actual occurrences the absurdities growing out of our decrepit hospital system. Let me give you one or two of the numerous examples that illustrate waste. It was ordered by a medical man closely connected with the government of the city hospitals, that for a month a tabulated account of all the materials used in all the divisions of that hospital be made out by the superintendent. The tables were made, and showed that enormous quantities of ethyl alcohol were being used in one of the medical divisions. Inquiry made to the visiting physician of that service brought to light the fact that he, the head of the service, absolutely ignored the leakage going on, day by day, no one knows how long. He referred the inquirer to his house-physician, and there the explanation was found. During a severe epidemic of typhoid fever, when almost every patient afflicted with the disease received several daily baths, to each bath a quart or more of alcohol was added as a matter of routine. Now this visiting man habitually orders in his private practice alcohol baths, and unconsciously repeated his habitual order at the hospital, where a conscientious house-physician carried it out to the letter. Of course the waste was instantly stopped.

My own house-surgeon once undertook to improve on the diet formulary. He considered the food served to the patients at breakfast and supper inadequate,—erroneously, because it was abundant, though monotonous,—and out of the fullness of his sovereign power ordered every man and woman to have an egg for breakfast and supper. This meant, for a service of 60 beds, 10 dozen eggs per day more than was necessary, 70 dozen per week, 280 dozen per month, and 3,650 dozen eggs per year. This, too, was stopped. The waste in costly dressing materials is incredible, and, as I have personally convinced myself, that on account of the constant changing of the house-staff, the only way to stop it would be to stand by and superintend the application of every dressing, a task which to expect of the unpaid visiting man would be unreasonable and absurd, and it would involve the daily expenditure of several hours of time.

To characterize these conditions, I may say that in its organization the American hospital is comparable to a water system, having one collecting and storing reservoir at one end, midway a certain number of distributing pipes, and at the other end a multitude of outlets of large and small caliber. The big reservoir is tight and usually well guarded by a magnificent body of expert financiers and business men, such as compose our boards of directors. Serious waste begins in the distributing pipes, which are mostly under the care of a medically inexpert superintendent. The thousand and one outlets at the other end have to-day no other guardians than the house-staff, composed of zealous young men recently graduated, possessing little practical experience in matters professional, none whatever in the economies of hospital, or, for that matter, any form of management. They are the ones to whose immediate and practically uncontrollable care and discretion is entrusted the distribution of everything the hospital authorities provide and pay for, and knowing the facts, no one can expect anything but careless waste. One of the greatest paradoxes of businesslike and practical American life is this absurdity.

The natural and only effective guardians of these thousand and one outlets, now standing wide open day and night, can and must be the men on the visiting staff, the chiefs of the services. But even these cannot accomplish anything unless their service is continuous and permanent, their responsibility strict and unbroken, and the great expenditure of time and labor exacted by their arduous task fairly compensated.

What the numerically magnificent visiting staffs of to-day cannot accomplish, two or three paid men would easily perform for each hospital; they would richly earn their pay by halving the total expense, and the patient, the governors, the medical men, and the public would all fare better.

That this plan is practicable with us is demonstrated by the flourishing condition of St. Luke's hospital, maintained at Bethlehem, Pa., by the industrial interests of the Lehigh Valley. It is governed in all its branches by one efficient medical director, who is well paid and gives the greatest satisfaction to his board of directors, to his patients, and to the general public.

The question is a very complex one, as every one knows who is familiar with the conduct of a modern hospital. It is fair to assume that all of those who are engaged in hospital work, lay as well as the professional, brings to it the utmost good will and the best intentions. But the incubus of a false system blinds many as to the true and unwelcome facts that are the cause of increasing difficulty, while those who see and wish to remedy them are utterly discouraged by the magnitude of the problem and by the fear of conflicting with personal interests. And yet, provided that the true diagnosis of the evil be correctly made, a gradual and non-revolutionary transition to a saner and better state ought to be found. It is vain to expect lasting relief from a material augmentation of income; the only rational way must be found by retrenchment. The magnitude of the task to him who shall have the requisite courage to attack this problem by the avenue of retrenchment can be realized by him only who knows how the very breath of

private and public life in these United States is unfriendly to the idea of economy. The Catilinarian method of subsistence heretofore in vogue—*"sui profusus, alieni appetens"*—is becoming more and more impracticable; appeals for more in order to dissipate more, are met by indifference and negation; the signs of a crisis are steadily gathering. Who will have the genius, force, and endurance successfully to meet the crisis by the application of critical remedies?

Incrimination and recrimination bandied about between the laity and profession will do more harm than good. The charge that medical men have no business knowledge and tact, that their management of hospitals is extravagant and impractical, is brilliantly refuted by the examples seen abroad. On the other hand, the precarious state of our hospitals may serve as a striking proof of the fact that the extreme predominance in hospital management of lay views, to the exclusion of a properly appreciated and respectfully considered medical participation, must lead, sooner or later, to certain bankruptcy.

Opposition to reform in the direction outlined by this paper must be expected from all sides. Medical men who complain that the hospitals are not converted into a free and general stamping-ground for every one having a doctor's diploma, will naturally be disgusted by further restricting the number of those who will have charge of hospital facilities. They must be shown, however, that the hospitals do not exist mainly for the indiscriminate benefit of the medical profession, but are here, first, for the benefit of the patients, and, secondly, for that of the community.

Restriction of the number of those who attend at our hospitals is the *conditio sine qua non* of economical reform, and is, moreover, urgently required to effect a betterment of the care for the individual welfare of every patient, a betterment which the prevailing system permits not.

Intelligent good-will and concerted action on the part of the hospitals must some day lead us out of the night of our discontent.

Before closing, let me thank you for the patience shown in listening to my remarks. Their purpose is not to attack anyone. It is rather a sincere attempt to uncover the cause of a grave and admitted malady, and to suggest a practicable remedy. It is the system only which is condemned.

That the remedy, "retrenchment," is unwelcome and uncomfortable, I admit; it implies the application of surgical measures, ever unpopular to and dreaded by those who need them most. Where else do you see a way of salvation? Soliciting and begging for more will avail not; the well grounded presumption of faulty management and waste must be removed from the minds of those who can give.

But I repeat, and do it confidently, that you do not need any outside help. I honestly believe that existing means are sufficient to bring about the reform needed.

---

## ESSENTIAL AND PAROXYSMAL TACHYCARDIA.*

By J. J. MORRISSEY, A.M., M.D.,

NEW YORK.

ADJUNCT VISITING PHYSICIAN ST. VINCENT'S HOSPITAL, VISITING PHYSICIAN ST. JOSEPH'S HOSPITAL.

THE following observations on tachycardia are supplementary to those which were published by the speaker some two and a half years ago in the MEDICAL RECORD, February 7, 1903, and embrace a review of the cases then noted, as well as additional facts concerning this very interesting condition.

We all understand how diverse the conditions are which may and frequently do produce rapid heart. In the living organism, with its interdependent relations, its complexity of structure, and intimate interaction of functional manifestations, it is difficult to conceive that when disease is established in one tissue or organ, however localized, it can continue without producing some perversion, both of structure and function in adjacent and associated parts. A morbid condition, in short, occurring in any region becomes thereby a disturbing factor in the environment of the surrounding area in which it tends to determine a secondary complication. The nature and severity of the latter will depend in great part upon the nature and extent of the primary disease, as well as on the relationship, structural and functional, that may exist between the original seat of the disease and the part secondarily involved. Thus it is a matter of common experience to meet with disturbances of the circulatory function, associated with, and attributable to a disordered digestion, where we find not only rapid heart, but cardiac irregularity up to complete intermittence, and even pains about the region of the heart often closely simulating angina. Surgeons, too, have reported that heart hurry frequently follows both minor and major surgical operations. Thus, Spencer Watson has reported a case of nasal polypi in which the pulse-rate was 120 per minute, the tachycardia being persistent. After the nostrils had been completely freed from obstruction, the cardiac trouble ceased. Excision of larynx has been followed by tachycardia. It has been suggested that this sequence ensued upon the division in the course of the operation of an abnormal cardiac branch of the superior laryngeal nerve, with functions similar to those of Cyon's depressor nerve. Dr. Toti, however, relates a case in which the patient developed intense tachycardia—160 to 180 beats per minute—thirty hours after the operation for the total excision of the larynx. He continued in that state for twenty-four hours and ultimately died from paralysis. If in this case the tachycardia was the result of the division of the nerve, it should have appeared immediately after the operation instead of being delayed thirty hours.

Numerous other examples of this phenomenon might be adduced to show the wide range of affections, both functional and organic, which develop, as it were, through intermediary causes, this sensitiveness upon the part of the heart.

But it is not with these illustrations, however interesting they may be, that we have to deal to-night, but with conditions closely allied with the nervous mechanism of the cardiac musculature, or depending upon functional causes whose area of influence extends over cardiac territory. First, then, let us be clear as to what we mean by tachycardia.

It may be classed under two heads, namely, Essential and Paroxysmal, and this classification may be subdivided into true and false. The true tachycardia, according to the speaker, finds its best illustration in permanent disease of the cardiac musculature, the false may be produced by causes far removed from the heart. There are certain definite peculiarities which distinguish true tachycardia from the evanescent "heart hurry" so frequently produced by the most trivial causes. (1) The attack is sudden in its onset, reaching its height almost immediately. (2) The patient may or may not be entirely unconscious of the great degree of palpitation. (3) There is generally a definite period covered by the attack. (4) The reversion to the normal condition is as sudden as the onset, the vestiges of the storm through which the patient has passed rapidly disappearing.

*Read at a meeting of the Section on Medicine of the New York Academy of Medicine, October 17, 1905.

There are a large number of people, and it may be safely said this number is increasing *pari passu* with the stress and strife of the twentieth century civilization, who are morbidly conscious of their heart's action, indeed of the functions of their cardiovascular system generally, or in particular parts. They feel flutterings at the heart, throbbings, flushings, pallors of the surface, disturbances of particular organs, noises in the vessels about the head, and apart from and in the intervals of these more definite sensations, they have a sense of the heart beating, and appreciate sometimes an intermission or a faintness in its action.

It is amongst the class of so-called "neurotics" that functional disorders of the heart so largely abound, a neurosis being defined as a functional, as distinguished from an organic disturbance in a nerve center, and the disturbance is generally manifested as a hyperesthesia.

Now some authors classify tachycardia as a pure neurosis, and for the sake of argument, let us admit that it is, but there are yet some unexplainable phenomena accompanying the acute development of the attack which would appear to remove it from the characterization of a pure neurosis. The attacks may persist for years with slight or prolonged intermissions. In some few cases they may follow the slightest subjective disturbance, in others they occur only when great mental agitation upsets the equilibrium of the system. In some patients there is perfect unconsciousness of the "heart hurry," while others complain bitterly of the ensuing distress. In the most typical cases the heart hurry has been observed to begin and to finish quite abruptly, as happened in a case of the speaker. Many people, especially women, suffer from persistent hurry of the heart, coming quite within the range of the lower degree of tachycardia, and it may be added in this connection that there is nothing to distinguish simple tachycardia from that which is the constant symptom of exophthalmic goiter, the rhythm and quality of the pulse being precisely the same. It is also to be remarked that there are cases which must be regarded as of a transitional kind, in which with no enlargement of the thyroid and with no more than a slight beadiness of the eyes, there are present the characteristic hurry of the circulation, cardiac murmurs, etc.; in other cases again, these circulatory phenomena precede the thyroid enlargement.

An abnormal excitation of the heart's contractions occurs as a very frequent, perhaps the most frequent, sequel of influenza. The tachycardia may be persistent for long periods, or it may be intermittent and accompanied by the other symptoms of palpitation. In some cases it occurs with or immediately after the initial fever, in others it manifests itself some weeks or even months after the original invasion.

We notice in the heart itself, during an attack, a decided accentuation of the cardiac sounds, and the presence of murmurs which rapidly disappear with the culmination of the disturbance. The action of the heart may be regular or arrhythmia may be present during the seizure. The cardiac dullness is measurably increased, acute dilatation rapidly supervening upon the beginning of the attack, and as quickly disappearing upon recovery. In cases of persistently rapid heart, the majority experience little or no discomfort. This is, however, quite in accord with our experience of essential tachycardia in general, for a person whose heart is beating 130 to the minute or more may be going about his usual avocation and claim he is quite well. The vasomotor tone of the arteries seems unaltered, the quickened action causes an increase of the tension within the artery, but the volume is reduced, the pulse is narrow, the arterial wall is not thickened. In the paroxysmal attacks dependent upon gastric disturbances, which frequently occur at night, we may find flatulence, nausea, gastralgia, and diarrhea, with short quick breathing, and a sense of failing heart. The heart hurry in this class of cases subsides when the stomach recovers from its disorder, though frequently there is more than one tract supplied by the pneumogastric involved, and in some cases one area disproportionately to the others. They are often accompanied by headache or interchanged with attacks of migraine, and may be indicative of one of the protean manifestations of a gouty diathesis. At any rate it may be safely said that dyspepsia stands in no defined relation with the degree of tachycardia.

This is clearly evidenced in the case of Mrs. M., 63 years of age, who for the past 25 years has had at intervals of two to three weeks attacks of tachycardia, in which the pulse-rate was said by the attending physician to be over 150. These attacks came on invariably between midnight and 2 A. M., and at first were attributed to indigestion, as they were accompanied by flatulence and great gastric distress, but without vomiting. Restrictions of diet and the usual remedies failed to relieve her, and after a time the attacks were unaccompanied by any indications of gastric disturbances. An unusually heavy round of social duties invariably precipitated an attack. After undergoing this heart hurry at more or less lengthened intervals for ten years, at the age of forty-nine there was an absolute intermission of one year without any change of environment or circumstances, her mode of life being practically the same. During the past three years tachycardia has returned, the attacks appearing about once in two weeks. She came under my observation about two months ago, complaining of pain in the right heel, with marked exacerbation on pressure. Under the administration of a saturated solution of potassium iodide, 15 drops 3 times daily, both the attacks and the heel-pain appear to have diminished. There is absolutely no cardiac disease discoverable in this case.

Tachycardia as to time may be classified as "short" and "long." The first accompanied with vertigo, epigastric distress, and at times a sense of cardiac expansion. The symptoms are mainly subjective in character. The pulse-rate may ascend to 200; in fact be practically unaccountable; it is not a gradual ascension, as if some slight interference with the inhibitory power of the heart was taking place, but rises immediately, while the resumption of the normal heart-beat may take place more slowly, the subjective symptoms, however, quickly disappearing. The "long" attack may cover a period of days, to the great distress of the patient, who may suffer seriously from the aggravated symptoms of cardiac failure, as dyspnea, cyanosis, and a feeling of impending death. Percussion demonstrates the presence of considerable cardiac dilatation, though the latter sign is more frequently manifested when the degree of tachycardia is slight. In a small minority of cases a permanent enfeeblement of the myocardium ensues, and then the dilatation may be lasting. Out of eleven cases (Bouveret) four ended fatally during the prolonged attack. In the remissions the patients suffer very slightly, though the fear of an impending seizure is constantly before them. The occupation of an individual does not appear to be a predisposing factor in the causation. The weak and the strong, the feeble and the robust, those who are engaged in mental occupation as well as those engaged in the more arduous labors of the shop and the factory are liable to suffer from this complaint. It is found more commonly between the ages of twenty and forty, and at-

tacks about equally both sexes. That it is also seen in those of advanced years, the following case will illustrate:

M. B., a woman of 70 years of age, came to me complaining of "heart disease"; she was of medium height, and of excellent physique for her years. Her family and personal history was negative except as to the conditions of her heart. She always had been active and energetic in her household, and was able to accomplish much except, as she expressed it, when her "heart beat fast," then she became confused, weak, dyspneic, and finally so exhausted that she was compelled to remain in bed for a day before feeling sufficiently able to resume her domestic duties. Not all attacks were of this aggravated character. At intervals of ten days or so she had suffered from slight attacks, which resulted in her retirement for an hour; assuming the recumbent position appeared to shorten the attack, or the fact may have been purely coincidental. She fully realized when the seizure was coming on by a feeling of numbness in the cardiac region—the calm preceding the storm, and then with almost cyclonic force her heart rapidly cleared itself, as it were, from its moorings, and began to palpitate with inordinate vigor. The attacks of dyspnea had no special connection with the tachycardia, as frequently she had to rest upon the street, but they were aggravated when the palpitation had lasted for a number of minutes. In some seizures, the attacks ceased almost as suddenly as they began, leaving her prostrated, in others they were prolonged for a number of hours. The pulse was 80, feeble, intermittent, and irregular. There was marked sclerosis present. While auscultating the cardiac region I suddenly heard the heart rebound, and then after a short interval, the pulsations increased. The patient asked to be seated. Her pulse count was 150, so far as could be estimated, a condition of delirium cordis preventing accuracy. Her eyes were staring, her face cyanosed, the peculiarly purplish condition of the lips demanding attention, while the perspiration was clearly seen on her forehead. Even before the administration of a stimulant, I felt the pulse stop and then, after a few seconds, resume its normal rate, the cyanotic hue at the same time disappearing. She was able to leave within an hour, though the prostration subsequent to the attack appeared extreme.

In this woman's heart a condition presumably of fatty or fibroid degeneration existed. The attack appeared to be of an anginoid character, though the closest investigation failed to show any sense of constriction or of pain. The clinical signs would appear to demonstrate fatty degeneration, though I am fully aware that the clinical diagnosis of that condition is not always borne out in necropsy.

Another case may be cited of a patient 40 years of age, with an acute febrile disease, due no doubt to influenzal infection. The heart became extremely dilated, the pulse-rate went up to 200, and there was great dyspnea. The physical signs showed that the extreme dilatation receded day by day until the 13th day of observation, when it was apparently normal. The rate of the pulse dropped from 200 day by day until on the sixth day it was 80, and afterwards 72. In this case an alcoholic neuritis was reinforced by an influenzal infection.

A woman whom I had frequent opportunities of seeing over a period of some weeks furnished some interesting details as to the probable cause of the tachycardia. She was 40 years of age, the mother of eleven children, and had never experienced any illness except that incidental to child-bearing. She was capable of doing, as she declared, a "good day's work," and had been interrupted in the pursuit of her duties only by attacks of palpitation. These seizures had supervened upon an accident occurring when she was eighteen years of age. In crossing a field she had fallen into an unused well, from which she was rescued with difficulty, some minutes afterward, in an unconscious condition. Physically she had not been injured, but the shock was of such magnitude as to produce an ineffaceable impression upon her nervous system. The attacks of tachycardia were very infrequent at first, occurring about once in three months, and independently of menstruation, pregnancy, or childbirth. They were also limited as to time, lasting but a few minutes and accompanied by a slight feeling of prostration, which rapidly disappeared. Without any definitely assignable cause, the attacks had lately increased, both as to severity and length. The patient attributed this to the systemic changes consequent upon the climateric, which may or may not have been the case. I saw her in two or three of these seizures, and though they were not so severe as in the first case mentioned, I believe the condition presented was entirely different in its nature.

The patient's normal pulse was 86, small, but of good arterial expression. There was neither intermittency nor irregularity. The apex beat was normally situated, and the systolic power of the left heart entirely efficient. In the first attack her pulse, from being normal, ascended immediately to 230, as nearly as we could estimate. Auscultation revealed a soft systolic bruit at the apex, and immediately confined to that situation, due undoubtedly to the acute dilatation present. The visible and palpable area of impulse was slightly increased and displaced to the left. There was no dyspnea, and but a slight suspicion of cyanosis. She complained of the palpitation and weakness, but otherwise was able to answer questions intelligently. The attack lasted about five minutes, the patient rapidly recovering and the pulse-rate resuming its normal character without any subjective symptoms.

Now these two cases represent to my mind two entirely different types of tachycardia, the first being produced possibly by myocardial degeneration, the second by profound shock to the nervous system. And though paroxysmal tachycardia is not associated with any clinically demonstrable disease of the heart, in three of the six cases which have come to post mortem myocardial disease was in evidence. If we consider that in these analogous disturbances of cardiac rhythm—tremor cordis and delirium cordis—there is practically always some form of myocardial disease present, we may admit that West's opinion, that the lesion of tachycardia is in the myocardium, is not without some force, as the failure to demonstrate some fault in the nerve supply of the heart does not prove that such does not exist. The great frequency of myocardial disease and the great infrequency of tachycardia show the latter not to be dependent upon the former alone. Nevertheless, myocardial changes in those cases, particularly occurring in persons of advanced years, may be a necessary, if not a principal factor in the production of tachycardia, at least so far as modifying the inherent automatic, and coordinate action of the myocardium is concerned.

We may, therefore, place the pathology of tachycardia in the region of theoretical speculation. Sufficient data have not as yet been furnished to establish it firmly on a scientific basis, but the limited amount of material at hand would show that tachycardia originates, not in one, but in several diverse changes.

The *treatment* of tachycardia has been unsatisfactory, as is to be expected where so many diverse conditions may produce similar symptoms. On general principles, I presume, more than with the

hope of accomplishing any definite good, digitalis has been administered. Where there is much dilatation, and yet sufficient potential capability upon the part of the myocardium to respond to the stimulating effects of the drug, something effective might be done between attacks. But digitalis cannot restore disintegrated cellular tissue, and the structural degeneration of the myocardium generally, in those cases in which tachycardia is found associated with myocarditis, advances to such a prohibitory extent that we can expect little from the most important drug in cardiac therapeutics.

In the case of which I had an opportunity of administering continuous treatment, and in which digitalis appeared to be of no avail, the fluid extract of convallaria majalis, in five-drop doses, four times a day, appeared to be somewhat effective, the patient claiming that it had the effect (1) of shortening the attack; (2) of lengthening the intermissions, and (3) of not producing the sense of constriction which followed the administration of digitalis. In a third case, which may be described as coming within the lower range of tachycardia, and in which there was marked arterial tension, with decided neurasthenic tendencies, I gave the bromide and iodide of potassium in combination, the first for its well-known sedative effect, and the iodide for its remarkably efficient action in dilating the peripheral arterioles, reducing the tension, and rendering the work of the heart less arduous.

In conclusion it may be stated that the treatment of tachycardia is that of the condition from which it arises, or with which it is associated; but we must remember (1) that essential tachycardia is not accompanied with indigestion; (2) that paroxysmal tachycardia and the forms of tachycardia accompanied by signs, no matter how slight, of Basedow's disease, are very frequently associated with dyspepsia; (3) that extreme cardiac arhythmia frequently occurs without any indication of stomach disease, and (4) that tachycardia in its various grades is, however, often but a symptom, a prominent expression of a neuropathic state which requires to be approached for treatment from many sides.

## THE SUBCATABOLIC MECHANISM INVOLVED IN THE ETIOLOGY OF COMMON COLDS.

AN ANALYTICAL SURVEY, BASED LARGELY UPON RECENT CONTRIBUTIONS BY THE WRITER IN THE FIELD OF MEDICAL BIOLOGY AND CHEMICAL PATHOGENESIS.

By HOMER WAKEFIELD, M.D.,

NEW YORK.

The following discussion of colds was inspired by a symposium on the same subject delivered before one of our New York State Medical Organizations about three years ago, in which I was greatly surprised to note that not one of the readers of those papers intimated the suspicion that any relationship whatever existed between the state of the distribution of the blood and the subject treated.

Four years ago, and in nearly every paper I have since written, I have emphasized the physiological significance and the pathological importance of serious deflections of the blood from the seats of oxidation, the capillaries of the periphery, to the splanchnic vessels, yet they have attracted but passing notice, never receiving the attention of many other passages of comparative minor import.

The present paper, by virtue of a detailed analysis of the pathology of colds, of the homologous nature of etiological factors and therapeutic agents, combined with a comprehensive application of the governing law of cause and effect, it is hoped will succeed in commanding the attention that its importance deserves.

Some idea of the importance of the recognition of the state of blood distribution may be conceived by recalling that the visceral venous stasis of general cardiac debilities, shock and collapse, are but exaggerations of conditions caused by blood deflections by cold. Even sedentation, with less pronounced perversions of circulation, is attended with serious pathogenic sequences, as is well known.

"Taking cold" is of such common occurrence, and its consequences are so varied and profound that the fundamental basis of the condition should be well understood and therapy founded upon it. Many a pneumonia could be aborted in its early stages, and many other diseases arising from this condition, thwarted by prompt measures of restoration of circulatory equilibrium.

"Taking cold" is a contributing or exciting factor, co-operating with all other factors of catabolic stasis, and subgrouped under suboxygenation, subalkalinity, and subcatalysis, classifications of the factors of oxidation and autolysis. As a contributing or exciting factor of etiology, taking cold or "a cold" plays important rôles in diseases, particularly that group known as "diathetic," but undoubtedly all diseases are unfavorably influenced by it.

Prefatory to what is to follow in the analysis of the mechanism of common colds, it should be stated that true colds are due to the unequal exposure of some part of the body to cold. The degree of temperature is subordinate to the state of inequality produced. In fact a cold may be produced by the extrinsic effect of either cold or heat, if sufficiently pronounced or abrupt to insure a localized action of definite heterogeneity from the balance of the economy. As an illustration, a cold plunge bath is not conducive to colds, even cold weather is not so productive of colds as changeable warm weather, and dry cold weather is not so conducive to colds as wet warm weather. The "green Christmas" with its humid and wet, changeable weather, has well earned its relationship with "a full graveyard."

However slight, a draft of air striking a localized part of the body is sufficient to produce a cold when its temperature is divergent from that of the balance of the body. When the body is very warm, especially if perspiring, a draft of very comfortable sensation produces a cold.

It is evident that some equilibrium of the body is disturbed, and this factor is divulged and explained by a discovery of the writer, hereinafter to be analyzed in the present relation.

It has been determined by the researches of Hill,[1] and others, that under the influence of superficial chill, the predominance of the blood is deflected from the peripheral vessels of the skin and muscles to the deeper (splanchnic) vessels, which possesses a very significant relation to the present subject. Complementary to this is the writer's[3] discovery that heat induces expansion and cold contraction, or, in other words, cold heightens, and heat lowers the specific gravity of protoplasm in general, not excepting that of the parenchyma. It is the writer's observation that the molecular weight or density of our parenchyma and all living protoplasm is increased by cold and decreased by heat. Cold is productive of high density, compactness, and tonicity, while heat induces low density, looseness of texture, flaccidity, expansion, dilatation, elongation, and atony. This is not a nervous effect, but a direct responsive reaction

of protoplasm, *per se*, as is attested by the fact that it is as marked in nerveless unicellular and multicellular organisms as in those of the highest types of nervous organizations.

A significant effect of heat upon the parenchyma of complex animal economies is observed in the dilatation of the blood vessels of involved tissues, and conversely is their contraction by the action of cold. This is particularly notable in the involuntary (unstriated) muscles and in cutaneous structures, which are not so directly contracted by and through nervous impulse as are the voluntary muscles. The condition produced by heat is one of a proportionate degree of flaccidity, atony, and what nerve men term "innervation." There is flushing, but sluggishness of circulation, and but a step removed from cyanosis. All such conditions of parenchyma are paralleled by dilated blood-vessels proportionate to the tissue rarefaction produced; the extreme condition being known as *vascularity* and *vascularization*, in general pathology.

The counterparts of heat and cold, in the production of the two conditions above described, are observed; of the former, in all factors of tissue suboxidation, viz., acidity, suboxygenation, subcatalysis, subautolysis, and more remote conditions so culminating, as irritation, fatigue, loss of sleep, worry, anxiety, etc. Conversely, conditions conducive to oxidation and catabolism promote the reverse condition, namely, density, contraction, tonicity, etc.

We have seen, however, that concurrent with the relaxation of heat and its equivalent factors, we have to deal with a state of hyperexcitability which is largely due to the accumulation of metabolic products, the oxidation of which is now in a state of stagnation and exaggerated irritation, thus produced by a degree of stimulation or irritation which would normally be deficient for the same responsive effect. For example, it is a common observation that anyone in a state of relaxation from heat, fatigue, etc., is particularly prone to take cold, and is inordinately sensitive to the slightest variation in temperature, and to drafts which do not otherwise even create discomfort.

Now let us analyze the common occurrence of "taking cold." We shall see that primarily a condition of disequilibrium is produced. A subject, during a period of normal heat balance, stands for a time in water, mud, or on damp, cold ground, the water facilitating the conduction of the lower temperature to the feet; a state of contraction of the tissues of the lower extremities is attained, the blood is ejected from the peripheral vascular areas to the more roomy reservoirs of the splanchnic veins, which readily dilate to receive it, with the result that a pernicious splanchic venous stasis is produced, concurrent with a capillary and arterial blood deficiency in the extremities and with an inevitable suboxidation of the dependent tissues in the extremities.

I have described in a previous paper,[3g] a definite and orderly biologic-retrogressive series of physical manifestations through which tissues pass, as they are progressively deprived of the factors of physiological oxidation (catabolism) which may be summed up as follows: (1) increase of irritability; (2) transient contraction (pain), tetany; (3) imperfect (breaking) contraction (tonic, succeeded by clonic contraction); (4) relaxation, flaccidity, rarefaction, expansion and elongation, loss of ability to restrain the transudation, first of water then of the blood (catarrhal and hemorrhagic); (5) disorganization; (6) colloidation; (7) disintegration.

The first stage, of hyperesthesia is observed in subcatabolized nasal mucous membranes, by sneezing; in the larynx by coughing, scraping, hawking, etc., followed by more or less painful tension or real pain. Flaccid, gelatiniform rarefaction, characterized in membranes and tonsils by spongy expansion and in the uvula (soft palate) by atonic elongation, is a common manifestation; watery mucous, mucopurulent, and finally purulent transudations and transitions, hemorrhagic expressions being more rare. Atrophy of parenchyma and interstitial thickening represent the late and chronic features. These are governed by the following law: This law I have described in an earlier paper,[3e] namely, the order in which the tissues succumb to subcatabolism: *Those tissues which require the highest, greatest catalysis, first succumb when the catalytic processes are retarded or arrested, and those tissues which are most difficult of digestion first succumb when the autolytic process is derelict.* Thus the epitheliums first succumb to oxidate deficiency, and autolysis is first observed deficient in fibrous tissue. The contrary of this law is as stable as the original, *i.e.* familiar examples of subcatalysis in these cases are observed in the highly organized and metabolically active structures of the eye and ear, which early and markedly exhibit the phases of the subcatabolic retrograde series, even to hemorrhagic expression, principally in the choroid and retina; and to painful catarrhal and purulent affections of the middle ear.

Modern observers are observing and recording, as never before, the intimate relations of eye and ear disease to those fundamental and predisposing conditions of subcatabolic origin, which are generally recognized as the diathetic group, and which so frequently find expression in eye, ear, and glanular disease, when the subcatabolism is locally magnified in the aggregate supraclavicular regions, by the complication and cooperation of chill. The softest, the most flaccid tissues, physiologically, first succumb to the several stages of subcatabolism. The parenchyma is first to indurate and succeed to the catarrhal, hemorrhagic and atrophic stages, while the interstitial is the one which thickens and hypertrophies from the same cause.

Let us take for illustration, a so-called cold in the head, not uncommonly contracted by a draft during the night, when the balance of the body is under cover, and often during warm or changing moderate weather. A contraction of the peripheral vessels, as above described, is first attained, the blood is largely determined to the splanchnic veins. The tissues of the head experience a suboxygenation, and as a consequence the mucous membranes of the upper air passages, or the lymphoid tissue of the tonsils or palate become indurated or increase in flaccidity, according to the areas involved, the interstitial thickening being observed when the original induration fails to disappear, thus it is observed that the original parenchymatous induration is superseded by a permanent fibrous hypertrophy.

The gum indurations and hemorrhages of scurvy, infantile scurvy, purpura, diabetes, etc., mercurial and other poisonings, are illustrative of the general subcatabolic sequences in soft tissues.

Paralleling the action occurring in parenchymatous tissues with that in the protoplasm of rudimentary organisms, we seem justified in identifying two catarrhal stages in the biological retrograde series of manifestations above mentioned, one at an acute stage of cell inspissation, during the climax of the stage of contraction, and the second when inability to restrain water transudation is attained, thus marking acute and chronic "catarrhal" conditions. Hydrothorax represents such a condition in the serous membranes. Edemas and general dropsy are representative of such conditions, locally and in general always resulting from some one or more factors of

subcatabolism, above named. Cardiac and renal cases not excepted.

Prolonged effects of colds are due to the perpetuation of the subcatabolism by the fact that both the tissue reduction of the suboxidation and the resulting maldistribution of the blood are slow of recovery.

The maldistribution of the blood has, from time immemorial, been treated by hot or cold air and water baths, cold and hot packs, massage, etc., all of which act more or less directly to that end. The most modern and best mode of therapy correcting this condition is undoubtedly the hypodermic administration of such general condensing and contracting agents as ergot (Livingston's method[2]) and preparations of the suprarenal glands, both of which act directly as protoplasmic constricting agents, and in therapeutic doses are selective for expanded tissues, owing to their hypersensitiveness, and through it, to their precocious response to environmental influences; in the same manner that such tissues exhibit a predisposition for cold, above mentioned.

Syndromes, with manifestations identical with those caused by unequal temperature exposures, are quite as frequently produced in certain individuals by other factors of subcatabolism, as acidities of foods and beverages, gastric and intestinal fermentation, etc., localized suboxygenation, and suboxidations, which from one or another intrinsic or extrinsic accident of life's activities, are productive of unequal sequences upon the body tissues, and hence upon the distribution of the blood.

Most practitioners are familiar with the manifestations of colds which are not traceable to "exposure," but very readily so to an acid stomach, a "heartburn," great flatulence, burning (acid) stools, or what not. Membranes indurate and exhibit manifestations similar to colds, when plugged or deprived of air by deformities, etc.

Tissues relaxed and rarified by subcatabolism or by any of its etiological factors, become correspondingly vitally depleted and disposed to bacterial infection. Thus medical observers note that, for example, the (lymphoid) tonsils are first and most infected, as they first and most succumb to factors of subcatabolism.

Tissues vary in their collagenous content, and thus as their cells, in most advanced subcatabolism, attain to disorganization and disintegration, we observe correspondingly greater collagenous exudations from mucous membranes, and more purely colloid protoplasm from lymphoid tissues. Bacterial infections appear to be most marked in lymphoid tissues.

Bacteriologists have recently determined in an extensive series of observations, that the pneumococcus is present in liberal quantities and in the active or virulent form, in the mouths of healthy and normal individuals, yet there is no pneumonia, even in a prodromal stage.* This only explains the sources of infection when pulmonary subcatabolism obtains. Healthy persons are almost constantly inhaling and exhaling tuberculous and other pathogenic organisms, yet they make ingress in subcatabolic areas only.

The multiplicity and the cooperation of several different factors of colds have been responsible for rendering the etiology obscure and difficult of analysis, and this brings us to the rôle of diathesis, dyscrasia, idiosyncrasy, and susceptibility[3g] in the pathogenesis of this syndrome. Moreover it suggests the several diathetic conditions, as aggravated by colds, acting in the rôle of exciting causes.

Areas suffering catabolic stasis being prone to infection, colds thus lead to pneumonia, phthisis, etc., secondary to laryngitis, pharyngitis, bronchitis, etc. An individual with a so-called scrofulous, catarrhal, or similar diathesis, is said to be predisposed to colds. The truth is they are etiological factors of catabolic stasis, and the superinduction of one upon the other, augments the original effect by the added effect of their cooperation. Gastrointestinal autointoxications, acidities, fatigue, mental and physical, from work, worry, anxiety, grief; oxidase (catalytic) debilities, incident to sexual excesses and vices, and the critical periods of sexual life, as puberty, menstruation, pregnancy, lactation, the menopause and sexual obsolescence of organs; all forms of suboxygenation, incident to vitiated air, respiratory defects, cardiac and circulatory deficiencies and obstructions, play their parts as antecedent collaborators of colds and their ultimate effects.

We have seen that the essential faults of colds have been more or less successfully treated in the past, but with only a vague idea of the real nature of the pathology of the condition, and less so of the etiology.

The maldistribution of the blood has been powerfully affected and restoration of equilibrium more or less accomplished by subjecting the entire body to even temperatures of hot or cold water, mud or air baths, and areas suffering most from anemia have been benefited by localized hyperemias accomplished by local irritation (the so-called counterirritation).

Oxidation has been accelerated by oxygen inhalations, alkalinity has been increased by the internal administration of alkalies, and most frequently of all that popular catalytic agent, quinine, has been utlized, but all of them largely empirically, and based upon the clinical observations of benefit derived. Comprehensive prophylaxis against sources of acidity and other factors of suboxidation was unthought of, and, in fact, changes of temperature, only have received any degree of consideration in the rôle of etiology.

*The recent demonstrations of the common existence of the pneumococcus in the mouths of healthy persons, under the auspices of the New York City Department of Health, is only confirmatory of previous observations. (See Roger, "Introduction to the Study of Medicine," N. Y., 1901, p. 134.)

**A Prehistorical Vesical Concretion.**—Elliot Schmidt has discovered in a prehistorical sarcophagus a vesical concretion. It lay between the two iliac bones of an adolescent sixteen years old. The age of the tomb has been estimated at 7,000 years or more. Examination of the vesical concretion showed that it consisted exclusively of uric acid, with an envelope composed of phosphates.—*Revue Française de Médecine et de Chirurgie*

# THE TEST-FECES; THEIR VALUE IN THE RECOGNITION OF INTESTINAL DISTURBANCES TAKING THEIR ORIGIN IN OTHER PARTS OF THE DIGESTIVE TRACT.*

By HEINRICH STERN, M.D.,

NEW YORK.

Before entering into the particulars of the subject I wish to state that its comprehension is materially facilitated by consulting my article "The Determination of Intestinal Functions by a Test-regimen" in the Medical Record of July 8, 1905.

"Test-feces" are the intestinal contents, irrespective of amount and consistency, which are discharged between thirty and forty-eight hours after ingestion of known quantities of the food habitually consumed by an individual. As we need a readily adaptable standard of comparison, it is obvious that we are compelled to disregard to a certain degree the individual demands, and that, practically, we must be satisfied with "test feces" which are the result of a test-regimen representing quantity and quality of foodstuffs habitually utilized and well borne by a majority of the populace. Consequently the amount of total calories for each kilogram of bodyweight during the twenty-four hours, when at rest, should be thirty. Of these, 35 per cent. should be generated by carbohydrates, 45 per cent. by fats, and 20 per cent. by proteids. The amount of liquid for each kilogram of bodyweight should be 35 c.c. A detailed test-regimen from which test-feces of a person weighing seventy kilograms may be obtained, will be found in the above-mentioned article.

The test-feces are to be submitted to a physicochemical, a macroscopical, and a microscopical examination for the particulars of which I again refer to my former communication.

Not every disturbance of intestinal function takes its origin in the intestines nor has its seat therein. The impairment of intestinal activity, indeed, is often the consequence of the inefficiency of digestive organs other than the intestines. The organ mostly at fault in calling forth intestinal disturbance is the stomach, but the liver and the pancreas are also frequently at the bottom of intestinal difficulty. The test-feces may disclose—with more or less certainty—the location of the primary disorder. The importance of the recognition of the original disorder will be appreciated when the therapy of a pertaining instance is taken into consideration. A rational treatment, of course, is to be aimed at the original disorder and not at a secondary phenomenon.

*Intestinal Disorders of Gastric Origin.*—That many of the transitory and milder intestinal disturbances arise on the basis of a gastric affection is a fact almost too well known to merit discussion again at this late day. We know that duodenal catarrh is never an independent affection, that certain forms of diarrhea are the direct result of gastric motor insufficiency, that obstipation is often the outcome of, or at least concurrent with, hyperacidity, that free alvine discharges may be set up in conditions of diminished gastric secretion, and that intestinal indigestion and hyperputrefaction are not infrequently dependent on a non-patent pyloric orifice.

In the most discrepant intestinal disorders of gastric origin Schmidt always found in the feces, after administration of a test-regimen, microscopically distinguishable débris of connective tissue. He maintains that this débris, as found in the feces, is a reliable index of the inefficiency of gastric function, and that a gastric affection stands at the foundation of all instances of intestinal disturbance in which the feces exhibit undigested particles of connective tissue.

For reasons of greater practicability and to avoid the deficiencies of Schmidt's test-regimen, I have been employing in my practice for almost a year a modification of the latter, as outlined in my previous article. This test-regimen, which conforms more to the American usages, contains in twenty-four hours two hundred grams of meat in the form of very rare beefsteak, while that devised by Schmidt exhibits, for the same period, but 125 grams of beef, almost entirely raw, but chopped. The test-feces obtained from my test-regimen, more normal for our purposes than Schmidt's so-called "normal-feces," invariably showed by the microscope small amounts of connective tissue particles. This was the case in all test-feces submitted to microscopical examination, even if they came from individuals who were entirely free from gastric disturbance.

While the presence of fragments of connective tissue in small amounts in the test-feces is probably without clinical significance, that of large amounts of débris of this character undoubtedly is significant. There is no gastric impairment in which the property of connective tissue digestion remains unimpaired. Why this should be the case is directly explainable by two eventualities only, namely, in hypochlorhydria and in non-patent pylorus. No reason can be assigned for the appearance of such considerable amounts of débris in the presence of hyperchlorhydria, atony, gastrectasia, and other pathological conditions of the stomach.

Contrary to Schmidt, I have never observed test-feces containing pathological amounts of undigested connective tissue, which were entirely normal in all other respects. Such feces are hardly ever well formed, but are mostly mushy and lumpy and possess an offensive odor. Their color seems always somewhat lighter than when the gastrointestinal tract is in a normal condition. However, as Schmidt has already observed, the effects of stomach disease upon the bowels are not uniform. The intestinal affection may prove to be a slight functional disturbance, or may appear as a complicated catarrhal process. The specific pathological condition of the intestines depends upon the nature of the gastric affection, its duration, the habitual nourishment, the irritability of the intestinal tract, etc. According to the extent and duration of the secondary, the intestinal, affection, other pathological elements may be found admixed with the fecal masses. The exhibition therein of large amounts of connective tissue fragments, however, invariably points to the gastrogenous causation of the intestinal disturbance, no matter how completely the phenomena due to the latter may overshadow all subjective gastric symptoms.

*Intestinal Disorders of Hepatic Origin.*—Disturbances of intestinal function are much more rarely the consequence of hepatic than of gastric disease. Almost all hepatogenous intestinal affections are caused by disordered biliary secretion.

We may conclude that biliary obstruction stands at the bottom of the intestinal disorder when the test-feces (1) are excreted in very large quantities; (2) when they present a grayish-white color; (3) when the sublimate test is negative; (4) when considerable masses of the ingested fat reappear; (5) when very large amounts of fatty acid flakes can be demonstrated; and (6) when there are no pathological amounts of other food débris present.

There is no such multiplicity of intestinal affections of hepatic as of gastric origin. There are but few pathological states of the intestines which may be caused by hepatic and biliary insufficiency. The principal one among such affections is probably catarrhal

* Read at the meeting of the New York State Medical Association on October 18, 1905.

enteritis, the acute as well as the chronic form. Enteritis called forth by hepatic disease may be so slight that a catarrhal inflammation cannot be demonstrated. The various localized forms of enteritis, as duodenitis, jejunitis, ileitis, and colitis, cannot be diagnosed from the test-feces alone. The more or less irritating free fatty acids, occurring in considerable amounts in the stools of biliary obstruction, may be the direct cause of the enteritic condition.

*Intestinal Disorders of Pancreatic Origin.*—When the pancreas is completely disintegrated—which is not a frequent occurrence in man—it is easy enough to recognize this fact and to associate therewith any subsequent intestinal disorder. In the great majority of instances of pancreatic disease, the glandular structure is not sufficiently impaired to give rise to any recognizable intestinal disturbance. The same may even be the case when the pancreatic duct does not permit passage of the glandular secretion. For these reasons, partial pancreatic destruction and secretory difficulties do not interest us on this occasion.

When total degeneration of the pancreas has ensued, enteritis with more or less pronounced catarrhal inflammation, supervenes as a rule. The absorptive qualities of the intestines are also usually interfered with. As a consequence of the latter, the individual loses in body-weight and becomes gradually emaciated. Atrophic conditions of some parts of the intestines may be a tertiary phenomenon.

Of course, attention to pancreatic destruction may be drawn by the glycosuria which frequently follows in its wake; this phenomenon, however, stands outside of our present consideration.

The test-feces, in the face of pancreatic degeneration, contain similar amounts of fat, as those in biliary obstruction. They differ, however, from the latter (1) by not being excreted in such large amounts; (2) by exhibiting normal quantities of biliary pigments; (3) by containing large quantities of muscle débris which are macroscopically recognizable; (4) by frequently presenting its fatty contents in the form of globules of neutral fat, when examined under the microscope; (5) by the occasional exhibition of putrefactive changes. Sahli's as well as Schmidt's methods for the recognition of partial pancreatic insufficiency are, the former too uncertain, the latter too impracticable, to be of any real merit. For the present, it is well for us to know that the examination of the test-feces, as performed by me, does not reveal any incipient or but slightly advanced pancreatic disease.

## MEDICAL EDUCATION.

By E. CASTELLI, M.D., L.M. (of Dublin),
NEW YORK.

When we leave the medical school with a diploma and enter the practice of our profession, we generally think that all we have to contend with in our career are the scientific difficulties and the commercial competition. It is a great mistake, for the principal difficulties are to be found in ourselves. Are we always fitted for the profession we have selected? Many times we are not. Generally, the student selects medicine as he would any other profession, without much consideration of the mission he is about to undertake. The law of every country seems to pay no attention to the fact that the rôle of a physician in society is a vitally important one— that he is a tremendous factor for good—with possibilities for more harm than we care to acknowledge, and, in consequence, the equipment of the physician should be better controlled.

To be worthy of the name, the physician must have special intellectual, physical, and moral qualities. The lack of any one of these is a menace to society. Let us pass in review the different and necessary requisites:

*Age.*—He must be a man when he enters his professional career. Is it not almost ridiculous to see a mere lad of twenty-two years, at the bedside of a nervous woman whose condition has been brought on by usual and necessary functions of life, or to see him attempting to minister to a man of the world, of family, of age, and experience, whose physical condition should not only be properly diagnosed, but the subtlely powerful influence of a dominant mind and personality brought to bear on the case? What can this boy on the threshold of his profession, whose only life has been the college life, whose only knowledge has been gained from books—what can he do for the patient that needs moral support and assistance as well as drugs? What do we know at twenty-two of the world of business, of its worries, of family responsibility, of moral duties, of the multitudinous complexities and perplexities of harassing life? Necessarily very little. A man of twenty-two cannot have lived much, while a man of thirty might, if he is intelligent. It is the knowledge of life that increases our sense of observation, and the suffering that rounds out, develops, and deepens our spirit of intuition. So our fuller intelligence, intuition, and character are the results of age, and the requisites of a physician whose mission is to deal with the psychological as well as physical needs of mankind.

We must not forget that the nerves preside over all our functions, that any shock to the nervous system produces derangement, while to assist it produces repair. We must not forget that suggestion is the principal factor of equilibrium of the nervous system, and the dominant element of repair in case of illness. Need we, then, be surprised that the Christian scientists have some successes? What is their point? It is simply to restore the equilibrium of the nervous system, and free it from the fears and worries of illness. While they are absolutely ignorant as far as pure medical science is concerned, we must confess they have appropriated the main psychological point of our profession. Our experience, intelligence, personality, may all be a potently suggestive power, and assist the patient in restoring the lost equilibrium; our medical skill must do the rest. Pretending to cure a patient by relying only on the action of the drug, is an absurdity. Let us be frank; let us tell the truth; it is time we brought into the medical education the moral element; it is time not only to ask, but demand of the profession to elevate its standard. Christian science, and all the "pathies," are but manifestations of our deficiency in one of the principal elements of our mission; they are the proof of our lack of knowledge, and if we do not change our methods and improve, we perish. We are struggling against a resistless tide. Mankind to-day thinks more, knows more, needs more, is more. The struggle of life is more complicated and the nervous system consequently is under a heavier strain. But mankind appeals for help and finds often only the dry physical scientist prescribing without helping, because we seem to forget the supremacy of the nervous system in all our functions. We must first reestablish nervous equilibrium and then prescribe. Our power of absorption and assimilation is a direct emanation of the nervous system, so our first duty in dealing with a certain class of patients is to know the mental conditions that have in part created, in part been created, by the physical ones. The

patient who realizes that he is understood, and so has faith in his doctor, has accomplished the first step toward recovery. The patient of to-day is often a nervous wreck, and his physical condition is the direct result of the lost equilibrium of the nervous system. We see, to-day, patients continually changing physicians, seeking something they do not find—relief. We all know of people who, having been treated by dozens of physicians, finally found what they sought, after having consulted a Christian scientist! It is a humiliating confession for our profession, but it is the truth; and while we may be proud of the scientific progress we have made, we must look still further for the professional requirements in which we are deficient. Look back on the physician of long ago; he was not only a scientist, but a man of culture, of worldly experience, of high psychological attainments. To-day, we are merely scientists: we derive our education from medical books alone. For that reason we are deficient, and society is slowly but surely proving it to us. It is time that we comprehended fully that we must be better equipped for our profession. The problem is a serious one and must be solved.

*Sex.*—To this argument there is only one question to ask: Is woman fitted for the profession of medicine? First of all she cannot have the worldly experience of a man; her sympathetic nature is a product of feminine weakness, but not of character; her worldly knowledge is generally gained from hearsay, and not experience. If married, and with children, she is absorbed because maternity intensifies her reason for existence, and as a natural and inevitable consequence everyone and all things become a secondary consideration the day on which she becomes a mother. The natural tendency of the woman is to lead a life of dedication to someone, husband or family, but not to humanity at large. When unmarried and deprived socially of needed experience, she may devote herself to humanity at large, as a result of this impelling craving she has for affection and dedication, but once married, the entire world is represented by her husband and children. The woman becomes a philanthropist only under three circumstances: When married to a philanthropist—because of her devotion to her husband's ideas, when she has lost that which she loved, and when she has failed to secure that which she desired. Stanford University would not exist to-day, if a mother had not been deprived of her child; the university is a monument erected to the memory of a lost one. A man's philanthropy, that of Carnegie, for example, has a broader significance, viz., the thought of humanity at large.

Take into consideration all the immense number of women doing philanthropic work, follow them in their career, and you will see the majority of them giving up this universal benevolence the day on which a husband and family are given them. It is not an indication of weakness or inconsistency of the woman's nature, but the incontrovertable proof of the wise consistency of nature to her laws.

Why should we consider a woman other than she is, or different from that which nature, by her physical conformation evidently intended her to be? Why should we try to thwart nature by making of the woman an exotic production? What would we say if asked to take her place in the economy of nature and the world? Manliness in a woman inspires as much contempt and ridicule, as womanliness in a man! But, aside from all considerations, one important factor of woman's nature that makes her unfitted for great achievements in the medical world, no matter how intelligent she may be, is her physical condition. A woman is systematically infirm during seven days of the month, that is to say, during nearly one-fourth of her life she is normally ill, and in consequence unfitted not only for our profession, but for any other in which clearness of judgment and suggestive power have as a foundation a physical equilibrium. The woman during seven days of the month is mentally and physically in a depressed condition. I have lived long in English hospitals where the number of women medical students is very large, and I have lived in a British lying-in hospital, where nine women physicians—six British and three Canadians—were in attendance. I always observed that a certain amount of carelessness, more or less marked, in the performance of their duties, a certain amount of nervousness and indecision before the solution of a diagnostic problem, occurred in the period that other signs declared to be the usual monthly crisis.

All women take their burden as a necessity, they endure more than their physical strength admits, simply because self-sacrifice is the woman's conception of duty. But, when these women that have endured so much, enter married life, they bring with them the marks of the past physical and mental strain that inevitably reflects itself on children and health. We physicians, generally, do not study the social condition of the woman's past life, and do not put it in rapport with the present one, when she comes to us as a nervous and physical wreck, and when she brings us weak and debilitated children. If we should carefully study these circumstances, we would find that strong children and physically prosperous families have as substrata, mothers that have lead normal home life.

In saying this, I have not the slightest intention of even implying that professional women are not useful, even though accomplishing their duty under unfavorable circumstances. There are probably few physicians having such a high conception of the profession as our women colleagues. I meet them every day and everywhere; at the bedside of the sufferer, at the clinical laboratory, at the social gathering, and at the scientific one, and I necessarily admire them; but this does not destroy the fact that if they achieve distinction in the profession, it is only at a mental and physical price, which it is a pity any woman should be compelled to pay. The spirit of abnegation and the will power of the woman when imbued with the conception of her duty, are such that she will suffer or die rather than fail to accomplish her conception of it. I admire these qualities in the woman; they are the born attributes of the sex, the qualities that Napoleon thought to be indispensable patrimony for the education of a great nation. "Give me the mothers," he said, "we need them to make good citizens and a great nation."

Napoleon, apart from any other consideration, was certainly one of the greatest connoisseurs of human nature; he knew that self-sacrifice, abnegation, conception of duty, were the natural qualities of the woman, and she only could instill them in children. Women can make nations stronger than men; it is not a paradox, it is an axiom. I think all men can acknowledge that the good in them came from their mothers. So let us render unto Caesar that which is Caesar's; let us protect society by dissuading from the suicide of her best element. A woman in the profession is a martyr from the day she enters it as a student, to the day in which she abandons it. She is forced every day of her life to compromise in the struggle between her natural tendencies and her assumed duty. While I acknowledge that she can do and does good in her profession, I think she does much harm by depriving

society of her natural help, and by making herself physically and psychologically deficient.

*Physical Qualities.*—The Latin motto, *mens sana in corpore sano,* expresses better than anything else that normal physical conditions are the substrata of harmony between animal and intellectual life. A sound organism is a necessary requirement in our profession, not only as a factor of equilibrium of all our systemic functions, but as an example to our patients. By sound organism I mean an organism kept sound by the fact of leading a rational life. In dealing with our bodies we are compelled to acknowledge that illness is the result of broken equilibrium in the rapport between the different functions of our body; an excessive or defective power of absorption, an excessive or defective power of elimination of the product of waste, an overstrain or sluggishness in the function of the nervous system, etc., are the real causes of illness. So, in order to benefit humanity, in order to be consistent with the things we say, we must make our own atmosphere an atmosphere of physical rationalism. Example leads the masses; as we expect an officer to be of example to his soldiers, a general to his officers, a pastor to his congregation, so we must expect a physician to be the example of physical rationalism to his patients, and to all those knowing him. I witnessed an amusing incident a few years ago, while attending one of the Paris clinics. A young peasant from the suburbs came to Paris to see Professor D——, *chef de clinique* in one of the best-known hospitals in France. He had been ill during the last six months with gastric troubles, and his country doctor had advised his going to Paris to consult Professor D——. He came one morning to the clinic, and presented to me the card of introduction from his doctor and asked me when and where he could see the professor. I told him that the professor was just finishing his tour in the wards, and would return to the hospital consulting room in a few moments. While I was speaking, the professor appeared at the end of the hall and walked towards us. "There is the professor," I told the peasant. "Go in the waiting-room and wait for him; when your turn comes you will see him." The peasant looked toward the end of the hall with the open-eyed curiosity of country people when waiting a great event. The professor passed, bowed, spoke a few words to me, and went towards the consultation room. The peasant said: "Is that the professor?" "Yes," was my answer. "Then," said the peasant, "there is no use in my seeing him; he is a sicker man than I am, and if he is such a good doctor, he would cure himself; he can't do me any good." The professor was a thin, pale, emaciated man, and to the ignorant peasant it seemed irrational that a man so famous as a health restorer, could not be in better health himself.

We are nothing but interpreters of nature; we are the connecting link between the struggling world and nature; when the organism is in opposition to the laws of nature, it loses the equilibrium of its physical functions. The physician is called to re-establish the lost equilibrium. What is there to do in case of illness but assist the natural processes of repair? For twelve years I have not taken medicine, not because I am unusually strong, or because I do not believe in drugs, but simply because, knowing myself, I keep my physical functions in their rational routine. I am sure the day will come in which the physician will be called as teacher in the schools, and asked to teach the rules of physical rationalism to students. That period will be the commercial crisis of the profession, as those manifested in other branches of human activity when new ideas or new discoveries make superfluous the old ideas and old methods. But it will be only a momentary crisis. When the machine substituted hand labor, thousands of laborers were left starving, but when the machine became a part of our commercial life, it gave occupation to millions of laborers. Our profession, old as it is, has not yet reached this crisis. While it has scientifically made progress, socially it has not done so. Social evolution has come into the field of religion, of social economy, of politics; why not in the profession of medicine?

We must admit that a better education in the rules of hygiene and physical rationalism would diminish sickness, and the unthinking might say it would restrict the field of usefulness of the physician. On the contrary, we shall then be far more necessary; we shall be called only when ordinary medical knowledge has not been sufficient to prevent sickness; only in those cases in which many of us today are compelled to ask for consultation, for the advise of those whom we consider the best. Some time we shall all be compelled to be the best, because elementary knowledge of medicine will be the patrimony of all.

*Intellectual Qualities.*—As a natural consequence of the requirement of medical evolution, the physician must be an intelligent and cultured man. Intellectuality appeals to mankind as physical strength appeals to animals. Culture is the right arm of the physician. We can suggest and help, not only because we have solid scientific foundation, but also because of other things we know. Culture means knowledge of mankind, and knowledge of mankind means power.

*Moral Qualities.*—These do not require discussion. We should have the highest moral conceptions. To have great and good moral qualities is an achievement of high evolution and perfection, and for that reason we must consider an inferior moral standard as a condition of incomplete development, and consequently as a condition susceptible of improvement. Only in this way can the physician be that which he should be—the most tolerant of men, a man whose faith in mankind never wavers, who never permits his poise to be disturbed by the unworthy things of life or its disappointments, a man who believes in doing good and does it. To be extremely tolerant is an indispensable requisite of our mission, a requisite that can only be attained by high moral education. We see every day too many things susceptible of the criticism of the so-called moralist, but we should not criticise. We must know that we are immoral when we follow our instinctive natural tendencies, and consequently immorality is nothing else but lack of control of our instinctive tendencies; in other words, immorality means weakness, and as such must be considered and forgiven.

Having explained my ideas on medical education I may ask myself if this ideal type of physician is possible to create. I acknowledge that it is not easy, but I know, also, that something could and should be done to improve our class, our profession.

The solution of the problem is involved in the great one of the selection and education of the medical student, a problem that only physician and legislator together can solve.

**Malta Fever in South Africa.**—P. D. Strachan believes that it is not generally known outside of South Africa that there is a disease apparently identical with Malta fever endemic in certain parts of the country. He has studied seventy-two cases presenting the clinical features of this disease.—*British Medical Journal.*

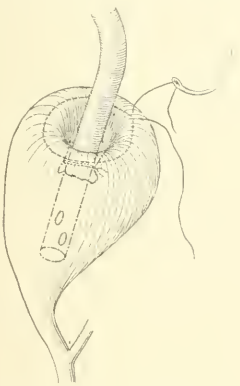
## VALVULAR CLOSING OF THE GALL-BLADDER AFTER OPERATION.

By H. E. ROCKEY, M.D.,

PORTLAND, OREGON.

PROLONGED leaking of the bile after either cholecystotomy, for calculi or drainage for inflammation, is one of the annoying features of gall-bladder operations. This was unduly so when the gall-bladder was fastened to the skin, thus making a complete epithelial lined canal, which not infrequently left a fistula that required a plastic operation to close it. The gauze collar of Murphy did much to obviate this, but it had its disagreeable features, and we gladly abandoned it for the purse-string suture of Mayo, which was a most decided step in advance.

I have now to offer a method which not only shortens the period of leaking, but in many cases prevents it altogether. It consists in a second purse-string of catgut placed beyond the first, thus invaginating the gall-bladder around the drainage tube and forming a valve. The first purse-string, which should be of No. 2 catgut, is inserted with a curved needle completely around the border of the incision. The drainage tube is now introduced to a depth of about two inches and the sutures firmly tied, taking care to turn in the



edge so that the peritoneal surface comes in contact with the tube. The second purse-string, which is to form the valve, is introduced by short stitches, which must not pierce the mucous coat, at a distance of from one-half to one inch beyond the first row. In a large gall-bladder a long valve may be made. If the gall-bladder is short, a half-inch valve around a tube that is not too large will often secure immediate closure. After this circular suture has been inserted, the tube is pushed inward a little as the suture is firmly drawn around the tube and tied. This forms a valve, acting on the same principle as do those of rubber in the interior of pneumatic bulbs. If properly constructed, the action is as positive. On the removal of the drainage tube, the intraabdominal pressure acting through the wall of the gall-bladder secures its immediate closure. After the valve suture is tied, the gall-bladder is attached to the peritoneum by a few stitches of fine catgut and the abdominal wall is firmly closed, superficial drainage being made by bringing the ends of the sutures of catgut from the fascia out alongside of the tube.

The drainage tube should be fastened to the skin by anchor stitches of silkworm gut, to prevent the tension on the purse-strings and consequent puckering of the valve. This is best done by passing a silkworm gut stitch at either side of the tube and tying a small loop above the first knot. A similar tie and loop with silkworm gut is made around the tube about one inch from the skin. A safety pin is then passed through the three loops, thus holding the tubes firmly in place. This simple device of loops and pins is a most important addition to drainage tubes, not only in the gall-bladder, but in the urinary bladder as well. A firm dressing is applied and a bottle is suspended from the bandage over the tube. The only attention that this will require for a week or ten days, is to empty the bottle often enough to prevent its running over. If it is properly adjusted the patient will seldom spill it, and the dressing will remain clean.

In about ten days the tube may be removed. In most cases the valve closes immediately and there is no leaking. In others there is a little leakage for a few days, but even in these, the ordinary period is much shortened. A strap of adhesive plaster may be drawn across the opening in the skin. The cutaneous sutures, which may be of either silk or silkworm gut, should remain for a few days longer. Union in vertical incisions requires longer time than in transverse incisions, and there is some tendency to separation if they are removed too soon. When the gall-bladder is much thickened, and especially if it is hard and contracted, this plan of closing cannot be used, but a gall-bladder thickened and soft from recent inflammation will, if capacious, make a good valve. The drainage tube should not be too large, otherwise the valve will not close immediately. A tube the size of a No. 30 F. sound is large enough. I sometimes use a No. 14 E. catheter. The additional purse-string for the gall-bladder valve requires but a moment of time, which is well compensated by the speedy and clean recovery that follows.

**The Triad of Hutchinson.**—C. F. Marshall draws attention to three of the chief signs of hereditary syphilis—interstitial ceratitis, malformations of the teeth, and deafness—which were especially studied by Hutchinson. This authority was the first to show the frequent coincidence of these symptoms, and also their causal relationship with hereditary syphilis. Interstitial ceratitis has also been named parenchymatous, in order to distinguish it from the superficial forms. It usually affects both eyes, but seldom both at the same time. The disease is of slow evolution. The whole duration may be from six to eighteen months. This affection is most common between the eighth and fifteenth years, though it is said to occur even in utero. Difference of opinion exists as to whether it is caused exclusively by hereditary syphilis, or whether it may also occur in the acquired form. The general treatment is that for syphilis in general. Syphilitic deafness is most common in hereditary syphilis at the same period when ceratitis usually occurs. This affection is usually bilateral. It is commonly associated with subjective noises in the ear, such as buzzing and hissing, and also with vertigo. Its pathology is not determined. It is usually rebellious to treatment. Hereditary syphilis is the most common cause of deaf-mutism. Various lesions of the teeth affecting both the first and second dentitions are caused by hereditary syphilis. This disease affects the teeth in two ways—by retarded evolution and by arrested development and malformation. Various types of dental erosions are noted, several varieties of which may occur in the same subject. Caries often attacks syphilitic teeth at an early age. White furrows are sometimes observed on these teeth. Irregular implantation of the teeth and malformation of the jaws are common in the subjects of hereditary syphilis, the most usual type of the latter being prognathism of the lower jaw. This prevents the inclusion of the lower teeth within the upper, and causes prominence of the chin. Like other signs of hereditary syphilis, dental erosions generally affect the first child more often than the later ones.—*Treatment.*

# MEDICAL RECORD.

*A Weekly Journal of Medicine and Surgery.*

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, December 2, 1905.

## THE HEALTH COMMISSIONERSHIP OF NEW YORK CITY.

ACCORDING to newspaper gossip, Mayor McClellan does not intend to reappoint Dr. Darlington as Health Commissioner of the city. We do not know why the Mayor does not wish to reappoint the Commissioner, and we do not even know that Dr. Darlington is not to be retained, but the mere rumor of his removal will serve as a text for some reflections on the evil of the present system of political appointments to the Health Board.

There are few positions of greater responsibility than that of health officer of a large city. In his hands is literally the power of life and death. The world shudders in reading of the Russian massacres, yet an incompetent or a corrupt Health Commissioner in New York may be almost directly the cause of as many deaths in this city in a single summer. The duties of Health Commissioner in this city call for the possession of talents of no mean order. The incumbent must be of unimpeachable honesty to resist the many and great temptations to "graft," of inflexible will to oppose the assaults of political leaders seeking preferment for their followers, possessed of executive ability of a high order to control the bureaus of his department and get out of each and every one of his subordinates all the good work of which they are capable, endowed with sober judgment combined with alertness, to enable him to act quickly and rightly in an emergency, and, last, but not least, he must be a sanitarian, a man of medical training, familiar with all the problems of public health, and able to sit in judgment on the acts of any of the specialists working in his department. Such is the ideal Health Commissioner for New York or any other large city. The ideal, like all ideals, is probably not attainable once in a century, but that it could be approached more nearly than it has usually been in the past is not to be denied. It is preposterous that a position calling for the possession by the one who fills it of such an aggregation of unusual qualities should be in the category of rewards for political services. Yet that is what it has been, with a few notable exceptions, ever since the office was created. We need not go back more than a lustrum to find an example of the evils of such a system, but we would have to go back many lustra to find an example of a truly ideal appointment to this all-important position.

The appointment of the present Commissioner two years ago was bad, and the fact that he has done far better than anyone believed at the time he would or could do is no disproof of this statement. His predecessor had been an efficient officer, and had had the experience of two years to fit him for the duties of his position. But he was dropped incontinently, and a new and inexperienced man, a practising physician, untrained in sanitary science, was put in his place. The new man proved himself to have honesty of purpose and executive ability, and has agreeably disappointed the medical profession of the city by the way he has conducted his department. During the two years of his incumbency he has gained experience, and is now, we doubt not, a much better sanitarian, theoretically and practically, than he was when he entered upon his duties. But now, according to the political gossips, he is to be dropped—perhaps to make way for some more active worker in the "cause"—but even if the new man is as good as Dr. Darlington was in the beginning, the whole process of learning at the expense of the health of the city will have to be gone over again.

We are not in Mr. McClellan's confidence, and he may have in mind the appointment of some man nearly approaching the ideal, to whom to entrust the health of this city—there are such in the country, and in this city—but unless he improves very markedly on the average of his appointments of two years ago, he will wrong the city. The MEDICAL RECORD holds no brief for Dr. Darlington and does not endorse all he has done as Commissioner during his term; but the administration of his department has been growing steadily better as he has gained experience, and unless the Mayor also has learned from experience and has grown in political righteousness, we fear a change in the Commissionership will not be to the advantage of the city. The Health Department of New York is exceptionally favored in having unusually competent heads of bureaus, who have been retained under successive commissioners of varying degrees of efficiency, but they have been retained, during some administrations at least, only because the Commissioners did not dare outrage public opinion to the extent of dismissing them. That is the only reason why we have not suffered more than we have in consequence of the present political system of appointments, but there is no guarantee that some bumptious appointee may not, some bright day, turn them all out and get a set of incompetent political heelers in their place.

The system is rotten, however innocuous may have been its workings in the recent past. We hope the Mayor will do what he can to mitigate its evils by continuing the now experienced Commissioner in office, unless perchance he succeeds in finding a better man for the place. But, whoever may be the appointee, the fact remains that the present system is bad; for the health of this great community should not be at the mercy of a mayor elected by a political party and with political debts to pay.

## LOBAR PNEUMONIA AS A SECONDARY DISEASE.

PNEUMONIA has increased to such an extent during recent years that the situation has come to be viewed with alarm, not only by the medical profession, but also by the municipal authorities. Public commissions have attacked the problem from various standpoints, but if we are to judge by the preliminary report of the New York City commission as an example, very little practical knowledge has been con-

tributed by this means which will aid in either the prophylaxis or the cure of the disease, and we suggested not long since that the general practitioner who treated many cases successfully might be consulted with advantage in this matter.

It is claimed by many that pneumonia is a self-limited disease, neither to be aborted nor cut short by any therapeutic means at our command, yet several methods of treatment have been attended with sufficiently satisfactory results to warrant the belief that something can be done to cure, or at least to modify the disease. Most of the remedies employed are symptomatic, and very few are directed against the pneumonic process itself, if we except the antipneumonic serum, the efficacy of which is still *sub judice*. It is quite evident that intelligent treatment of any disease must necessarily depend on a recognition of the etiological factors which underlie the latter, and in the case of pneumonia we are by no means certain that we have found the true cause. The pneumococcus of Friedlander has been accepted, in part at least, as the pathogenic factor, although it has been found in the buccal cavity and other portions of the respiratory tract in perfectly healthy individuals, and it apparently becomes endowed with a special virulence only when there is present a lowered power of resistance or a stimulus is supplied by some other organism. It has also been noted that the classical symptoms of pneumonia are accompanied by other conditions, and among these especial significance has been ascribed by M. W. Brinkmann, in an article in the *Journal of Advanced Therapeutics*, to distention of the stomach and intestines, with or without enlargement of the liver and spleen. The arguments brought forward to account for the clinical phenomena and the pathological processes which characterize the disease are marked by ingenuity and simplicity, but although they are suggestive in a certain sense, they will scarcely be accepted as sufficiently convincing to explain all the aspects of the pneumonic symptom complex. Respiratory difficulty is an early and prominent symptom of pneumonia, which is accounted for by Brinkmann by a reduction in the capacity of the chest cavity due to the upward displacement of the diaphragm by pressure from below. This necessitates an increase in the number of respirations in order to compensate for the lessened degree of lung expansion. When the capacity of the lung is finally reduced to such an extent that the necessary amount of residual air is encroached upon, the pneumatic support for the organ is removed to the same extent and the pressure is likewise diminished on the delicate capillaries which surround the pulmonary vesicles. The minute blood-vessels then become distended and their walls grow very thin, so that an exudation of serum and leucocytes results, which continues until the cavity is sufficiently plugged to afford a support for the walls of the vesicles and their surrounding capillary network. Brinkmann interprets this as a conservative process which prevents tears of the vesicles, hemorrhages, and a possible collapse of the lung, and also serves to account for the other symptoms of pulmonary inflammation, so-called, viz., the pain and circulatory difficulties.

The pulmonary condition being thus assumed to be entirely a mechanical one, the treatment should be directed towards the relief of the upward pressure on the diaphragm, so that the physiological expansion of the lung may be restored. Brinkmann holds that by this means not only is the fever reduced and the general condition of the patient improved, but he claims to have observed an absorption of the pulmonary exudate within two or three days after the alimentry canal has been brought to a normal state. An abundance of fresh air and the avoidance of nitrogenous foods are the *sine qua non* of his method of treatment, after the bowels have been cleared satisfactorily.

The insistence upon fresh air, unloading the bowels, and the avoidance of taxing the digestive system are points of undoubted value in the management of a case of pneumonia, but the success following the institution of such treatment is no argument in support of the theory we have just noted, the condition being of course found with many other acute infectious diseases, accompanied by a rise of temperature and more or less gastrointestinal disturbance, the relief of which always exerts a beneficial effect on the patient. The error in this, as in many other instances, has been to mistake the effect for the cause, and we still await a solution of the pneumonia problem which is capable of closer scrutiny.

---

## The Effects of Certain Bacteria and Their Toxins on the Heart Muscle.

Attention was directed by a number of writers during the early part of the last century to the possibility of a pathological process involving the myocardium during the course of an infectious disease. These observations were limited, however, to macroscopic findings, and it was not until Virchow's researches in this field were published that we learned that the true cause of the cardiac weakness in typhoid fever, for example, could be found only in the parenchymatous changes which take place in the tissues of this organ. The condition of the heart in diphtheria was next studied, and from the observations made since then we now know that a variety of pathological processes may develop during or after an infectious disease, which are characterized by alterations in the muscular substance, including fatty or albuminoid degeneration of the fibers, atrophy of the latter, or a change in the form and shape of their nucei or of the interstitial connective tissue. A few years ago Tallquist studied the effects of streptococci and their toxins on the heart, and more recently M. Björksten ("Arbeiten aus dem Pathologischen Institute der Universität Helsingfors," vol. 1, Nos. 1 and 2) has carried on a similar investigation, dealing with the effects produced by a variety of other bacteria. For this purpose rabbits were employed, and the bacteria were injected directly, or filtrates of bouillon cultures were employed. The species included *B. coli communis, B. typhi abdominalis, Pneumococcus,* and *Staphylococcus pyogenes aureus.* As a general thing the subsequent examination of the hearts of the experimental animals disclosed isolated patches of degeneration in the muscular tissues, either waxy, hyaline, or parenchymatous, and usually limited to single fibers. The most noteworthy fact was the apparently uncertain and irregular character of these changes. The longer the animal survived the invasion of the disease, the more marked became the interstitial changes and the less prominent the degenerative changes. The injection of the living bacteria into the animals was also found to be more productive of extensive alterations in the cardiac tissues than that of the filtrate of

bouillon cultures. A fact of considerable interest is that after infection with all the species used except the staphylococcus, but few changes were to be observed in the immediate vicinity of the bacteria themselves where they had settled in the tissues. The staphylococci were usually the centers of small abscesses. The direct involvement of the heart in degenerative processes during the course of infectious diseases does not appear to be as extensive as we have often been led to believe, and the symptoms referable to this organ, as well as the lesions noted, must be referred to another source.

### Depletion by Means of Saline Purgatives.

Saline purgatives are used to lower the blood pressure and thus prevent the rupture of a blood vessel, and consequent apoplexy, or to prevent further extravasation in a case in which the vessel has already burst. Lauder Brunton says that the regular use of aperients is especially necessary in gouty persons with contracted kidney and high blood pressure. How far their utility is to be ascribed, however, to their direct effect in lowering the blood pressure, and how far to the removal of waste products which might raise the pressure, it is impossible to say. The utility of purgatives after apoplexy has occurred may be doubtful, and though usually administered, they probably do no good if the arterial tension is abnormally high; purgatives, especially the salines, lower it, as the sphygmographic tracings show. When a considerable quantity of serum is withdrawn from the intestinal vessels, the blood pressure is necessarily diminished elsewhere. Free transudation from the blood-vessels of the intestinal canal lessens the amount of work which the kidneys have to do, and, if these organs are hyperemic, removes the congestion. Saline cathartics are, therefore, important remedies in the treatment of renal and cardiac dropsy. Free purgation also influences the condition by reflex action. The lessened hyperemia of the kidneys, the diminution of the blood pressure, and the reflex stimulation of these organs, resulting from the action of the purgative, are frequently followed by greatly increased activity of the renal function. Saline purgatives probably have their greatest use, however, in the treatment of gouty individuals. Their action has recently been made the subject of investigation by MacCallum, who concludes that the purgative is caused by an increase in peristalsis and by increased secretion of fluid into the intestine, both of which can be directly observed. The investigator is also of the opinion that even when these salts are introduced into the intestine, they must be absorbed into the blood before they can produce their purgative effect, and that they affect the intestine by increasing the irritability of the nerves and muscles, as Loeb has suggested. Their action in producing less solid feces is not due to the prevention of the absorption of fluids from the intestine, but to the production of an increased secretion of fluid into the intestine.

### Open Wounds as a Factor in Scarlatinal Infection.

The danger of scarlatinal infection through an open wound has been quite universally recognized. In many instances, however, the cases reported as surgical scarlatina are probably erythemas due to vasomotor disturbances or to the absorption of toxic material from wound secretions. The genuine cases must be separated into those in which the infection is simply coincidental, usually taking place before the wound is made, and those in which there is a true inoculation, where the wound serves as a portal of entry for the infectious material. A number of undoubted cases of the latter type are on record, among the most recent of which are two reported by Charles Herrman in the *Archives of Pediatrics*, October, 1905. One little patient remained free from the disease although he was constantly among the other members of the family who were ill with scarlet fever, until he received an extensive burn of the arm. The latter was neglected, and not even covered by a protective dressing, and in thirty-six hours after the injury the child developed a scarlatina which ran an ordinary course. The wound was covered with a dirty exudate, but healed as soon as the rash disappeared. The throat symptoms were not marked, and the submaxillary glands were not enlarged. In the second case the path of infection was through a vaccination wound which had been similarly neglected, and in this child the same exceptions to the usual symptoms were noted. The period of incubation in both of these cases failed to correspond with that usually assumed as characteristic of the disease, but there is no doubt that it depends very largely not only on the virulence of the contagious material and the susceptibility of the particular individual, but more especially on the place and mode of entrance of the specific contagium. It is evident from this and similar case reports that the shorter and more direct the route, the more rapidly the virus enters the circulation and the shorter the period of incubation. It also seems that although an invalid may be immune to infection in the ordinary way, he can readily contract the disease by direct inoculation through an open wound.

## News of the Week.

**Medical Examiners of New York State.**—At a conference held in Albany between representatives of the State medical boards and State medical societies, for the purpose of discussing the advisability of substituting a single State medical board for the three now existing, it was decided to retain for the present the plan of having three boards of three different schools. In the matter of the combined baccalaureate and professional course of seven instead of eight years leading to the degree of M.D., the progress made during the past year was approved, and the conference appointed a committee to prepare a syllabus acceptable to the medical colleges of the State, and which should be the foundation of an elective course, to be introduced into the junior and senior years of the colleges.

**The Edward N. Gibbs Memorial Prize.**—The New York Academy of Medicine announces that the sum of One Thousand Dollars will be awarded to the author of the best essay in competition for the above-mentioned prize. The subject of the essay shall be, "The Etiology, Pathology and Treatment of the Diseases of the Kidney." Essays must be presented on or before January 1, 1907. Each essay must be in English, typewritten, designated by a motto or device, and accompanied by a sealed envelope, bearing the same motto or device, which shall contain the name and address of the author. No envelope will be opened, except that which accompanied the successful essay. The Academy reserves the right, according to the direction of the donors, not to award the prize if no essay shall be deemed worthy of it. The Academy will return the unsuccessful essays, if claimed by their respective authors, or by authorized agents, within six months. An essay must show originality in order to obtain the prize. The competition is open to the members of the regular medical profession of the

United States. The original of the successful essay shall be the property of the Academy, and, according to the deed of gift, will be published in its transactions. The essays must be transmitted to the Committee of the Trustees of the New York Academy of Medicine on the Edward N. Gibbs Memorial Prize, 17 West 43d Street.

**Tuberculosis Sanatorium for Long Island.**—The trustees of the Long Island Open Air Sanatorium, to be erected near Medford, L. I., have issued an appeal for funds. The sanatorium will be for the open-air treatment of consumptives, and, as it will receive no help from the city, people interested in the cure of tuberculosis are asked to contribute. The sanatorium will be for the use of patients from Brooklyn and Long Island. The estimated cost of the land, building, and equipment is $50,000.

**A Course in Sanitary Engineering at Trinity.**—The faculty of Trinity College will offer next autumn a new course in sanitary engineering; it will be a branch of the general course in science now offered. The course is designed for students who desire to unite with the fundamental engineering branches a knowledge of those phases of chemistry and biology which relate to the problems of public health. The fundamental requirements of the course are four years of chemistry, three of biology, and two of civil engineering.

**Football Fatalities.**—A newspaper estimate of the serious accidents to players occurring during the present football season, places the deaths at nineteen, and the seriously injured at one hundred and thirty-seven. Ten of those killed were immature boys of seventeen years or less, but three of the victims were seasoned collegiate players. Body blows, producing internal injuries, were responsible for four deaths, concussion of the brain claimed six victims, injuries to the spine resulted fatally in three cases, blood poisoning carried off two players, and other injuries caused four deaths. Among the injuries that have not resulted fatally are: Broken collar bones and shoulders, 19; broken legs, 31; broken arms, 9; fractures of some portion of head, 19; broken ribs, 3; spinal injuries, 3; concussion of brain, 3. It is supposed that if complete records from all parts of the country could be obtained that the total number of casualities of more or less serious character, would be greater than 1,000.

**The Tuberculosis Exposition** was opened in the west wing of the American Museum of Natural History, Seventy-seventh street and Central Park West, on Monday evening of this week. Health Commissioner Darlington delivered the opening address, and was followed by Morris K. Jesup of this city, and Talcott Williams of Philadelphia. The idea of the exposition is to show, by means of models, photographs, charts, and diagrams, the methods which are being adopted in this country and Europe to prevent and cure consumption. There are models of sanatoriums which are in use in the different States, as far west as Colorado, and in Canada. Chicago has exhibited models of her hospital buildings. Pennsylvania also has a fine exhibition, and New York State shows a model of the tuberculosis sanatorium at Raybrook. The manner of caring for the tuberculous in tents on Blackwell's Island is shown, and there is also a model tenement house, in miniature, alongside of which is a model of one of the dark rooms, which the new law is trying to do away with. The exhibition, which is free, will remain open until December 9.

**Mismanaged Public Baths.**—In its recently issued annual report, the New York Society for Improving the Condition of the Poor asserts that the management of the public baths in this borough is grossly insufficient. The baths are closed at 8 instead of 10 o'clock in the evening, the water supply is deficient in some, valuable space is not utilized in others; one has remained uncompleted for months, although it could easily be finished in a week; the payroll and repair accounts for all baths are unnecessarily high; men are carried on the payrolls for months and months before the opening of new baths; nearly one hundred attendants are paid for services at the floating baths for weeks after these baths are no longer used; and from twenty-nine to thirty-nine men were paid last winter, ostensibly to sit around and watch fifteen floating baths, stored in one place.

**The Jewish Fair,** for the raising of funds for the Jewish Hospital of Brooklyn, was opened in the Forty-seventh Regiment Armory on Monday evening of this week, by Governor Higgins.

**A Marine Laboratory for San Diego.**—Through the persistent efforts of Prof. Ritter of the department of zoology in the University of California, San Diego, Cal., will soon have one of the most complete marine laboratories in the West. The San Diego Marine Biological Association, composed of many of the wealthiest and most influential men of that city, will endow the new institution with a sum sufficient to produce an income of $10,000 a year, besides building a large laboratory, museum, and aquarium, with a full equipment of apparatus. The system of work will be of like character to that of certain important astronomical stations, and a regular staff of experts will be employed.

**A Dogless Town.**—Owing to the death from hydrophobia of a little girl in Hackettstown, N. J., the town authorities decided to exterminate all the dogs in the place. The dog that caused the child's death, it was learned, had bitten about fifty other canines, so that no less radical measures seemed safe. In two days seventy animals were killed, and it was expected that the remaining thirty or more would be promptly discovered and sacrificed.

**A Physician Rewarded.**—Dr. Heber Jones, president of the Memphis Board of Health, has been presented with a purse of $10,000, subscribed by a large number of citizens, in appreciation of his successful efforts in maintaining a prohibitive quarantine during the recent yellow fever epidemic. Dr. Jones was compelled to give up his practice temporarily, owing to the exacting nature of his duties.

**Tax on Nostrums.**—The Commissioner of Internal Revenue on November 24 issued a circular, defining the duties of druggists and manufacturers, relative to patent medicines containing large amounts of alcohol. This circular, which is addressed to all collectors of internal revenue, is supplementary to the order issued on September 12 last, when the Commissioner ruled that all dealers selling patent medicines which contain spirituous liquor as a chief ingredient must pay the federal tax, as retail liquor dealers. It was also held that the manufacturers were liable to the payment of the special government tax. The order of September 12 was to become effective on December 1 of this year, but protests were received from a number of manufacturers and dealers, declaring that they had on

hand large stocks of the so-called medicines, that they acquired them in good faith, and that the imposition of the government tax would cause them to suffer great loss. Accordingly, Commissioner Yerkes has directed that the rule be not applied to manufacturers until January 1, 1906, and not to druggists and other dealers until April 1, 1906. For several weeks the International Revenue Bureau has been analyzing many patent medicines believed to contain alcohol or spirituous liquor as their chief ingredient. The analyses have not been completed in all cases, but a partial list of the medicines which fall within the terms of the Commissioner's order has been made public by the Bureau, and the articles on the tabood list can no longer be handled without the payment of the special tax.

**Increased German Taxes.**—In order to meet the ever-increasing expenditure for the army and navy, the German government proposes to levy heavy additional taxes on beer, tobacco, cigarettes, and cigarette paper

**Ewald Festschrift.**—In addition to its regular issue the *Berliner klinische Wochenschrift* on October 30 published in its usual form a Festschrift, dedicated to Prof. C. A. Ewald, the senior editor of the journal, in honor of his sixtieth birthday. It contains over forty scientific contributions from friends and former pupils, among whom are Professors von Leyden, Senator, and Eulenburg, and Drs. J. C. Hemmeter, Max Einhorn, Salkowski, Jürgensen, Posner, von Hansemann, and W. C. McCarty.

**Opposition to a Sanatorium.**—The local Board of Supervisors has been petitioned by forty taxpayers and property owners of Newburg, Washingtonville, Mountainville, New Windsor, and Blooming Grove, Orange county, to reconsider its action of last summer in giving permission to the city of New York to build a sanatorium for consumptives at Otisville. The petitioners fear that the dairy interests of the region would be injured by the presence of the institution in Orange County.

**Election of Hospital Staff.**—The medical staff of Blessing Hospital, Quincy, Illinois, at a recent meeting, elected Dr. Kirk Shawgo, physician in charge; Dr. Wm. S. Knapheide, surgeon in charge; Dr. John H. Rice, gynecologist in charge; Dr. Melinda C. K. German, obstetrician; Dr. Clarence A. Wells, anesthetist; Dr. Frederick M. Pendleton, oculist and aurist, and Dr. George E. Rosenthal, pathologist.

**A New Tuberculosis Camp** is to be established near Blue Island (Illinois) for the benefit of Chicagoans suffering with this disease. Mrs. Edward L. Gaylord has donated 160 acres of land to make the institution one of the most modern of its kind in this country. She will also provide a fund for the maintenance of the camp. The preliminary equipment of the institution will cost about $5,000.

**Verdict for Druggist.**—The Philadelphia cutrate druggist who was suing collectively several associations of druggists, on the ground that they were rendering it difficult for him to get stock, was awarded $20,738 damages on November 26. The suit was brought for $100,000.

**Antivaccination in Kansas City.**—The authorities of Kansas City, Mo., have declared against compulsory vaccination, and by repealing the former ordinance have rendered the measure obligatory only when the disease is epidemic.

**Texas State Homeopathic Medical Association.**—At the annual meeting of this society, held at Dallas, the following officers were elected: *President*, Dr. Walter C. Herzil of San Antonio; *Vice-Presidents*, Drs. V. C. Bowers of Greenville, and Walter L. Mitchell of Galveston; *Secretary*, Dr. J. F. Bass of Austin; *Treasurer*, Dr. Lloyd B. Pollock of Fort Worth.

**Pee-Dee Medical Association.**—At the annual meeting of this association, held in Florence, S. C., on November 1 the Society of the Sixth Councillor District was absorbed by the older organization. The following officers were elected: *President*, Dr. J. L. Napier of Blenheim; *Vice-Presidents*, Drs. James Evans of Florence, J. S. Dusenberry of Conway, Lawson of Darlington, and Henslee of Dillon; *Secretary and Treasurer*, Dr. Benjamin G. Gregg, of Florence.

**Hospital Bequest.**—St. Luke's Hospital receives a bequest of $3,000 to endow a bed in the children's ward, by the will of Miss Alice Hamilton, who died on September 15.

**Return of Dr. Koch.**—On October 21 Dr. Robert Koch returned to Germany, after having spent almost a year in travel in the tropics, for purposes of scientific observation.

**Medical Study in Germany.**—According to recently published statistics, the number of medical students has been steadily decreasing in Germany. In the year 1902-1903, the total number of aspirants for medical degrees in all of the German universities was 6,232, which was the lowest figure noted in about twenty years. The maximum was reached in 1887-1888, when 8,513 medical students were enrolled. In 1890-1891 the number of medical students to 1,000 students in all departments was 296; in 1902-1903 the proportion was only 178. In 1892-1893 more students chose medicine than any other profession, but ten years later both philosophy and law were more popular.

**Yellow Fever in Havana.**—Yellow fever seems to be spreading very slowly in Havana. On November 28 twenty-seven cases in all had been reported since the beginning of the epidemic.

**A Tragic Ambulance Accident.**—Dr. Clarence Bartow, a Roosevelt Hospital interne, was killed at Fifth Avenue and Twenty-sixth street, at 1 o'clock on the morning of November 26, by a collision between an ambulance, of which he was in charge, and a large sight-seeing automobile. Dr. Bartow was on his way back to the hospital with an urgent case and the two vehicles came together with tremendous force. The concussion hurled Dr. Bartow to the ground, and his skull was crushed against the asphalt. He was taken to Bellevue Hospital in a cab, but died on the way. Dr. Bartow was twenty-seven years old and graduated from the College of Physicians and Surgeons with the class of 1905. He had been at Roosevelt Hospital only since July 1 The driver of the ambulance escaped without injury.

**Death of Prof. v. Kolliker.**—On November 2 Prof. R. A. v. Kölliker, the nestor of German anatomists, renowned both as an histologist and as a zoologist, died at Wurzburg, at the age of eighty-seven years.

**Sir John Scott Burdon-Sanderson,** regius professor of medicine at Oxford University from 1895 to 1904 died on November 24, at London.

**The Late Dr. A. P. Dudley.**—At a meeting of the New York Obstetrical Society, held October 10, 1905, the president appointed a committee to

draw up a suitable testimonial in memory of their late associate, Dr. Augustus Palmer Dudley, who died July 5, 1905.

"This committee wishes to express the great sense of loss felt by the entire society upon the announcement of his demise, inasmuch as Dr. Dudley was always a congenial companion, of loyal nature and with a high ideal of friendship. His natural abilities contributed not a little to enliven the scientific discussions of our society, and his contributions to the literature of our specialties were always read with gratification and profit. His appointment to several hospitals and to professorships in two medical colleges attest a skill of high order as a surgeon and marked proficiency as a teacher.

"The committee recommends that a copy of this testimonial be spread upon the minutes of the society, and that other copies be sent to the medical journals, and to Dr. Dudley's family, with the expression of deep sympathy from the members of this society for their sad bereavement."

(Signed) Bache McE. Emmett, George H. Mallett, James N. West, *Committee.*

**Obituary Notes.**—Dr. Julius A. Ruge of St. Louis, Mo., died on November 14, at the age of sixty-nine years. His death was due to heart disease. Dr. Ruge was born in Denmark, and came with his parents to this country when he was three years old. He studied medicine under his father, Dr. Charles J. Ruge, and later graduated from the Humboldt Medical College in St. Louis, about 1860. In the fall of 1862 he was commissioned assistant surgeon of the 31st Missouri volunteers, infantry, and served in this capacity until after the fall of Vicksburg in 1863.

Dr. Henry Hobart Maynard of Los Angeles, Cal., died of uremia on November 4 at the age of seventy years. Dr. Maynard was born in Ohio and was graduated from Rush Medical College of Chicago. He had practised in Los Angeles for twenty years, and for fifteen years he was a member of the United States Board of Examining Physicians for Pensions.

Dr. F. H. Hopkins of South Boston, Mass., died at Antrim, N. H., on November 17. He was a graduate of Harvard Medical School in the class of 1903, and had since practised in the peninsular district.

Dr. W. A. McCord of Lewisburg, Tenn., died on November 14, at the age of forty-seven years, after a long illness, due to gastric disease.

Dr. James Montogomery Holloway, one of the most prominent and oldest physicians of Louisville, Ky., died on November 13, at the age of seventy-two years. Dr. Holloway was born in Lexington, Ky., and was graduated from Centre College, at Danville, Ky., being a member of the class of 1855, notable for the number of distinguished men graduating in it. He then matriculated in the University of Louisiana, now Tulane University, being made interne at Touro Infirmary, when he received his degree. After that he studied under Dr. Warren Stone, of the Charity Hospital, of New Orleans, a noted surgeon of that time. At the outbreak of the war he entered the Confederate service as a private, but was almost immediately made a surgeon, with the rank of major. In this capacity he served with distinction in the field for a year, after which time he was placed in control of the Richmond hospital service, where he remained until the close of the war. He then settled in Louisville, where he became very prominent and occupied numerous chairs in the local medical schools. In 1882 he was elected president of the Tri-State Medical Association.

Dr. John I. French of Winchester, Mass., died on November 18, at the age of forty-five years, after a long illness following an attack of grip. He was graduated from the Tufts Medical School and settled in Winchester eight years ago.

Dr. J. P. Aiken, formerly residing at Woodland, Cal., and for several years physician to the soldiers' home at Yountville, died, at the age of sixty-four years, on October 26, at Makawao, on the island of Maui, Hawaii, where he had lived during the last ten years.

Dr. Amouretta M. Beecher, a cousin of Henry Ward Beecher and Harriet Beecher Stowe, died on October 9, aged eighty-six, after a brief illness, at Santa Barbara, Cal. She was born in Connecticut, received a medical education, and became prominent as an educator; for four years, she was at the head of the Hartford School for Girls. Her later life was devoted to charity, with especial reference to the good of her sex.

Dr. Emma D. L. Burd of Yonkers, N. Y., died on November 22 in her sixty-second year. Dr. Burd was born in Brooklyn and was graduated from the University of the State of New York when forty-seven years of age. Her father and grandfather were physicians, and she took up the study of medicine at an advanced age, merely as a hobby.

## Correspondence.

### OUR LONDON LETTER.

(From Our Special Correspondent.)

KING'S BIRTHDAY HONORS—ARMY SANITATION AND FEVERS—INTRATHORACIC DERMOIDS—RECOVERIES FROM INJURIES TO CERVICAL VERTEBRÆ—LUPUS AND RODENT ULCER AND *X*-RAYS—GASTROENTEROSTOMY—DUODENAL ULCERS—NOTIFICATION OF TUBERCULOSIS—WOMEN'S HOSPITAL—ROYAL SOCIETY—OBITUARY.

London, Nov. 10, 1905.

The King's birthday being yesterday, a list of honors appeared, as customary, and contains some names of medical men. Dr. Barr of Liverpool and Mr. A. Chance, president of the Dublin College of Surgeons, received knighthood. Dr. Cargill of the N. Nigeria protectorate is made a companion of St. Michael and St. George, as also Dr. Thompson, for sanitary services under the colonial and foreign offices, and Dr. Armand Ruffer, president of the Egyptian sanitary board. Sir F. Semon gets a step in the Victorian order. Professor McFadyean, principal of the Royal Veterinary College, is a medical graduate and receives a knighthood.

It is not a long list. Allied to it I may add, though not a medical man, Professor Darwin, president of the British Association, who is made K.C.B.

On Thursday, at the Royal United Service Institution, Dr. Leigh Canney delivered a lecture on the scheme he proposed four years ago for the suppression of fever in armies in the field. He entitled his lecture "The Toleration of Enteric Fever by the Army," and in vigorous terms blamed the want of progress in sanitary organization and the prevention of fevers in the Indian and South African armies. He set forth the grounds on which he held that these diseases were preventable in civil and military life. In the late Russo-Japanese war there was, he said, a striking demonstration of the success of the plan he advocated.

The conditions of immunity, he held, were (1) a trained water section, 2 per cent. of strength, non-combatant; (2) a trained sanitary pioneer section of 2 per cent. combatant; (3) expert sanitary officers; (4) training and education of all officers in sanitary matters; (5) responsibility of non-medical officers for executive sanitary work; (6) responsibility of the same for the incidence of enteric, dysentery, and cholera in their units; (7) training of men in the advantages; (8) transport of water sections to be used for no other purpose and to be largely independent of all other transport—reserve fuel to take precedence, when required, of everything except one day's ammunition; (9) establishment of a tradition that it is dishonorable and a crime to use any fluids for drinking purposes which are not approved and allowed.

Dr. Canney admitted the existence of other causes, but regarded them as only subsidiary, and declared that if the liquid avenues of the bacillus were effectually closed there would never be more than a few sporadic cases.

On this point there are many who would enter a demurrer and would say that the admission of sporadic cases being possible under his system shows that there must be other "avenues" than water. Still, if the most frequented avenue were closed, no one seems to doubt that thousands of lives would be spared. There seems, too, reason to fear that Dr. Canney is right in the warning that the lesson of the Boer war has not been learned, and that if it were necessary for our troops to march over the same ground the same disasters would recur. If so, the blame would rest on the politicians—not on the army medical service.

The Clinical Society, on the 27th ult., had an interesting exhibition of cases and specimens, some of which I may name. There was one of intrathoracic dermoid in a woman of 26 who had had a cough for 8 or 9 years and said hair had come up hundreds of times. The sputum was free from tubercle bacilli. Mr. Spencer referred to a specimen in the Westminster Hospital museum and said these tumors usually grew near the thymus—a region of physiological rests. Mr. Godlee said they usually communicated with a bronchus, and if drained did not heal, but remained moist. Mr. Shaw spoke of two having been cured, one by removal and one by drainage. Seven such cases have been surgically treated.

A series of cases of recovery from severe injury to the neck without spinal symptoms, excited considerable interest. In two skiagrams had been shown at a previous meeting, viz., fracture of pedicles of the axis, and one of fifth cervical vertebra. Rotary dislocation of the axis, lateral fracture with dislocation, subluxation of the atlantoaxial articulation, and lateral fracture of the atlas complete this remarkable series. Dr. Fagge remarked that skiagrams of spinal cases were very untrustworthy, so he doubted the diagnoses. One case he thought was caries. Mr. Corner, who exhibited the cases, replied that when two were shown to the society last January the members confirmed his diagnosis.

A Japanese girl of 10 months, with the pigmentation of the Mongolians, elicited the remark that the blue pigment of these cases was in the deeper layer of the corium, began in the fifth month of intrauterine life and often disappears after the second year of age.

Two cases of lupus, which became epitheliomatous after *x*-ray treatment, provoked diverse opinions. A case was quoted in which the same occurrence took place after only three applications. Another in which scraping was followed by epithelioma. It was said, however, by another member that, though this is a rare complication of lupus vulgaris, any variety of cancer may supervene upon any of the gravalomata.

A case of rodent ulcer of eight years duration cured by nine applications of *x*-rays was shown. The president, Mr. Clutton, preferred the knife as a rule, for though the rays did good, he had found the growth usually returned in a year or two.

Mr. Mansell Moullin has given to the Medical Society some account of sixty consecutive cases of gastroenterostomy for gastric and duodenal ulcers. In four cases no ulcer was found. Of the others four had died. In one of them no cause of death was found at the post mortem. In the other three the cause was preventable. Of the remaining 52 cases, 42 were cured, not merely relieved. Many had been under observation three or four years, and their digestion is as good as ever. A relapse of symptoms had sometimes occurred, but only required 24 hours in bed with abstinence of food and purgation. The cases might be classed as those in which there was some mechanical difficulty, as stenosis, and those in which an ulcer was unhealed. In the latter, if a long period of rest was followed by but brief relief, it was no use repeating it and exposing the patient to the risk of perforation. Gastroenterostomy gave a prospect of permanent cure with a mortality less than when perforation had occurred. It was considered better not to excise the ulcer. If symptoms continued, gastroenterostomy might afterwards become advisable.

Mr. Cuthbert Wallace thought the direction taken by the extravasated fluid depended on the position of the patient when the perforation took place. As to irrigation, pathologists had shown that it destroyed phagocytes, and so seemed contraindicated.

In reply to questions and remarks, Mr. Moullin objected to Murphy's button in any case. He admitted that hourglass stomach added to the difficulties, but could be met. Mr. Smith said the liver dullness varied much in the cases

At the same meeting, Mr. Maynard Smith read a paper on "Duodenal Ulcer," based on 13 cases at St. Mary's Hospital since 1900. Ten were operated with six deaths and four recoveries. Two classes of acute perforation were named: one with profuse escape flooding rapidly the peritoneal cavity; the other with slight escape localizing itself for a time in the right kidney pouch, but later further escape took place with overflow into the pelvis. Experimental evidence of the occurrence of this last class was given. The differential diagnosis from appendicitis was considered, and it was stated that both conditions had coexisted in reported cases. Drainage of the pelvis by suprapubic incision and of the right renal pouch by a right lumbar incision was the best method of treatment.

Dr. A. T. Schofield, at the inaugural meeting of the Kensington Health Society on Monday, said that since the National Health Society was started, twenty years ago, no less than eight years had been added to the life of every person in the country. But much more remains to be done, for at least 200,000 needless deaths occur every year. He said many births do not come to the knowledge of officers of health until the registrars furnish the death certificates of the children, because the law permits registration within 42 days, a period which he held legislation should reduce.

The Kensington Council of 1902 put into operation a scheme of voluntary notification of tuberculosis, and offered bacteriological examinations and disinfection after death or removal of patients. The medical officer of health, Dr. O. Dudfield, now reports the comparative failure of the scheme. He has only had one application for examination of sputum in the three years. As to disinfection, 895 rooms in private houses were infected in that period, but only 469 were disinfected. Assistance was refused as unnecessary in 129 cases and as inconvenient in 297. Dr. Dudfield thinks disinfection should be made compulsory, as it is in measles—a less fatal disease. This caused last year 2,261 deaths in London, mostly of young children, whereas the deaths from phthisis were 7,738, of which 80 per cent. were of persons at the working period of life. It is significant as to the inefficiency of voluntary notification, only 27 cases were notified by other than poor law medical officers out of a total of 680 deaths in Kensington in three years.

The Archbishop of Canterbury on Friday opened an additional ward at the New Hospital for Women, which he pronounced a great gain to the forces engaged in the relief of suffering. He knew the value of good nursing and medical care, as he had been laid up for considerable periods. But, he added, hospitals were not only directly useful. They did good indirectly by opening a new world of kindness and helpfulness to people who elsewhere could not have realized it. Even to those who had a good home, illness was not altogether a misfortune, for after recovery patients might often feel they had had a good time and seen a side of life different from the rough and tumble of healthy existence.

Mr. Davies then described the hospital as a monument of the devotion of Mrs. Garrett-Anderson, who opened a dispensary in 1855, which five years later became a small hospital but grew until a larger building became necessary. In 1889 the Princess of Wales, now the queen, laid the foundation stone of a larger hospital, since which a cancer ward, a nurses' home, an operating theater have been added, and now the present extension.

A case of scarlet fever occurred in the cruiser *Challenger*, lying off Chatham dockyard. After some delay caused by correspondence between the town clerk and the admiral superintendent as to whether the port sanitary authorities were responsible for the cost of removal, maintenance of patient, and disinfection of the ship, the crown authorities undertook to pay.

The Royal Society has awarded to Professors Sherrington and Poynting for researches on the central nervous system and on electro-dynamics, respectively

Dr. H. T. Griffiths died last Friday, aged 52. He was a St. Georges and Cambridge student, M.A., 1879, in which year he took the double qualification in London, and two years later his M.B., proceeding to M.D. in 1884. He had been medical registrar at St. Georges Hospital.

Surg.-Lt.-Col. Mulvaney, R.A.M.C., died on Tuesday, age 51. He joined the army service in 1880 and became lieutenant-colonel in 1900.

Col. J. C. G. Carmichael, M.D., of the I. M. S. (retired), died on the 23d ult., aged 60, after distinguished service extending from 1868 to 1900.

Dr. J. Jamieson, M.D., and F.R.C.S., Edin., died on Friday last, November 3, aged 64.

## OUR PARIS LETTER.

(From Our Special Correspondent.)

CONSERVATIVE SURGERY IN TRAUMATISM OF THE EXTREMITIES—SURGERY OF THE PANCREAS—PLASTIC SURGERY OF THE FACE—SURGICAL TREATMENT OF TUMORS OF THE BLADDER—HYPERTROPHY OF THE PROSTATE—CYSTOSCOPY BY DIRECT VISION—EARLY INTERVENTION IN UNILATERAL RENAL TUBERCULOSIS—INTERNATIONAL CONGRESS ON SURGERY.

PARIS, Oct. 20, 1905.

THE French Surgical Association held the opening meeting of its 18th Congress on October 20, in the large amphitheater of the Faculty of Medicine in Paris. This session

was presided over by Dr. Chauvel, Medical Inspector of the Army, assisted by Dr. Walter, Secretary-General. The numerous members of the Congress came not only from the large clinics of the Parisian Hospitals but also from other parts of France. There were besides many foreign physicians who had responded to the invitation of their French colleagues.

The President chose as the theme of his discourse, "The Health of the Army in Its Various Aspects." After some remarks by the Secretary-General, the Congress took up the first question of the day—"Conservative Surgery in Traumatism of the Extremities." H. Nimier especially emphasized the new attempts at conservative therapeutics which are becoming more and more reparative in nature. His conclusion was that thanks to greater facilities of earlier diagnosis, conservative surgery ought now to be able to attain the correction of primary lesions not only by the application of bloodless methods, but, if it is required, by operative intervention practised without delay as soon as the indication presents itself. Professor Le Dentu in the discussion which followed, favored specially conservatism according to the old meaning of the term. He considered the question from various points of view: primary amputation which is necessary only in certain exceptional cases of severe crushing. The speaker declared himself to be in favor of antiseptic irrigations. In case of acute gangrene of large extent, antiseptic irrigations together with the most incessant surveillance of the patient will do much to ameliorate the condition. As to complementary operations, such as osseous resections, autoplasties, and grafts, in spite of the great progress made in these lines in late years, they ought still to have our most careful attention, and no effort should be spared to bring these methods to perfection. Kirmisson, conservative to the extreme, gave a report of his personal statistics which included ten severe traumatisms of the extremities in children, five of the upper extremities and five of the lower, which are treated by conservative methods. Boeckel of Strasburg gave his statistics relating to tardy complementary operations. There were 35 cases, all of which were cured by conservative methods. Paul Delbert insisted upon extreme systematic conservatism especially in the treatment of extensive traumatisms.

The second question of the day was "Surgery of the Pancreas." F. Villar of Bordeaux presented in succession the functional symptoms of diseases of the pancreas and their physical signs. It appeared from this résumé that the diagnosis of pancreatic affections was often impossible and always difficult. From the point of view of special diagnosis of surgical affections of the pancreas, the speaker considered the annular pancreas, spontaneous hernias and displacements, traumatisms of this organ, acute and chronic pancreatic infections, and so on. He considered also the therapeutics of the affections of the pancreas and treated this question in three chapters: First the technique and the general indications for operations in pancreatic affections, then the medical treatment and opotherapy in maladies of the pancreas. He concluded with a study of surgical treatment of pancreatic lesions. Villar considered the best route to the pancreas to be the anterior abdominal or transperitoneal route, with median or right lateral incision. Thus there were three routes open to the operator, the gastrohepatic, the transmesocolic, and the gastrocolic. The last is the most simple and direct. In the course of the discussion which followed, a number of communications were made by Garré of Breslau, Lejars, Doyen, Thierry, Morestin, Cranwell of Buenos Ayres, and Auvray. All of these authorities contributed their personal observations, giving interesting statistics in favor of the special proceeding advocated by them.

Aside from these two questions, other communications were presented to the Congress concerning the surgery of the uterus and its adnexa, the surgery of the stomach, of the intestine, of the rectum, of the appendix, and of the esophagus.

Depage of Brussels presented a communication on "Plastic Surgery of the Face." He discussed the various surgical interventions which aim to overcome deformities or lesions which cause functional troubles. In the discussion which followed, Professor Berger stated that he had for twenty-five years employed the Italian method in autoplastic operations, and he dwelt upon the general and special indications and the contraindications to this method. The general indications were the impossibility of finding at hand the necessary materials for reparation, the fear of the recurrence of the affection in the flaps employed for reparation, and the desire which the surgeon had to spare the patient any disfigurement. As to special indications, Berger thought that in the case of the eyelids blepharoplasty by the Italian method gave truly wonderful results. For the lips chiloplasty by the same method also gave most excellent results. It was otherwise with the nose, for it was only in partial rhinoplasty that one might find any aid. The contraindications above all concerned the age of the patient. The inconveniences were the complexity of operation, the possibility of non-union or of gangrene of the flaps; the generally pale color of these flaps which sometimes contrasted disagreeably with other parts of the face; the fact that the transplanted tissues were not always to be depended upon which made it difficult to utilize them in such operations as those relating to the lobule of the nose.

Broca and Kirmisson took up the discussion concerning the surgery of harelip.

Girard, Doyen, Reverdin, Pozzi, and Campenon, all presented to the Congress interesting communications relative to surgery of the face.

The French Association of Urology held its 9th session from October 5 to 7, Professor Forgue of Montpellier presiding. The following topic was discussed: "The Surgical Treatment of Tumors of the Bladder." Rafin of Lyons advocated intervention by hypogastric cystotomy in all cases of pediculated tumors. Surgical intervention in such cases was far more uncertain in its results when the tumor was infiltrated. Before operating, then, the nature of the tumor should be determined by study of the clinical symptoms, by rectal touch, and especially by cystoscopy. Weinrich of Berlin gave the results which Professor Nitze has obtained by his intravesical method with his operative cystocope.

Motz then discussed the hypertrophy of the prostate from the anatomopathological point of view. The speaker thought that the lesion known under the term hypertrophy of the prostate, was in reality accompanied by atrophy of the prostate, and that it was the periureteral glands which were developed around the prostate which were the true cause of increase in the volume of this organ. It was this that explained the fact that in the enucleation of the prostate by the transvesical method of Freyer the true prostate was left intact with its ejaculative ducts, while the part taken away consisted of the periureteral glands transformed into adenomyomata.

Proust gave a résumé of the operative indications for prostatectomy. He declared himself an advocate of the transvexical route in the larger number of cases; by the method of Freyer—believing this operation to be the method of choice. Nicolich of Trieste, Legueu of Paris, Loumeau of Bordeaux, and Pauchet of Amiens, shared this opinion, while Rafin believed the perineal route to be superior on account of its safety.

Luys finally presented the advantages of cystoscopy by direct vision over cystoscopy with a prism. After showing the instruments that he considered necessary for performing cystoscopy with direct vision,—a simple matter in both men and women—the speaker explained the advantages of this method of examination which allowed a complete examination of the entire vesical cavity. Catheterism of the ureter was made very easy even in cases of highly inflamed bladders. One of the most interesting applications of cystoscopy by direct vision related to the extraction of foreign bodies from the bladder. The speaker reported the case of a patient from whom he had extracted a portion of sound which had been for one month in the bladder.

An interesting discussion followed concerning the early intervention in unilateral renal tuberculosis. Most of the surgeons believed in early nephrectomy as soon as the diagnosis of unilateral renal tuberculosis was made. Finally Nicolish of Trieste emphasized the value of radioscopy and radiography in the diagnosis of renal calculus. Radioscopy gave information concerning the location and the size of calculi.

The first Congress of the International Society of Surgery was held at Brusels, September 18 to 23, 1905. Professor Kocher of Berne, presiding. Among the questions discussed was that concerning the value of blood examinations in surgery. Four reports were presented: two of these were in French by Depage of Brussels and Ortiz de la Torre of Madrid, one in German by Sonnenburg of Berlin, and one in English by Keen of Philadelphia. For the second question, the treatment of prostatic hypertrophy, there were three reports, one in French by Von Rydygier of Lemberg, one in English by Harrison of London, and one in German by Rovsing of Copenhagen.

The third topic treated of surgical interventions in the non-cancerous affections of the stomach. Monprofit of Antwerp, Rotgans of Amsterdam, Mattoli of Rome, and Jonnesco of Bucharest, presented papers in French. Mayo Robson, of London, spoke in English and Von Eiselsberg of Vienna spoke in German. Finally the question of the diagnosis of surgical affections of the kidneys was considered in three papers; two in French by Albarran of Paris and Giordano of Venice, and one in German by Kümmel of Hamburg.

The 8th session of the French Congress of Medicine was opened September 25, at Liège, Bienvenu-Martin, Minister of Public Instruction of France, presiding. de Trooz, Minister of the Interior and of Public Instruction in Belgium, Francotte, Minister of Labor, and Beco, Secre-

tary General of the Department of Agriculture, honored the opening session by their presence. Professor Lepine of Lyons took charge of the program of the Congress. Three important topics were discussed. The first was: "The Clinical Forms of Chronic Rheumatism." Those who spoke on this subject were: J. Teissier of Lyons and R. Verhoogen of Brussels. The next topic was: "Dechlorated Regimes." F. Widal of Paris and L. Beco of Liége spoke on this subject. "The Secretions of the Pancreas," was the third topic and was discussed by Hallion of Paris and Falloise of Liège.

## OUR LETTER FROM CONSTANTINOPLE.

(From Our Special Correspondent.)

OPENING OF THE SEASON—INFLUENZA—OPERATION ON THE SULTAN'S SON—A TRIENNIAL CONGRESS OF LEPROSY AT ATHENS—YALLOVA AS A HEALTH RESORT—HOSPITALS IN TURKEY—DUTIES OF THE MUNICIPAL HEALTH OFFICERS—STRINGENT VACCINATION LAW—CIRCUMCISION IN HONOR OF THE SULTAN'S ACCESSION—PRECAUTIONS AGAINST CHOLERA.

CONSTANTINOPLE, September 30, 1905.

THIS date ushers in the early autumn rains, and conventionally, is the end of the Bosphorus summer season, when the world and its doctors return to town. Not that people go to the country for the benefit of the doctors, but that doctors now go for their share of the pleasures and amusements.

A mild form of influenza was prevalent in the early summer, with the unusual characteristic of superficial tonsilitis. But for the disproportionate debility of the patients so affected the cases might have been considered as ordinary catarrhal sore throat.

His Imperial Highness, Ahmed Effendi, son of the Sultan, was operated upon for hernia—the radical cure—by Dr. Djemil Pacha, in the presence of His Majesty. "In proof of the Imperial confidence in Ottoman physicians, and also in proof of His Majesty's appreciation of the progress of medical science in the Empire under the glorious reign of His Majesty, it was commanded that the operation should be performed by Ottoman surgeons." The operation was completely successful, and the surgeons, physicians, and nurses were rewarded. Dr. Djemil Pacha was promoted to be a marshal of the Empire. The General Dr. Ibrahim Pacha, chief of the Hamidiah Hospital, received the order of the Medjidiah in brilliants, and Dr. Kambouroglou the Imperial order of the Osmaniah; the nurses and other attendants were honored according to their respective positions.

Dr. Zambaco Pacha has notified Dr. Magina, professor in the faculty of the University of Athens, that he has devoted the sum of 10,000 francs towards the organization of a medical congress to be held every three years at Athens. The interest of this sum, 1,500 francs, will be granted to the Medical Laureat of the congress; the subject of the congress, leprosy.

This year the thermal establishment of Caury-Yallova has been conducted by Dr. Sioti with great success, and has attracted a large number of patients. The charges have been reduced, the general service has been extended and improved, and Yallova is becoming a favorite resort for invalids from every part of Turkey and the Greek islands, thus reviving its ancient reputation as a health resort, an account of which was given in a former communication.

The Greek and Armenian communities here have contributed largely towards the extension and further development of their respective hospitals. The Italians are considering the question of instituting a sanatorium for the treatment of tuberculosis, and Dr. Zeri of the Italian hospital went to Italy in connection with this object. The Imperial solicitude for hospitals is well known. They are included in the category of educational establishments, and it is announced that "the strongest desire prevails in Imperial quarters to place them all on a level with similar institutions in western Europe, and that there may be neither doubt nor difficulty about it, His Imperial Majesty has decreed commands to that effect." This boom in hospitals must eventually affect the general medical practitioners. The number of doctors of Turkish, Greek, and other nationalities is yearly increasing, and larger hospital accommodation is being provided, besides outdoor clinics. But the hospitals are not confined to the poor. They nearly all receive paying patients at a rate much lower than that of the fees of the ordinary practitioner.

In spite of the increased and increasing number of doctors, one reads in a local paper "that from the public health point of view the duties of the Municipal Health Officers are innumerable and require readjustment. These doctors are named to the posts with a salary of 500 piastres monthly, immediately after having terminated their studies. They are obliged, at all hours of the day and night, without extra remuneration, to attend the sick, sometimes at many hours' distance. They act as accoucheurs, ophthalmologists, rhinologists, etc. Besides these, they fulfil the duties of medical jurists in case of crime, examine the products imported into the custom houses of the maritime towns, attend sick prisoners, examine candidates for the police, give advice to the municipal council on the food products on sale, vaccinate children, inspect the cities with reference to cleanliness, and, in case of need, do veterinary work, and have to render detailed reports of what they do and see. "It is necessary," then concludes that remarkable protest, "that the multiple duties should be diminished, and, above all, that the municipal doctors should be chosen as good accoucheurs, experienced and able surgeons, and at the same time be able to treat contagious diseases, seeing that one man cannot usefully fulfil all."

An official notice has been issued to the effect that in accordance with the dispositions of the new law of vaccination, no person can contract marriage, or travel in the interior without exhibiting their certificate of vaccination. It would be interesting to learn the results of such a drastic law. It will probably remain a paper law.

On the anniversary of the Sultan's accession, no fewer than 2,026 children were circumcised in batches of 200 or 300, by Dr. Djemil Pacha and his assistants of the Hamidiah hospital. The expense of this rite of childhood is felt by the poor, and it has been the custom in Eastern countries where circumcision is practised, to take advantage of such high occasion to have the children circumcised gratis, *en masse*. The operation is now done with antiseptic precautions. It would be interesting to know the results as compared with the non-antiseptic days, when many untoward accidents followed the operation.

The security that brings neglect of hygiene, has been disturbed by the appearance of cholera in Europe, and by Imperial order, the High Commission of Hygiene are taking measures for preventing the contagion of cholera, and certainly not before they were needed, for the city and suburbs require a thorough purging of accumulated impurities. The instructions formulated are, to say the least, simple though negative. "(1) The principal quarters of the capital to be kept in a state of perfect cleanliness. (2) Municipal agents ought to submit to severe disinfection all kinds of food sold in the streets. (3) Doctors of the different quarters ought to examine carefully the sick. (4) Houses ought not to throw rubbish into the streets." Simple though the instructions are, they would require a hygienic Hercules to carry them out. This refers only to the internal sanitary precautions. The general quarantine board has been fully alive to the occasion, and has only to modify or extend the operations in force against Egypt.

On the day of His Majesty's accession the direction of the Imperial Society of Medicine forwarded the diplomas of the American Faculty of Medicine at Beyrout for distribution, and the prizes of the civil school of medicine were also bestowed.

Dr. Robert Hannington, physician to the Scotch Mission to the Jews for twenty years, has resigned his post in consequence of ill health. His departure is regretted by his special clientêle, as well as by the Anglo-American communities. Dr. G. Post has succeeded Dr. Otley at Robert College, Hissar.

## Progress of Medical Science.

*Boston Medical and Surgical Journal, November 23, 1905.*

**The Use of the Biograph in Medicine.**—W. G. Chase details his experience with this invention with reference to the depicting of pathological motion and notes the experience of others along this same general line. The resources, as to patients, of the Craig Colony were placed at his disposal and he was able to biograph twenty-one separate epileptic seizures, including one case of status epilepticus. For the photographic details of the work [the original paper must be consulted. The author believes that this method of illustration will play an important part in the future of medical teaching. He has been able to secure pictures of one rare case of double nystagmus in which the movements of the eyes are clearly seen. He has pictured a group of rhythmic idiots, each with his individual motion and keeping time to music. An interesting series of photographs accompanies the paper. In some of them the case of status referred to, is pictured in both the stuporous and convulsive stages. When these pictures are passed through the biograph and are magnified by its projection apparatus to life size, the very action of the muscles may be studied.

**A Simple Method of Measuring and Graphically Plotting Spinal Curvature and Other Asymmetries by Means of a New Direct-Reading Scoliometer.**—The method described by G. W. Fitz calls for (1) a scoliometer consisting

essentially of a sheet of transparent celluloid with rectangular graduations and with two level glasses set at right angles to each other for determining the level of both the horizontal and vertical lines of graduation; (2) a black flesh pencil for marking the spinous processes of the vertebræ, anterior-superior spines, clavicles, scapulæ and such other points as it is desired to measure for record; (3) card catalogue cards, 12 by 8 inches, graduated to quarter-inch squares, or 6 by 4 inch graduated to eighth-inch squares (or such other size and graduation as desired), for recording and plotting. Full directions are given for recording with this device the amount of spinal deviation, the measurement of lateral deviation with reference to a true vertical line, the measurement of the lateral contour of the trunk, the lateral displacement of the shoulders in relation to the pelvis, the lateral tilt of the pelvis and for measuring anteroposterior curves and shoulder levels. Several other uses of the instrument are also of value as for instance, recording the lateral or anteroposterior deviation of the head, the level of the eyes, horizontal and vertical position of the arms, etc. Fitz believes that in the hands of an observer of even moderate skill this instrument will furnish a means for a complete study of the significant points in the progress of a case of scoliosis under treatment and will avoid the necessity of using photography for that purpose, even for the demonstration of improvement when showing cases or publishing results since the plotted curves on the cards are equally complete and exact and the measurements themselves are much more definitely comparable.

*New York Medical Journal, November 25, 1905*

**Significance and Management of Chronic Uterine Hemorrhage.**—G. E. Shoemaker analyzes the causes of chronic uterine hemorrhage. Many cases call for surgical intervention which should preserve if possible the pelvic organs and functions. Passive congestion yields to local treatment by support. Boro-glyceride tampons and the correction of constipation are advisable. The author's experience with drugs for the condition noted is unsatisfactory. Until diagnosis is established no systematic treatment is possible. In cases suggesting malignancy examination must be made of a bit of tissue. Bleeding fibroids cannot be expected to stop bleeding simply because the natural time for the menopause may be near at hand. A marked hemorrhage near the time of the menopause calls for careful examination; as it may be due to malignant tissue. Changes in the endometrium associated with bleeding may not be accompanied by any very decided uterine enlargement, and careful examination may fail to indicate their presence. The most common change is a granular degeneration. A proper curetting usually relieves all symptoms. Severe hemorrhages may accompany development of a hydatidiform mole. Malignant degeneration of placental tissue is rare. It gives continuous hemorrhage and the death of the patient rapidly follows. Concealed or irregular cases of threatened abortion or retained placenta may be puzzling. Many patients are unwilling to give a clear or correct history. Extrauterine pregnancy of an abnormal type is a source of confusion in diagnosis as some patients do not show any missed or delayed periods, have no typical tearing pains or collapse, and instead of the brownish discharge have free bleeding so that the case is regarded as one of ordinary miscarriage and the real danger is overlooked.

**Appendicitis in Children.**—Illustrative cases are reported by C. C. Barrows. In his experience the disease is unusually common between the ages of five and twelve years and much more frequent in the country than in the city. Many cases start from a colitis and the disease seems more frequent during the season of unripe fruit. The appendix being a part of the colon does not escape the inflammation existing in that part of the bowel. On account of its slender caliber, the shortness of its mesentery or its abnormal position it fails to get rid of the products of inflammation, and by pressure the circulation in its mucosa is interfered with. It sloughs or is easily infected by the bacteria which infest the bowel. Diagnosis in children is extremely difficult. The patients almost invariably suffer from pain referred to the umbilicus, as a rule are nauseated and have vomiting with constipation. They have a great dread of being moved or touched. From the beginning of the attack abdominal rigidity is present and is a most important point in diagnosis. The question of fever is relatively of minor importance, but a rapid and increasing pulse rate and respiration are of grave significance. At times the disease begins with a well-marked rigor and the author regards this as suggestive of developing rapid gangrene. He considers an increasing leucocytosis with an increase in the polynuclear cells and of the fibrine of considerable help in the establishment of a diagnosis, but insists that we must not exclude the bedside clinical history of the case. As soon as the diagnosis is established prompt surgical intervention is called for in every case.

**Scopolamine-Morphine-Chloroform Anesthesia.**—M. K. Isham reviews briefly the literature of this subject and gives some pharmacological points with reference to scopolamine. She then analyzes the results obtained in thirty-four operative cases under the anesthesia sequence named in the title. The standard dose used was 0.01 grain of scopolamine hydrobromide and one-sixth grain of morphine muriate dissolved in 1 c.c. of distilled water, one, two or three injections were given according to the nature of the operation and the reaction of the patient. More than one injection for a laparotomy caused a degree of muscular contraction which interfered with the operation. One injection two hours before operation gave the best results. In no case was the anesthesia sufficient without the chloroform. The author enumerates the following advantages of the preliminary injections; less chloroform is required, fear is abolished, nervousness and pain preceding operation are lessened, suppression of the stage of excitement preceding muscular relaxation; long duration of sleep following the operation; lessening of nausea and vomiting is exceedingly doubtful; the necessity of an anodyne is not nearly so frequent; no increase in the amount of mucus and saliva; this decreases the troubles of the anesthetizer, and also, which is of greater importance, diminishes the possibility of postoperative pneumonia; it ought also to lessen the nausea and vomiting, absence of albumin in the urine; harmlessness, when used intelligently. Disadvantages are, its variety of action, *i. e.* the variability of reaction in different patients; vasodilatation and consequent hemorrhage, which, however, may be controlled by injections of ergot; muscular contraction; the inconvenience of giving the injections so long before the operation; the interference, in some cases, with sterilization; and the readiness with which both the crystals and the solution decompose.

*Medical News, November 25, 1905.*

**A Pieseometer for the Accurate Determination of Abdominal Rigidity.**—T. W. Kilmer has devised an instrument for this purpose which consists of a delicately tempered and accurately tested spring concealed in the handle of the instrument. This spring is accurately gauged so that it will take so many pounds pressure to press the small knob at the end of the plunger a given distance into the tissue muscle for instance. This plunger is so arranged that it may be drawn out to any distance from one-eighth of an inch to three inches. The metallic disk is used, as it were, as a horizontal line. The index of resistance of a given part of an abdomen is a fraction, the numerator of which is the number of pounds' pressure which it takes to press the plunger up to the horizontal line (metallic disk) into the abdominal tissue. The denominator of this fraction is the length at which the plunger was set. Judgment is required in the use of the instrument as regards the length of the plunger. It may be necessary in a very fleshy person to extend the plunger to the extent of an inch or an inch and a half according to the amount of fat under the skin. Also the plunger must be extended to the same distance in each examination of the same point on the same patient.

**A Case of Perforation of an Ulcer of the Duodenum, with Remarks on the Diagnosis and Treatment of this Affection.**—The patient of C. G. Cumston was a man of forty-three years who for some time had had attacks of epigastric pain coming on an hour or two after eating. One morning immediately after breakfast he was seized with a sharp pain which he located under the liver. Bilious vomiting ensued and in a few hours he was collapsed with tympanitic abdomen. Operation was advised as soon as the first stage of shock had passed away and the abdomen was opened late in the afternoon of the same day. Inspection of both surfaces of the stomach revealed no perforation. The upper part of the duodenum appeared collapsed and just below a large quantity of dark fluid, having an intensely acid reaction, escaped. The diagnosis of a perforated ulcer of the duodenum was made and it was believed to have taken place on the posterior aspect of the organ, because all the portion of the duodenum that could be inspected showed no evidence of perforation. As the patient's condition was very poor, the stomach, transverse colon, and omentum were pulled together with sutures in order to prevent if possible a leaking of the fluid into the general peritoneum, and two large drainage tubes were inserted and the wound packed with iodoform gauze. For the next forty-eight hours the patient remained in a very serious condition, and at the end of this time it was evident that the general peritoneal cavity had become infected and that a general peritonitis was present. Consequently, an incision was made in the median line just above the pubis, the abdomen thoroughly washed out with salt solution and drained by two large tubes. After this second interference the

patient's general condition began to improve steadily and after a very slow convalescence, covering about eight weeks, he finally recovered.

*American Medicine, November 25, 1905.*

**Relation of Stomach Disorders to Diabetes Mellitus.**—John P. Sawyer reports 19 cases which illustrate that much may be accomplished for the comfort and relief of many diabetics by direct attention to the condition of the stomach. Of these 19 patients, 14 gave evident histories of previous dyspeptic trouble, one of alcoholism without dyspepsia, three of slight indigestion, and only two reported a complete freedom from dyspeptic disturbance. As to the duration of the glycosuria, 9 of the 19 have been diabetic for years, 7 for months 1 possibly for a month, while in 2 the period is thought to have been from 1 to 6 weeks. From these considerations, as well as from the clinical history, all may be excluded from the range of alimentary glycosuria. Among them were cases of the severest type, as well as of the milder forms. With reference to the condition of the stomach, 16 show abundant catarrhal mucus, clumpy, sago grainlike in the contents of the stomach; 2 do not show this catarrhal process, and from 1, owing to age and disinclination, no test-meal was obtained. As to motor function, 10 show a considerable failure, and of the 18 cases, the secretion of hydrochloric acid in 8 is increased; 7 show normal proportions, 3 show less than normal or absent. Of the 19 cases, all but 2 show definitely active catarrhal processes, and in every case of the 18 there has been marked subjective benefit—gain in strength, weight, freedom from thirst, and polyuria—gained by direct attention to the catarrhal process. The most striking influence has been observed on the polyuria and thirst. In some cases the percentage of sugar has undergone no change, but there has been in these cases a great reduction of the total excretion of sugar per day, owing to the great change in the quantity of urine excreted, and the clinical course of this group of diabetics has been much more favorable under direct treatment of the stomach than without it. Moreover, the cessation of this treatment has been followed by the recurrence of the difficulty with prompt relief on resuming the treatment directed to the catarrhal process. In most of the cases lavage formed an important part of the treatment, antiseptic and alkaline solutions being used.

**The Ambulant Treatment of Internal Hemorrhoids.**—Collier F. Martin asserts that the treatment of internal hemorrhoids by hypodermic injection has fallen into disrepute among surgeons because it is the accepted method of the advertising quack. The many complications and accidents must not be ascribed to the method itself, but to the unscientific and unsanitary technique employed by this ignorant class of irregular practitioners. It is to be remembered that the injection method is a surgical procedure as truly as the clamp and cautery or the ligature operations, and is therefore not a method to be employed by the general practitioner. The advantages of the injection method are that the patient need not give up his business while under treatment and is not required to take an anesthetic like ether or chloroform. The treatment is usually painless and the complications few if the case be properly handled. The disadvantages are that, in a few instances, the treatment may be a little prolonged, and where the piles are greatly thickened and fibrous they do not completely disappear. For these cases the author usually employs the ligature, operating under local anesthesia. The complications, such as pain, hemorrhage, and strangulation, can be avoided by performing a free divulsion of the sphincter muscles under nitrous oxid anesthesia. This anesthetic is quick, safe, and non-irritant, and the patient need not be confined to bed after the operation. About four days after divulsion, or when the primary soreness has subsided, the treatment by injection may be commenced. He employs a fifty per cent. solution of phenol (Bobœuf), injecting from 7 m. to 10 m. of this solution directly into the center of the pile. The injection is made through a conical speculum, care being taken first to swab off the surface of the pile with an antiseptic solution. The speculum is then withdrawn, allowing the rectal walls to collapse, after which the syringe may be removed. After introducing a suppository containing 3 m. of ichthyol the patient may return to his usual occupation. These suppositories are also used twice daily—one after stool and one at bedtime. Treatments should be given at intervals of from two to seven days and should be continued until all of the hemorrhoidal masses have disappeared. The method, if properly used, is perfectly safe, and when it fails to cure, no harm has been done and one of the other operative methods may be tried.

**Purpura Hæmorrhagica During Pregnancy.**—B. Van Sweringen reports a case of purpura in a young woman of twenty-five, which appeared in the fifth month of her first pregnancy. Hemorrhages occurred from the gums and nose, into the cellular tissue and skin, and appeared in the urine and vaginal discharge. From none of these localities was the bleeding very profuse or serious at any one time. Continuing, however, over a period of two or three weeks, considerable anemia was produced and the prognosis was rendered unfavorable because of the serious nature of the reported cases. Many of these show that premature labor occurs in those who develop purpura during pregnancy, and when this does supervene, death of the mother from hemorrhage generally follows. In Dr. Van Sweringen's case the hemorrhagic tendency subsided, the pregnancy went to term, the delivery was accomplished by forceps and was followed by no unusual hemorrhage, the puerperium being perfectly satisfactory. The treatment adopted consisted of rest in bed, 5-grain doses of calcium chloride with 1 grain of extract of suprarenal gland every three hours and gelatin ad libitum. Several cervical cauterizations in the early months of pregnancy, done to relieve a severe nausea and vomiting, are looked upon as possible causes of the condition because of the purulent discharge which followed. Absorption of infectious material from the cauterized areas seems probable, although no leucocytosis was present. The case is cited to show that the prognosis of purpura may not be so bad as the literature of the subject indicates.

*Journal of the American Medical Association, November 25, 1905.*

**The Influence of Liver Congestion and Cirrhosis on the Splenic Connective Tissue.**—From a study of thirty-eight cases meeting the needed conditions as to age, date of autopsy, well-marked liver lesions and freedom from complicating infections made to determine the causes of the increased splenic firmness in hepatic congestion and cirrhosis, H. A. Christian found that in twenty-eight (73.6 per cent. there was an increase in connective tissue framework following chronic passive congestion and cirrhosis of the liver. In some of the ten cases in which there was no increase in the connective tissue, the liver was equally firm, showing that the consistence is partly dependent on vascular distension, and partly on connective tissue increase. This connective tissue increase is mainly in the reticular tissue of the pulp and with little or none in the white fibrous and elastic tissue. In some cases of cirrhosis, in addition to the pulp reticulum proliferation, there is an increase in the connective tissue about the smaller splenic arteries and in the Malpighian corpuscles. The increased firmness of the spleen found in congestion and cirrhosis of the liver are probably only in part due to simple mechanical hindrance to its circulation.

**Postoperative Pelvic Exudates.**—W. F. B. Wakefield has made a study of the postoperative conditions following pelvic operations, and concludes that exudates or indurations exist, to a greater or less extent, in about sixty per cent. of the patients thus operated on. These are seldom observed until after the woman begins to take up her active duties again, and this perhaps accounts for the scantiness of the literature on the subject which he remarks. He regards these conditions as of extreme importance, and as often tending to a state of invalidism as pronounced as that existing before the operation. After operation there is left an impaired circulation, with more or less venous stasis and edema following, and the presence of a greater or less amount of embryonic connective tissue. If now the patient, at the time when, under ordinary conditions the embryonic tissue is undergoing absorption, resumes her habitual activities, there are exactly the conditions favoring pelvic exudates and indurations. Careful observation has convinced him that these bad results can be prevented by a prolonged convalescence and a very gradual resumption of active life, aided when possible, by general hygienic and local depletory measures. In the former, he includes such measures as tend to improve the general circulation, light massage, alcohol and salt friction rubs, tepid sponge baths, etc. Local depletion at this stage consists in copious hot douches once or twice daily. If, some time after operation, pelvic induration or tumefaction exists, physical exercise must be restricted, the excretory organs, especially the skin, kept active, and local stimulating and depleting measures, the hot douche and the depleting tampon, and the local use of electricity may be beneficial. He has never found incision and drainage necessary.

**Prepernicious Anemia.**—F. W. Langdon has had under his observation during the past decade a number of patients whose chief symptoms were of a distinctly mental and nervous character, but who in the course of time were found to present the characteristic blood conditions and bodily signs of pernicious anemia. In some the nervous and mental symptoms appeared to be secondary to, in others to precede the development of, the anemia. These latter tend to raise again the questions which he says have not been satisfactorily answered: 1. Does the impaired innervation at times lead to morbid functioning of the blood-forming or blood-destroying organs? 2. Does the

blood deterioration lead to the nervous symptoms? 3. Is there a common cause for both? The third question he thinks eventually will be answered in the affirmative. In a few cases he has been able to follow their development from so-called "secondary anemia" to the pernicious type as shown by the blood test. Clinically, these cases collectively have seemed to present a rather characteristic syndrome, the principal features of which are given by him as follows: 1. General ill health. 2. Mental symptoms, viz., intermittent attacks of loss of inhibition, peevishness and gradual mental deterioration. 3. Sensory disturbances: (a) Subjective, consisting of intramuscular and articular dull aches and pains, seldom accompanied by effusion and never by true inflammatory action. With these, and perhaps rather more frequent, are sensations of numbness, tingling and weight in the extremities, especially the legs. (b) Objective sensory disturbances; these are common and consist in patchy losses of pain and tactile sensibility about the feet and ankles. Sometimes there may be only retardation of sensation at first. Tabes is excluded by the other positive and negative symptoms. 4. Plus knee jerks, ankle clonus, and the Babinski sign are sometimes present. 5. Ataxia of gait and station is often present. 6. Diarrhea of the mucous type is apt to occur sooner or later. 7. The peculiar lemon yellow tint of pernicious anemia occurs in the later stages. A combination of all these signs or a majority of them should suggest the possibility of a pernicious or prepernicious anemia, and a careful blood examination may then confirm the diagnosis. Eight cases more or less typical of the condition are reported.

**The Transplantation of Organs.**—Alexis Carrel reports experiments by himself and Dr. Guthrie at the Hull Laboratory of the University of Chicago in the autotransplantation and homotransplantation of organs. At first difficulty was experienced in adapting the organs to the new blood supply by vascular anastomosis, but after a new method of suturing had been perfected, the operation became comparatively easy. A few of the results are given. The kidney has been transplanted into the cervical region of a dog and a comparative study of the urine from the transplanted and the intact kidneys made the third day after the operation. The heart of a dog has been transplanted on to the carotid and jugular of another dog. The heart was beating and the blood circulating through it. With Dr. Guthrie he established an arterial circulation through the right inferior thyroid vein of a dog which had symmetrical hypertrophy of the thyroid glands. Marked changes occurred, and it thus appears that the reversal of the circulation in only one vein of a gland may alter the physiological process. It is possible that we may thus add to our knowledge of the pancreas, spleen, etc. Carrel suggests that organ transplantation may become of importance in a clinical point of view: that perhaps myxedema, idiocy, etc., may be thus modified, and that even heteroplasty with organs of the higher apes may be of practicable advantage. Much more animal experimentation, however, will be required before the method can be utilized on man. While it is impossible to say yet what practical results will be obtained, he thinks it possible and even probable that it will open up new fields in therapeutics and biology.

**Transperitoneal Ligation of Renal Vessels.**—George Walker concludes from a study of the subject that with the ordinary methods of performing lumbar nephrectomy there is danger that the operator may squeeze out tuberculous or malignant material, and thus cause a general infection He gives his reasons for this belief in detail, and in order to prevent such a possibility proposes the following operation: "Do a laparotomy, push the intestines to one side, incise the posterior peritoneum, expose the renal vessels, put a double ligature around each of them, cut between and free the distal end for a short distance. In passing the ligatures it is well to include a certain amount of the immediately surrounding tissue, so as to pass around and ligate the lymph tract, which is not visible, but which runs alongside of and very near to either the artery or vein. The peritoneum is then closed posteriorly, and the anterior abdominal wound sutured in the usual manner. The patient is then turned on his side, and the usual lumbar nephrectomy is done." He notes the objection that the procedure produces two separate wounds, but thinks that the opening of the peritoneum under proper precautions does not add to the mortality of the operation. On the other hand, he believes that removal of the kidney through the laparotomy wound or performing a simple transperitoneal nephrectomy would probably be more dangerous than by removing it by the lumbar route.

*The Lancet, November 18, 1905.*

**Meningitis Caused by Camphor Poisoning.**—The patient of T. H. Walker was a child aged two and a half years, to whom had been given by mistake a teaspoonful of camphorated oil instead of castor oil. When seen by the author, some six hours later, the child was unconscious, with rapid, uncountable pulse, bathed in a cold sweat and in convulsions. Potassium bromide was given per rectum and a small hypodermic of strychnine for the pulse. The patient gradually improved, but on the third day symptoms of meningitis developed. Tincture of gelsemium was given, but without effect, and on the fifth day the case seemed hopeless. Caffeine was injected and after one or two more critical days the child began to improve. From this time he did well, except that the right arm and leg were paralyzed. A slight return of power was later noted in the leg. The author's diagnosis was meningitis from camphor poisoning, with which view Prof. T. Oliver, who saw the case, coincided.

**Diphtheria in a Patient Seventy-nine Years Old With Subsequent Freedom from Gouty Symptoms.**—J. Birt reports the case of a woman of seventy-nine years who gave a definite history of exposure to the disease and in whom he injected 2,000 units of antitoxin. The left tonsil was covered with exudation, the glands were extremely tender, albumin occurred in the urine, and the patient was very ill. Thermometer registered 101 degrees, pulse was 96. She reacted well to the injection, and in a day or two was much better. Clinical diagnosis was confirmed by the culture test. The patient stated that two hours after the injection all the old gouty stiffness and neuritis from which she had suffered for eight years had disappeared. The right tonsil now began to be involved and the antitoxin was repeated. A rash followed the second injection, localized about the site of the latter. It was quickly relieved, however, and the patient went on to convalescence, and on the eighth day from the initial attack was quite comfortable. The point of interest in the case is the fact that in two hours after the first antitoxin injection the neuritis and general goutiness had disappeared and one is led to suppose (according to the author) that this must have been due to either the diphtheria or the antitoxin.

**Bier's Osteoplastic Amputation.**—J. H. Pringle gives his impressions, derived from twenty-four personal cases of this form of amputation, the object of which is to furnish a stump which will bear pressure. This is, according to Pringle, really the only gauge of its utility. He thus describes the method as applied to the middle of the leg. A flap of skin and subcutaneous tissue is cut, preferably from the anterointernal aspect of the limb and reflected with care that there is no damage to the periosteum covering the shin surface of the tibia. Next, three sides of a rectangular flap of periosteum are cut on the shin surface of the tibia, the two lateral incisions being made just beyond the margins of this surface of the bone, and the transverse incision about one and a half inches down from the base of the skin flap. With an elevator the periosteum is raised about one-third of an inch upwards from the transverse incision and then a fine saw is applied and a thin flap of bone, still adherent to the periosteum, is cut from the compact bone of the shin surface. If it consists of the whole thickness of the compact layer of bone it is no matter. Its length must be equal to the transverse diameter of the tibia, but it may be made long enough to cover the transverse surfaces of the tibia and fibula as well. When the bone flap is cut sufficiently long its base is snapped through, but the periosteal bridge connecting it to the bone of the stump is to be most carefully preserved. The bone flap being held up out of the way a short posterior flap is cut; the bones of the leg are cleared and sawn transversely. The prominence of the sharp shin border of the tibia should be removed as well as any irregularities that may be present at the margins of the bone flap. After the vessels are tied the bone flap is sutured by the margin of its periosteal covering to the edge of the periosteum of the bone of the stump and to the muscles of the stump also, so that it flaps down close over the sawn end of the tibia. The results are illustrated by the accompanying illustration. As soon as the wound is healed the patient is encouraged to walk on the face of the stump. At the end of four weeks a wooden pin leg is fixed to the stump by plaster-of-Paris bandages, and the patient is allowed to get up.

**A Case of Advanced Mammary Cancer Treated by a Combination of Operations and the X-Rays.**—The case is reported by Marmaduke Shield and H. L. Jones, their patient being a woman of forty-six. An initial free operation was first performed. Five months later recurrent nodules appeared, and in two months several were removed. Several more were removed two months later. Recurrence still persisted and *x*-ray treatment was begun, for two months twice a week and later once. The patient took five grains of muriate of quinine on the mornings of the days of applications. Within three weeks the patient commenced to improve. The applications lasted ten minutes, the tubes used being of soft or medium hardness and the current between 0.5 and 0.8 milliamperes There was no dermatitis and but little pigmentation.

The face and parts of the arm and forearm were alone protected. The scar tissue all changed in the direction of greater softness and suppleness. In six months the patient was again examined and there was no sign of carcinoma present. The case is reported because, first, now that cancer research is carried on, every case strikingly benefited is worthy of record, and second, because the case teaches that we should not hurriedly assume that all recurrent cancer is hopeless but should avail ourselves of all known reputable methods of relief.

*British Medical Journal, November 18, 1905.*

**Clinical Remarks on the Operative Treatment of Simple Fractures.**—W. Arbuthnot Lane states that it is now more than thirteen years since he devised the operative procedures in the treatment of simple fractures of the long bones, which he has systematically employed with uninterrupted success. He believes that this is the most efficient method at our disposal. The details of the operation are as follows: The skin is first made thoroughly clean. This sometimes takes several days. Moist compresses with careful scrapings are most effective in getting rid of suspicious material. After this a germicide is applied to make the skin as clean as possible. An incision is made which is large enough to enable the surgeon to deal effectually with the fragments. This incision should be made in a place which will involve a minimum chance of damage to important structures, and which will offer accessibility to the wound. The skin should be excluded from the wound by attaching sterile cloths to the cutaneous margins by forceps. After the fragments are exposed they are examined, and when all clots and material intervening between them are removed, they are brought into accurate apposition. Much traction may be necessary, as well as the leverage action of elevators and the approximating influence of powerful long-handled forceps. Strong compression forceps are used if there be any bleeding. When the fragments are accurately apposed, screws, silver wire, or staples, retain them in position. The screw is generally the most efficient; but great care must be taken in drilling the hole to make it the right size for the barrel of the screw, otherwise the bone may be hopelessly comminuted. If much oozing is expected, a drainage tube may for a day or two be employed with advantage. Generally a splint is required after the operation, but in certain cases it is impossible to employ any support. The writer then cites the history of several interesting cases, presenting cuts of the lesions and of the special instruments used.

**A Case of Traumatic Asphyxia.**—W. Sibbald Robertson reports the case of a child three years old, who was knocked down by a cable car and tightly wedged between the "cow-catcher" and the ground. He was extricated with difficulty. At first he was thought to be dead, but he was soon noticed to breathe and his face assumed a bluish-black tint. There was a cut on the forehead which was stitched. There was also an abrasion on the right side of the chest, extending in the anterior axillary line from the upper border of the third rib downwards for six inches, and a corresponding abrasion on the back. The intense blue-black color of the face and neck was far deeper than in extreme cyanosis. The skin was normal below a distinct line of demarcation round the neck at the level of the middle of the clavicles. The discoloration was rather less on the ears, and faded where the forehead met the hair. The skin of the hairy scalp seemed simply congested. Through the blue skin of the face and neck there were shining many minute spots which were most conspicuous near the line of demarcation. Pressure made no difference to the color. There was a lozenge-shaped hemorrhage under each conjunctiva. There were no retinal hemorrhages and the pupils were normal. Vision did not seem to be affected. Nothing abnormal was detected in the heart, lungs, or nervous system. On the eleventh day, the child looking still somewhat swarthy, was discharged. The conjunctival hemorrhages appeared to be unchanged.

**Chloroform Syncope and Direct Manipulation of the Heart.**—T. Rudolph Smith and Wm. Robert Daglish describe this case. The patient, a man sixty-three years old, was put under chloroform for an examination of the rectum for malignant growth. In a few minutes both pulse and respiration altogether ceased, the apex beat could not be felt, the pupils began to dilate, and the face became livid. Three minutes later the abdomen was opened in the middle line and just below the ensiform cartilage, the diaphragm was relaxed, and the heart was reached without difficulty by the fingers and pressed forward against the ribs. The heart was gently kneaded and in about sixty seconds it was beating feebly but fairly regularly. In a few more seconds respiration began. Artificial respiration was then stopped. In a few minutes the wound was closed. Recovery was uninterrupted.

*French and Italian Journals.*

**The Nasal Origin of Lupus.**—Escat declares that the nasal cavity is the constant primary focus of the lupus process. He recalls the law of Audry: lupus of the face always comes from the nasal fossæ; it may be added that pharyngo-laryngeal lupus always descends from the nasal fossæ. Since the nasal cavity is the only one of the upper air cavities where primary virulent tuberculosis is not observed, the question arises, is not the torpidity of this form of tuberculosis (lupus) due to the bactericidal function of the nasal mucus (Lermoyez and Würtz), which makes the nasal fossæ a veritable physiological laboratory for the attenuation of Koch's bacillus. —*Le Bulletin Médical*, October 11, 1905.

**Concerning the Epidemic of Grippe in the Winter of 1904-1905.**—F. Bezançon and de Jong, aside from their own original work, have studied the foreign medical literature on this subject. They refer to their conclusions concerning the rarity of the cocco-bacillus of Pfeiffer and the frequency of the saprophytes of the upper respiratory tract (pneumococci, enterococci, catarrhalis, and so on). Works giving identical results with the ones obtained by these authors have been published at the same time or afterwards by investigators in other countries. They all confirm indisputably the bacteriological conclusions reached by Bezançon and de Jong. In fact the various foreign writers have never found, or at least have rarely found in previous epidemics, the cocco-bacillus of Pfeiffer. They have been impressed, on the contrary, by the predominance of cocci and in particular by that of catarrhalis.—*Le Bulletin Médical*, October 14, 1905.

**Syphilitic Phlebitis.**—Jullien states that far from being a rare complication of this disease, syphilitic phlebitis is often noted at an extremely early stage of the affection. He has observed a case in which the patient was obliged to go to bed on account of malaise and fever, suffering at the same time with violent pain, located in one of the saphenous veins. On examination a rash was discovered. The phlebitis proved to be the first symptom, by means of which the syphilis manifested itself. In another case the beginning of the infection was coincident with a fracture of the leg, which monopolized the attention of the physician and a phlebitis developing on the other side was not interpreted as a syphilitic manifestation until long afterwards. However, when attention was called to this side, the phlebitis served as an excellent guide for the date of contamination. Jullien thinks that this phenomenon often passes unnoticed or else is falsely interpreted.—*La Médecine Moderne*, October 11, 1905.

**Albuminuria and Nephritis in Infancy.**—Ernesto Ballico calls our attention to the much greater frequency of albuminuria and nephritis in babies than is usually recognized. The infant has kidneys that are undeveloped at birth, and they must gradually accustom themselves to the demands of metabolism. The administration of unsuitable foods is a frequent cause of nephritis, and many cases of eclampsia, supposed to be due to teething, are really nephritis. Cold, gastro-intestinal troubles, bronchopulmonitis, infectious diseases, skin diseases producing poisons, drugs administered, and malaria are some of the causes of nephritis. Scleroderma in infants is simply subcutaneous edema. When the mother has nephritis and eclampsia, the child has also frequently albuminuria, the poisons that affect the mother producing alteration in the child as well. In autopsies alterations of the kidneys of all grades of seriousness are found. There are cases in which the ordinary symptom of albuminuria is absent, while tube casts may be revealed by the microscope. The author advises a thorough and accurate urinary examination in all cases in infants.—*Rivista di Clinica Pediatrica*, October, 1905.

**Treatment of Adenitis from Venereal Ulcers.**—Gino Migliorini describes his method of treatment of adenitis resulting from venereal ulcers, which takes the place of excision with its long period of repair. He incises the abscess, scrapes the walls, and cauterizes the interior with chloride of zinc, then tampons with sterile gauze and closes. Or he makes a small opening in case there is none as yet, presses out the pus through the opening, and then injects the sac with nitrate of silver solution, one per cent., and empties it. He then refills the cavity repeatedly until the liquid comes out clear, washes with sublimate and dresses without drainage. This is repeated each day until there is no more pus, then every second day. He claims for this method several advantages over other procedures. There is more rapid cure; more glands are preserved; it is adapted to any case; narcosis is not necessary; it does not result in an ulceration; the depth of the cavity is small after four to eight treatments; the patient can soon come for daily visits only; cicatrices are small; edema of the leg is never produced.—*La Riforma Medica*, October 14, 1905.

# Book Reviews.

The Medical Record Visiting List, or Physicians' Diary, for 1906. New Revised Edition. New York: William Wood & Company.

This visiting list, so well known to the profession, has been revised to increase the amount of matter calculated to be useful in emergencies. Tables of the doses of drugs, the duration of pregnancy, antidotes, solutions for subcutaneous injection, artificial respiration, signs of death, and hints on the making of wills, are among the important items found in the first thirty pages of this pocket volume. In addition to the usual visiting list, there are pages for special memoranda, consultation practice, obstetric engagements and practice, record of vaccinations and of deaths, addresses of nurses and of patients, and for cash accounts. The book is well made, is handsomely bound in flexible morocco, and is of convenient size.

Sobre o tratamento cirurgico do mal de Bright pela Nephrocapsectomia, operaçao de Edebohls. These de Concurso. Francisco Soares Branco Gentil, Chefe de Clinica Cirurgica da Escola Medico-Cirurgica de Lisboa. Cirurgiao dos Hospitaes. Lisbon: Libanio da Silva, 1904.

Professor Gentil's monograph deals with every aspect of the question as to the surgical treatment of Bright's disease, giving a complete review of the entire literature of the subject, including a list of references occupying over thirty pages, as well as the results of personal researches. Naturally, the work of Edebohls is given due prominence, and his technique, as well as the modifications introduced by others, are given in detail. The most interesting part of the book is the personal investigations of Gentil on the effects of decapsulation in animals. He concludes that the new capsule formed over the kidney is more vascular than the old, and that the new vessels (both arterial and venous) supply the parenchyma. The new vessels form within the new capsule, are abundant, and have an important bearing upon the renal circulation. They anastomose both with the parenchymatous vessels and with those of the adhesions forming about the kidney. These vessels do not disappear even after a year after the decapsulation, and the new capsule always remains permeable to these new vessels. The author therefore supports the claims of Edebohls, and his book may be regarded as a defense of the Edebohls operation, although he gives the objections and contraindications to this procedure, quoting various authorities. The illustrations show the steps in the operation and the effect of decapsulation on the kidney. It is unfortunate that the book appeared in Portuguese, as it should be widely read by American surgeons who wish a complete résumé of the subject from the pen of an unbiased observer.

Methods of Morbid Histology and Clinical Pathology. By I. Walker Hall, M.D., Lecturer and Demonstrator in Pathology, Victoria University of Manchester, etc., and G. Herxheimer, M.D., Prosector to the Städtisches Krankenhaus, Wiesbaden. Philadelphia: J. B. Lippincott Company; Edinburgh: William Green & Sons, 1905.

This book may be said to represent for morbid histology what Arthur Bolles Lee's "Microtomist's Vade-Mecum" does for normal microscopic anatomy. It covers both new and old methods of pathological histology, and includes also a chapter on clinical pathology which, however, is merely intended to give the methods employed in clinical investigations which might be useful to the pathologist, who examines the fluids, secretions, and excretions along with the morbid tissues. The subject-matter of the book is arranged conveniently for practical work. The general methods of study of fresh objects, the freezing methods, and the modes of fixation and hardening, decalcification, imbedding, sectioning, clearing, mounting, and staining are first given in sufficient detail for actual work. Next are taken up the special methods, such as staining of nuclei, of cell granules, etc., and finally the staining of special cells and tissues by the various methods specially devised. The methods of staining and examining bacteria, moulds, and other fungi, and the animal parasites, also form useful chapters in the book, though these are not so completely worked out. While the authors disclaim any originality in the work, and frankly state that it is a compilation from various German and English text-books, as well as from the original papers in which the methods appeared, the work contains practical suggestions, which are the result of the authors' own experience. A very useful feature of the book is the index of authors, which appears at the end, and which is very complete. The writer of this review has had occasion to consult this index for a number of references on staining methods, and has found it thoroughly up to date. The book, undoubtedly, will prove both useful and satisfactory in its own field.

The Principles of Bacteriology: A Practical Manual for Students and Physicians. By A. C. Abbott, M.D., Professor of Hygiene and Bacteriology and Director of the Laboratory of Hygiene, University of Pennsylvania Seventh Edition, enlarged and thoroughly revised. Philadelphia: Lea Brothers & Co., 1905.

This work is now so well known that it takes rank with the few text-books that are recognized as standards for the undergraduate study of the subject. In the present edition special attention has been given to the subject of infection and immunity, a field in which far-reaching advances have been made since the appearance of the sixth edition. Students will find in the chapter on immunity a condensed résumé of this difficult and complicated subject, an account of the historical development of this theme, and sufficient bibliographical references to enable them to seek further information in the original sources. Care has been taken to make the nomenclature conform to the recognized standards, and to the suggestions of systematic bacteriologists. The most important advances in technique have been included, although no attempt has been made to give a complete account of all the methods. In all respects the new Abbott is an improvement upon the older editions, while it presents the same satisfactory features that have made the former issues popular.

Elementary Manual for the Chemical Laboratory. By Louis Warner Riggs, Ph.D., Instructor in Chemistry in Cornell University. First edition; first thousand. New York: John Wiley & Sons, London; Chapman & Hall, Limited, 1904.

This is essentially a laboratory manual, to be used under the guidance of a competent instructor. The book begins with a few simple experiments; the author then takes up the study of some representative elements, and shows their acid, basic, or salt-forming functions. The next part treats of quantitative analysis. Here approved methods of volumetric analysis are employed to demonstrate the fundamental laws of chemistry, and to give practice in chemical arithmetic, and in general laboratory manipulation. The student is taught the importance of correct theoretical reasoning, and the absolute necessity of accurate measurement. Modern views of ionization or electrolytic dissociation are used throughout the work in the explanations of reactions in solution. We commend this little volume to the attention of teachers who, with but little time at their disposal, wish to present to their pupils as large an amount of chemistry as possible. The student who has conscientiously worked through this book will have done a considerable amount of thinking, and will, at the same time, have acquired a good training in chemical methods and philosophy.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia; assisted by H. R. M. Landis, M.D., Assistant Physician to the Out-Patient Medical Department of the Jefferson Medical College Hospital. Philadelphia and New York: Lea Brothers & Co., September 1, 1905.

The present number of "Progressive Medicine" contains articles on Diseases of the Thorax and Its Viscera, Including the Heart, Lungs, and Blood-Vessels, contributed by Dr. William Ewart; Dermatology and Syphilis, by Dr. William S. Gotthcil; Diseases of the Nervous System, by Dr. William G. Spiller; and Obstetrics, by Dr. Richard C. Norris. These articles present a readable and critical résumé of the various contributions that have appeared in the periodical literature during the past year. There are a number of illustrations; and the volume is quite up to the high standard of previous numbers. From start to finish there is not a dull or uninstructive page.

Manual of Chemistry: A Guide to Lectures and Laboratory Work for Beginners in Chemistry. A text-book Specially Adapted for Students of Medicine, Pharmacy, and Dentistry. By W. Simon, Ph.D., M.D., Professor of Chemistry in the College of Physicians and Surgeons of Baltimore, etc. Eighth Edition, thoroughly revised. Philadelphia: Lea Brothers & Co., 1905.

The eighth edition of Simon's excellent text-book, which is well and favorably known throughout the country, has been delayed in order to include the changes and additions of the new pharmacopeia which has just appeared. The changes made in this edition are too numerous to mention here, and it will suffice to say that the book has been thoroughly brought up to date, especially as to the parts on organic chemistry, and on dental and metallurgic chemistry. The book is, in one respect, unlike many others of its kind in that it is intended primarily for students of medicine, dentistry, and pharmacy. A considerable section of the work is devoted to physiological chemistry, including the consideration of the animal fluids and tissues, digestion, etc. The essentials of these subjects are concisely given, and Simon's book will undoubtedly prove of value to students who desire the entire subject of chemistry, organic and inorganic, analytical and physiological, covered in a single volume.

SECTION ON MEDICINE.

*Stated Meeting, Held October 17, 1905.*

DR. CHARLES H. LEWIS IN THE CHAIR.

**Pneumonia Followed by Pneumococcus Meningitis, with Autopsy.**—Dr. WARREN COLEMAN made this clinical report. The patient was 30 years old and entered Bellevue Hospital July 17 and died September 14. About July 10 she began to suffer from headaches which had been constant. On admission her temperature was 103.2°, pulse 120, and respirations 30. Indistinct signs of pneumonia over the upper part of lower and middle lobes of right side were noticed without any evidences of meningeal involvement. She also had a gonorrheal vaginitis. On July 19 there was a negative Widal and the blood showed 100 per cent. hemoglobin, red cells, 5,184,000, white cells, 10,600. One week after admission the temperature dropped to normal and the pulmonary signs had cleared somewhat. From this time on the temperature was of a septic type, and careful physical examinations failed to assign any cause for the temperature although there was present certain pulmonary signs, but no râles. Voice and breathing signs over this certain area were diminished. August 1 showed hemoglobin 78 per cent., red cells, 4,640,000, white cells, 16,000. Ten cubic centimeters of blood gave the streptococcus in pure culture. On August 6 there was no pain or tenderness in any part of the body. On the 14th the patient became stuporous, with intense headaches, rigidity of neck, and pain on moving the head. On the 16th, the patient was very stuporous but could be aroused. The headaches were continuous and rigidity of neck was very marked. There was a distinct Kernig's sign. Examination of cerebrospinal fluid was negative. On the 19th the pupils became unequal. On September 5, the patient was markedly emaciated. On the 7th, there were 23,000 whites and on the 8th the cerebrospinal fluid was found to be bloody. Cultures at this date showed the pneumococcus. On the 13th, there was strabismus with coma. The white cells were 16,600 and the reds, 2,552,000. Death occurred on the 14th. At autopsy there was found a great excess of cerebrospinal fluid and the pia mater over certain parts was very much thickened. There was a marked difference in the size of the cerebellar hemispheres and of the occipital lobes. The diagnosis at autopsy was healed (?) suppurative meningitis.

**Primary Carcinoma of the Pancreas with Metastases in the Liver, Vertebral Column, and Calvarium.**—Dr. Coleman reported a case of a patient, 30 years old, a driver, recently a porter, who was admitted to Bellevue Hospital July 24 and who died September 16. There was no cancerous history in the family. He drank a quart of beer a day but no whiskey. On July 1 his neck began to grow stiff and painful and he discovered a lump just below the occiput. About July 7 he complained of pain in the left upper quadrant of the abdomen which was constant and bore no relation to meals; the abdomen was somewhat swollen. On July 20 the lump on the side of his head was very tender. On admission to hospital the patient was pale, somewhat emaciated, and slightly jaundiced. He lay in bed with neck rigid and had difficulty in rotating the head. At the level of the third cervical spine was a hard mass. The abdomen was greatly distended, the enlargement being uniform. There were no evidences of venous obstruction. The liver extended from the fifth rib to two and one-half inches below the free border in the mammilary line. Its surface was smooth. The liver gradually increased in size, and during the last week of life nodules could be made out indistinctly on its surface and its edge became quite irregular in outline. The abdominal veins did not become distended. The nodule over the frontal bone became larger, softer, and more tender. The head movements beame more and more difficult. Hypertrophic cirrhosis of the liver was the obvious diagnosis, but there were no evidences of venous obstruction and the jaundice was very slight and soon disappeared and the spleen could not be made out as enlarged at all. The rapid enlargement of the liver and the changes in the nodules upon the head and neck made it evident at last that the case was one of neoplasm with metastases in the osseous system. A diagnosis was made of hypernephroma upon the uniform and massive enlargement of the liver, the absence of marked emaciation or cachexia, and the spinal metastases. The autopsy was performed three days after death. The liver weighed eleven pounds and eight ounces and the surface of both lobes were thickly studded with nodules; the left lobe was almost entirely converted into a mass of tumor nodules many of which were umbilicated. The spleen was normal. The pancreas had a tumor mass in its tail about the size of an apple. The calvarium was the seat of tumor metastases, one over the frontoparietal region, the other in the region of the posterior fontanelle. They infiltrated the entire bone, were soft and succulent in their internal aspect. The third cervical vertebra was the seat of metastasis. There was also a fusiform metastatic deposit in the eighth left rib as well as in the third lumbar vertebra. The anatomical diagnosis was carcinoma of the pancreas, with metastases in the lymph nodes and the osseous system.

Dr. L. F. BISHOP, in discussing the first case, reported one of a similar nature that he had seen a week before. A strong previously healthy Italian was seen at twelve o'clock. He complained of pains in the muscles and all over the body with rigidity of the back of the neck, evidently a case of meningitis although not of marked severity. Instead of the condition proceeding as it usually did the patient became worse, maniacal, and died twelve hours after admission to the hospital. The coroner came unexpectedly and the Junior was called upon to make the autopsy. Smears from the spinal cord and brain were made too late to be satisfactory. There was present meningitis, very much conjested but no pus and he believed the case to be one of pneumococcus meningitis.

**Essential and Paroxysmal Tachycardia.**—Dr. JOHN J. MORRISSEY presented certain observations on tachycardia (see page 891).

Dr. W. H. KATZENBACH remembered seeing a case of tachycardia in which the pulse rate was 240, and had been counted several times by different observers. He recognized the fact that it was difficult to count pulses above 180 or 200.

Dr. EGBERT LEFEVRE said it was possible to relate a number of cases of abnormal cardiac rate due to a number of conditions. For years the loss of pneumogastric control had been the theory most accepted, but after comparing the treatment and etiological factors it had been found that this theory did not hold. He referred to two cases in which there was well marked reflex irritation. He had seen three physicians with this condition. In two cases the irritation was from a calculus in the pelvis of the kidney; in another case it was due to the passing of a gallstone. For some time before the colic came on there were attacks of tachycardia. Cases had been traced to marked reflex irritation due to an unstable nervous system. At the meeting of the American Medical Association in Saratoga some time ago Dr. Hare advocated in cases of tachycardia a combination of tincture of aconite and digitalis on the theory that aconite increased the inhibitory action of the pneumogastric. The action of digitalis upon the heart muscle was still a question. In cardiac neuroses the combination worked very well. This condition was becoming more frequent and he did not think as formerly was merely a neurosis. It was probably some disease of the myocardium affecting the cardiac ganglia, and, in all probability, the neuromuscular system was affected primarily.

Dr. L. F. BISHOP said that he had seen a woman only last Friday who had right hemiplegia associated with aphasia. The case was one which was considered to be of

no particular interest. On Monday evening following she developed rapid heart action and on Wednesday the pulse rate was 200. The heart was feeble but the sounds were clear and regular. The patient did not seem to be very uncomfortable. The interesting point was the possible connection between tachycardia and the right hemiplegia. He thought there was some nervous accident whereby inhibition had been thrown off, allowing the heart to run away.

Dr. JOHN J. MORRISSEY said that myocardial degeneration of the heart was at times accompanied by tachycardia which became quite prominent and should be treated. Oftentimes tachycardia occurred in people who became quite nervous; this was denominated "heart hurry." In examining certain persons for life insurance this heart hurry often developed but before the examination was over passed away and the heart resumed its normal rate. There were other cases in which the heart hurry continued for some tme after, and he called partcular attention in that he believed that they pointed to an early development of an interstitial nephritis, a point he had never seen alluded to.

**Exploration of the Chest and Physical Signs in Beginning Pulmonary Tuberculosis.**—Dr. GEORGE MANNHEIMER read this paper. He said that the diagnosis of beginning pulmonary tuberculosis was a very difficult matter. It had to take into consideration in the previous and present history of the patient, it attached importance to minor symptom and combinations of symptoms in the general status, it required a most minute examination of the chest, and took cognizance of signs that seemed trifling to the inexperienced. By inspection and mensuration we ascertained the shape of the thorax, local flattening and retraction, the circumference of the chest and its relation to the height of the patient, which should not be less than one-half the maximum expansion, which should be at least 5 cm. The acromial ends of the clavicles should be on an even plane and higher than the sternal ends. The movements of both sides of the chest should be compared by looking over the shoulders of the patient, or from below upwards, or tangentially across the chest, and by watching the angles of the scapulæ. When the diaphragm phenomenon could not be observed in the usual way the fluoroscope would reveal it. The reader gave directions for palpation and directions for determining the extent of expansion. He said that the art of percussion and auscultation had made little progress during the last decades. At present we had arrived at a stage where we had different names for the same sign and when we came to the interpretation of that sign we were at sea. A uniform terminology was needed, stating as nearly as possible what the various signs sounded like, and a more thorough knowledge of the mechanism of their production should be gained by studying the corresponding lesions on the cadaver. Everybody percussed differently. Most physicians had accustomed themselves to the use of one method to the exclusion of others. Where physical signs were marked any method would reveal them, but where they were doubtful methods should be varied. In doubtful cases one should use not only finger-finger percussion but also pleximeter-finger or plexímeter-hammer percussion, also touch percussion and auscultatory percussion. One form of the latter, thoracic transsonance, percussing on the clavicle and listening in the supraspinous fossa, gave a short and dry note in case the corresponding apex was indurated. He considered the time-honored finger-finger percussion the best all-around method. For the detection of amphoric resonance nothing was better than the so-called pleximeter-rod percussion. One should percuss both during inspiration and expiration. Interspace should be compared with interspace and both light and strong blows should be used. One should not percuss too long over one area, as it led to confusion. He practised percussion on the hooked finger, as it imparted very well the sense of resistance. The most satisfactory way to percuss the apices was to stand behind the sitting patient, who kept the shoulders slightly bent forward, absolutely quiet and the hands resting on the knes. The most reliable way was that recommended by Koenig of Berlin in 1889. When the tuberculous process advanced below the clavicle, the percussion not very commonly became hyperresonant or vesiculo-tympanitic. The loudness of this must not be taken as normal, but should arouse our suspicion. Light percussion in the recumbent position revealed the additional dull quality and increased resistance. Compensatory emphysema around a healing or healed lesion might obscure the interpretation of these signs. Auscultation would help to clear any doubt as to which was the diseased side. As to how large a focus must be to be amenable to detection by percussion, Oestreich's very careful and extensive observations had shown that a single solid focus underneath the pleura must have at least the size of a cherry, and a conglomeration of foci each the size of a pea. It was especially in the area of the pamus apicalis posterior of a bronchus that the first symptoms were found which consisted in a change in the character of the breath sounds and not in the appearance of râles. He who waited for râles before he made up his mind that he was dealing with incipient tuberculosis missed his or his patient's chance. The normal vesicular murmur became rough instead of being heard as an even continuous breezy sound; it would be perceived to consist of a series of short puffs, following each other in rapid succession. It might be loud or low. It was heard principally during inspiration at the apices and presupposed areas of normally functionating tissue permeated by small foci of consolidation. Interrupted breathing was one of the easiest signs to recognize. It might be heard over the entire lung in patients with pleuritic pain, or in excited, embarrassed, or shivering patients when it had no significance. The second most common change in the respiratory murmur of a tuberculous apex was a diminution of its intensity. In our text-books stenosis of the small bronchi by catarrhal swelling was held responsible for a large array of auscultatory signs. He found that not only the rough, the diminished, and the interrupted breathing were ascribed to it, but also the increased vesicular, the broncho-vasicular breathing, prolonged expiration, and all sorts of râles. This universal explanation for such diverse phenomena was very unsatisfactory. Most râles were large, median, or fine. In apex disease they were usually fine. When large they meant cavity formation. They might then be at the same time consonant or ringing. This distinction between consonant and non-consonant râles was not sufficiently brought out in the American text-books and not duly appreciated by many practitioners. They had the same significance as bronchial breathing and bronchophony. In searching for râles we should auscultate beyond the margins to be found by percussion during quiet breathing, and we should not forget the cardiac area. The term subcrepitant râles should be abolished, as no two physicians would agree as to their nature. Small exudates or pleuritic thickenings at the posterior bases were frequently present without giving subjective signs; they were of diagnostic importance and should be searched for. We had to guard aganst mistaking for râles those sounds produced by the rubber of hair under the stethoscope, certain esophageal sounds, etc. If heart sounds were distinctly heard in circumscribed areas of the lung distant from the heart, local infiltration might be suspected. Râles were elusive; where their recognition was of great diagnostic importance it would be necessary to examine the patient in the morning on waking, before he had cleared his air passages, or he utilized methods that tended to increase secretion in the respiratory tract. Any sputum furnished in this way was carefully examined for elastic fibers and tubercle bacilli. It was necessary to make the sputum homogeneous by any of the various methods devised for the purpose. It should be centrifuged and the sediment examined. The positive findings at the Bedford Station Sanatorium had become much more numerous since the house staff had adopted the sediment method at his suggestion. He emphasized the

great diagnostic value of tuberculin. Signs of local reaction should be searched for along with the general. Vocal resonance and vocal fremitus were usually tested together. Bowles' stethoscope revealed the bronchial whisper better than the ordinary bimanual. He said it was well to remember that although dullness of percussion, bronchial breathing, consonant râles, bronchophony, bronchial whisper, and increased fremitus were equivalent signs for the diagnosis of an infiltration, they needed by no means occur together in a given case, but any one of them might be heard alone and would point to future development. Another point to be remembered was that there existed normal difference between the right and left side. In view of the difficulty of making a diagnosis of incipient tuberculosis, as a rule it should not, and in many cases it could not, be made after one examination, for the reason that it was based in the anamnesis and general status, on certain physical signs which were localized to a circumscribed lung area and which were persistent. This imposed upon us the duty of repeated examination, the intervals between which were useful for the purpose of ascertaining the temperature and examining the sputum.

Dr. Egbert LeFevre said that nearly twenty years ago a meeting was called by Dr. Quimby, where physicians from different dispensaries brought patients with well marked physical signs. These patients were placed in different rooms about the academy and all the physicians took turns in listening and then wrote down the name of the sound they heard, and also were asked to interpret the sound. It was found that hardly two men called any one sound by the same name, although they were unanimous as to its significance. He spoke of the chaotic condition of the nomenclature, but until writers of text-books got together and were brought into closer contact one could not expect order. With regard to percussing the apex, he said that the method of Koenig had gone through different languages, had been discovered and rediscovered. It had never had widespread acceptance as a method of examination. It was difficult to map out the apex of the lung with any degree of accuracy, although areas of resonance over the lung could be. Most text-books taught that a wider area was to be obtained in full inspiration than in expiration; if a full breath was taken, the muscles were held rigid, the clavicle was elevated and the area of resonance was narrower than at the time of quiescent respiration. If a deep inspiration was taken and then the muscles of respiration relaxed, there would be a ballooning out of the apex and there would occur an increase in the resonance, and one would be better able to judge to what extent the apex of the lung was distensible. He referred to the proper interpretation of the physical signs, and believed that the physicians were trying to place too much pathological and etiological significance to the various physical signs encountered. It was the anatomical condition of the lungs to which we should direct attention. The physical diagnosis of incipient tuberculosis had its limitations. Reversal of opinion had happened again and again, but since the introduction of clinical methods more hard and fast diagnoses were being made.

Dr. Alfred Meyer said that it was a good thing to have ideals, even though we never expected to attain them. It was in that spirit that the paper was written. It was a good illustration of the non-obtainable. It was not necessary to have every one call the physical signs by the same name, so long as their significance was understood. The botanist had greater difficulty in recognizing the description of flowers by the sense of smell than the physician had in recognizing the physical signs in the chest from their description. So far as making a diagnosis of incipient tuberculosis was concerned, it was important to remember that we erred in using too forcible percussion. He advocated the use of the light stroke. He advised that men plug their ears with cotton in order to exclude hearing and learn to recognize such an entity as feeling or resistance from whatever cause. He then described the method by which he mapped out areas of resonance. Adventitious signs might appear when the patient coughed. If in doubt as to the presence of adventitious signs at the apex, he advised auscultating the heart with the patient not breathing, and immediately after shifting the stethoscope to a point over the apex. In summing up all the evidence, he said there still would be a certain number of cases in which one could not say that tuberculosis was present. In reference to finding the bacilli in the sputum, he offered certain figures obtained from the Bedford Sanatorium. The sputum was examined in 43 cases 312 times with negative results. Then the method with caustic soda and sedimentation was tried, and only five gave positive results after eighteen examinations.

Dr. E. Libman spoke of the difficulty of properly interpreting sounds. He said that too much stress was laid upon the lungs as such and not upon the rest of the body in the diagnosis of incipient pulmonary tuberculosis. The glands above the clavicle should be more often examined. He mentioned the method of finding the tubercle bacilli by centrifuging the sputum and shaking with formalin and alcohol. In this way the tubercle bacilli could be found when otherwise they could not. This was the method of Quensel, the Norwegian.

Dr. Charles H. Lewis said that he was skeptical as to one's ability to make a diagnosis of incipient pulmonary phthisis on examination of the apex alone; there must be clinical symptoms as well. In going over the chest in these suspected cases one should make very careful notes and know exactly the condition, so that when the patient returned for other examinations he had data for comparison, and which no man seeing a case for the first time could have.

Dr. George Mannheimer said that in making a diagnosis of pulmonary tuberculosis in its earliest stages every detail should be studied. At Bedford Sanatorium boiling the sputum with caustic potash had been tried, but he had tried mixing it with a five per cent. carbolic acid solution. This he believed to be a good method, because the carbolic acid broke up all the mucus and did not interfere with the subsequent stain by carbol-fuchsin.

---

SECTION ON SURGERY.

*Stated Meeting, Held October 6, 1905.*

Dr. Samuel Lloyd, Chairman.

**Suppurating Mesenteric Cyst, Sinus Six Months after Operation.**—Dr. C. A. McWilliams presented a woman who had been admitted to the Presbyterian Hospital April 1, with the following history. She was 50 years old and her menstrual history was without interest. Ever since she was a child she had attacks of pain in the lower abdomen which left her after a few hours and which was relieved by lying down and warm applications. When 18 years old a professor in Bresden advised operation for supposed tumor of the uterus, which was refused. The attacks continued more or less ever since. The abdomen at these times was prominent in its lower half, but not markedly so until two weeks before she presented herself, when she felt cold and sick. The abdominal pain was in the lower right quadrant. For several days prior to admission she complained of chills, fever, and sweating. The bowels had moved every day during the acute attack and was entirely mucous. Urination was accompanied by severe pain in the lower abdomen. A little before one week prior to admission she discovered a tumor in the abdomen which gradually increased, rapidly in the past day or so. Her temperature was 104° and pulse 120. The patient did not appear to be ill. The abdomen was prominent as though it had been ballooned out by a mass beneath. It extended higher in the right iliac fossa than in the left. It was tender, particularly in the right flank. The surface of the mass was smooth and elastic. When pressed upon

through the abdomen no impulse was felt *per vaginam*. Rectal examination was negative. The diagnosis was extremely difficult. His own belief was that there was an ovarian cyst with a twisted pedicle. The house surgeon believed it to be appendical abscess. Operation was immediately performed. When the peritoneum was opened a large cystic tumor was discovered lying between coils of intestines and covered by peritoneum, extending to the left side down to the left iliac fossa and the right flank. It was as large as an adult head. With cannula and trocar 2,500 c.c. were removed. The opening into the cyst was enlarged and its cavity was found to be immense, extending to the diaphragm, behind the stomach, down to the left iliac fossa and extending to the pelvis on the right side. No attempt was made to extirpate the mass, because it seemed absolutely impossible to do so. It was a mesenteric cyst, and the intestines were so firmly attached that any attempt at removal would have probably been followed by gangrene. The wound was drained and an uneventful recovery followed. The examination of the fluid gave the following: The fluid separated into two layers on standing, the lower portion making up two-thirds of the sample, and was heavy, yellowish, and white in color. It was alkaline in reaction with a specific gravity of 1.018. No reducing bodies were found with Fehling's solution. Polymorphonuclear pus cells were found. The culture showed bacilli that stained at both ends but did not look like pathogenical bacteria. The point of interest in the case was the discharging sinus. The withdrawal of the tube was followed by a collection of fluid in the left iliac fossa the size of a grape-nut. The replacement of the tube was followed by a disappearance of the collection. He wondered if the cyst was going to heal. If it did not heal internally he did not know what further could be done. So long as the tube was kept in it drained well.

**Endothelioma of the Jaw.**—Dr. A. V. Moschcowitz showed a patient who had been recommended to him in May. A swelling was noticed in the lower jaw eighteen months prior to the time he consulted him. He paid but little attention to it. The patient was a steward aboard a steamer. When he examined him he found a swelling the size of an egg occupying the left half of the lower jaw, covered by bone similar to parchment paper often found in malignant growths. The portion of bone covering it was seen to be filled with fluid and was believed to be a cyst. Only two diagnoses were considered, echinococcus cyst and an ordinary cyst. The tumor was aspirated and a fluid containing albumin was withdrawn. On June 18 he was sent to the hospital and an incision was made in the mucous membrane to resect the entire outer wall with the intention of suturing the posterior wall lining to the external mucous membrane in order to obviate the long period of healing. After resecting the wall the small tumor appeared, which determined him to change his course of procedure. The specimen was sent to a pathologist, who pronounced it to be an endothelial sarcoma. It took a long time to granulate and heal. Some of the posterior or bony wall became exfoliated.

**Enteric and Mesenteric Cysts, with Report of an Unusual Case.**—Dr. James C. Ayer read this paper. He said that cystic tumors occupying the lumen of the intestinal canal were of such rare occurrence as to make them of pathological interest rather than of surgical importance; yet the possible origin of certain of these cysts would seem to classify them with other tumors similar in character but different in location, which, from their comparative frequency, rendered them of practical importance to the surgeon. After a careful search of literature he had been able to find but one case at all resembling the one that he reported. He related the history of the patient, a male, 23 years old, who at the time of operation had a temperature ranging from 97.5° to 99.5°, pulse between 100 and 116, respirations between 20 and 28, blood count, 4,000,000 red cells and 15,000 white cells. The differential count gave 85 per cent. polymorphonuclear cells, 8 per cent. large lymphocytes and 7 per cent. small lymphocytes. No tumor could be made out by examination, though there was tenderness at McBurney's point. The case was diagnosed as one of recurrent catarrhal appendicitis. At the time of operation inspection showed that the lumen of the cecum was occupied by a mass as large as a duck's egg and of similar shape. The mass was tense, fluctuating, and smooth, and that portion of gut wall opposite the mesocolic attachment was freely movable over it. The cecum was opened by an incision parallel to its circular fibers and the tumor delivered. It was covered by what appeared to be congested, eroded, and transformed mucosa. It was apparently sessile over about one-fifth of its surface, that portion being attached to the mesocolic border. The lower extremity lay free in the cavity of the cecum. The ileocecal valve was found to be patulous, the upper half being fused with the outer covering of the tumor. The upper end was more sessile than the lower, and terminated in a sort of funicular process, about two inches in length, lying in contact with the mesocolic wall of the gut. An incision through the presenting wall of the tumor in the line of its longest diameter resulted in the evacuation of from three to four ounces of a clear viscid fluid, which was not saved. The cavity of the cyst was lined with a smooth glistening membrane of a grayish color. The cyst wall was three sixteenths of an inch in thickness, firm, hard, and somewhat friable on its outer surface. The interior lining was smooth and firm, conforming in shape to the outer surface except that it did not extend into the funicular process at the upper end. At the point of attachment there was a pocket extending for about two inches between the layers of the mesentery of the ileum. On account of the firmness of its incorporation with adjacent structures no attempt was made to enucleate the cyst. The free portion of the cyst wall was trimmed off to within a quarter of an inch of its point of fusion with the gut. The wound was closed in the usual way, and the patient recovered. The excised portion of the cyst wall was lost, unfortunately, so he could not give the results of a pathological examination. In order to arrive at a definite conclusion as to the origin of this cyst he briefly reviewed the question of cysts of the intestine, mesentery and general abdominal cavity in the light of recent pathological investigations. The subject resolved itself into two classes, cysts of the gut and cysts of the mesentery. The reader reviewed the classifications of Braquehaye and Moynihan. Dowd had made a simpler classification of mesenteric cysts into embryonic cysts, hydatid cysts, and cystic malignant disease. Dr. Ayer had adopted Dowd's arrangement but had enlarged it to include cysts of the intestine itself. There were minor amplifications which had been suggested by reports of recent cases. He considered: (1) Cysts arising from the glandular structures of the intestinal wall. These cysts originated in an occlusion of the mouths of the intestinal glands, following some inflammatory process, generally a chronic enteritis or colitis. These cysts were generally multiple and varied in size from one to four cm. in diameter. They might occur in any portion of the colon or small intestine, but were generally found in the former. The morphology of the submucosa would indicate the possibility of retention cyst formation in that structure, although it was doubtful if cysts originating here could be differentiated macroscopically from cysts of the mucosa, unless they were of very small size. (2) Parasitic cysts (hydatids). He said that these might occur in the mesentery as well as in other parts of the body, and should be considered as primary in the structure in which they were found. He had no record of this kind of a cyst, though Nannotti had collected twenty-nine cases and Psaltoff and others had made similar observations. This form of cyst was due to the growth of the tænia echinococcus, and the diagnosis was generally made by the peculiar, laminated character of the cyst wall, and by the finding of scolices or hooklets in the cyst cavity. The scolices were often absent. The normal echinococens fluid was clear or slightly opalescent, sometimes turbid from

admixture of disintegrated scolices or fragments of the parenchymatous layer. It contained no albumin, but sodium chloride, succinic acid, ptomaines, and toxins. Its specific gravity was 1,000 to 1,015. (3) Embryonic cysts. These originated from remains of fetal organs; from snared off portions of the intestine; from sequestrations of portions of the various retroperitoneal organs and from dermoids. Under this heading belonged the major part of the cysts found in the abdominal cavity. In this connection he mentioned those extremely rare congenital cystic tumors of the abdomen which contained a more or less well developed fetus. He then considered the etiology of each of these at length. (4) Cysts of the normally placed retroperitoneal organs. He said that instances of these cysts were very numerous. The pancreas was the most likely to give rise to a mesenteric cyst. (5) Cystic malignant disease of the mesentery or intestine. This was of rare occurrence, only a few cases being on record. In regard to the diagnosis of the nature and method of production of the cyst in the case that he had reported he said that he was obliged to arrive at his conclusions by a process of elimination in the absence of histological details. From the presence of the curious diverticulum of the cyst which lay between the layers of the mesentery of the ileum he concluded that the cyst was either mesenteric or retroperitoneal in origin. This, together with the thickness and density of its walls, excluded it from cysts originating from the mucosa or submucosa of the gut. The clearness and homegeneity of the fluid excluded it from cysts of hydatid origin and also excluded a dermoid. Cystic malignant disease was also excluded for obvious reasons. This left to be considered embryonic cysts and cysts of normally placed retroperitoneal organs, of which the latter could safely be thrown out as there was no organ in the vicinity to give rise to such a cyst. It could be excluded from embryonic cysts arising from ductus omphalo-mesentericus on account of the relation of this cyst to the ileocecal valve and the position it occupied in the lumen of the colon and mesentery. The walls of the cyst were not suggestive of a snared off portion of the intestine or a cyst arising from Remak's diverticulum or from an atypical diverticula. This left but two varieties of embryonic cysts, those due to fetal rests and those due to sequestrations. He was inclined to throw out the latter because the "rests" were a more frequent source of cysts than were sequestrations. Recognizing the tendency of these "rests" to undergo cystic degeneration, and postulating the existence of such a process in the present instance, it was not difficult to conceive the chain of events beginning with a tiny retroperitoneal "rest" *in fœtu* and ending with the same structure, which had undergone cystic degeneration and became many times enlarged, and had migrated between the layers of the mesentery during the development of that structure as far as its attachment to the gut, there pushing before it the structures forming the wall of the intestine and eventually lying within its lumen.

Dr. Charles N. Dowd said that the subject under discussion had two distinct kinds of interest, first, the surgical, and second, the embryological or etiological, the latter purely a scholastic one. The diagnosis of mesenteric cyst ws seldom made, yet it was a condition that all should bear in mind, and many explorations were made with the feeling that the condition encountered might be mesenteric cyst, which would necessitate a change in the procedure. The etiology was interesting to consider, and he believed that embryonic cysts embraced a large proportion of the cases and they involved structures of various organs in a remarkable way. In one instance there was supposed to be a multilocular ovarian cyst, and yet the cyst was found in the transverse mesocolon, an ovarian embryonic sequestration.

Dr. Warren S. Bickham referred to an experience he had with a patient who weighed over 300 pounds, with a fatal termination and without the recognition of the condition prior to death. So much adipose tissue precluded any successful efforts at examination. This patient complained of intense pain and soon become unconscious, and, when he saw him, was practically pulseless. There was nothing to indicate the source of trouble except a history of pain. While preparations were being made for abdominal section the patient died. The post mortem revealed a tumor the size of a cocoanut, which communicated with the lumen of the small intestine through an opening which appeared to be open, probably had been open for an indefinite length of time, and this tumor had ruptured, with considerable hemorrhage following. The opening admitted one finger easily through the remnant of the tumor sac into the lumen of the gut. This rupture occurred during sleep, and how it occurred he was unable to say, unless, being a large man, in turning. How long the patulous condition had existed he was unable to say.

Dr. Everett J. McKnight of Hartford, Conn., briefly reviewed the history of a case he had already reported at the annual meeting of his State Society last year, and which had already appeared in the transactions. A boy, 13 years old, have the history that from infancy he had had repeated attacks of pain, colicy in nature, coming on at intervals of months and lasting two or three days. He then had constipation and vomiting. His last attack lasted two weeks and there was less vomiting, no movement of the bowels, and for three days prior to death there was fecal vomit. The attending physician had ordered salts and there was an immense distension of the abdomen with fluid. The temperature was normal, but the pulse was weak. An exploratory operation was advised. The small intestine was followed back from the ileocecal region, and what appeared to be a volvulus was found apparently adherent to the pelvis. This proved to be a cyst 4 x 3 1-2 inches attached to the side of the intestine and part of the mesentery. It was perfectly loose and nonadherent. After untwisting the gut the obstruction was relieved, but the boy died, possibly being drowned by the fecal vomit. An immense amount of fecal matter had come from the mouth. The contents of this cyst was pinkish in color, with a specific gravity of 1,060, containing epithelial cells and detritus, cholesterine crystals and blood. The tumor was lined with nonciliated columnar epithelium.

Dr. Samuel Lloyd said he saw a case last year in which he was unable to say whether the cyst was a pancreatic or a mesenteric one. He found the mesocolon separating the cyst, as had been described in Dr. McWilliams's case, the case being treated in a similar manner. The pancreas and other organs were normal and the patient appeared to be perfectly well. Dr. Lloyd suggested that, in Dr. McWilliams's case, if the fistula did not close a secondary operation should be performed, splitting up the cyst wall, laying it open; this might enable him to get rid of the fistula.

Dr. C. A. McWilliams replied that the cyst extended from the top of the pelvis to the diaphragm and practically involved the whole length of the mesentery, thus preventing such a course as advised by the chairman.

**Inguinal Hernia in Early Childhood.**—Dr. E. W. Peterson read this paper. He said that it was generally agreed that in children under four or five years of age, where uncomplicated hernia existed, the treatment should be mechanical, and that if the rupture occurred or persisted after the fifth or sixth year, that only a small percentage of cases would yield to mechanical measures. DeGarmo claimed that ninety per cent. of cases under three years of age could be cured by the application of a suitable truss. In regard to the permanency of the truss cure, Lloyd was of the opinion that a large number of the so-called truss cures relapsed at some time or other. Dr. Peterson considered only those cases in children under five years of age, and stated that about forty per cent. of all cases of hernia occurred under the age of fourteen years. The condition might be present at birth and not appear until the child began to walk. The speaker was of the opinion that the cause of hernia in every case was due to defective develop-

ment, and rarely, if ever, to constipation, whooping-cough, crying, etc. He agreed with Hamilton Russel and Deanesly that the essential cause of hernia was the presence of a preformed sac of congenital origin, and that the strain acted simply as the exciting cause. He believed, further, that this developmental imperfection was as much of an abnormality as hypospadias, imperforate anus, hair lip, etc. In more than two-thirds of the cases of rupture in early childhood the sac was of the acquired variety. He had operated upon infants one week after birth and had found a sac of the acquired type. He had also operated upon two cases of bubonocele, where the rupture never passed below the external ring, yet in both cases an acquired sac reached down into the scrotum almost to the testicle. The sac of an oblique inguinal hernia was always adherent to the structures of the cord, and, no matter how recent its origin, he had never seen a case that could be reduced into the abdomen. Symptoms of hernia in early life were very much the same as in adult cases, though pain did not seem to be so common a symptom in childhood. The reduction or retention of a hernia often immediately relieved a restless or crying child, and many reflex gastric, intestinal and nervous symptoms disappeared promptly when a rupture was properly supported or relieved by operation. These reflex disturbances deserved a more prominent mention than given them in textbooks. The conditions which might be mistaken for hernia were various forms of hydrocele, femoral hernia, inguinal adenitis, psoas abscess, orchitis, undescended testicle, etc. The cases in which operation was positively indicated were: (1) Those in which strangulation existed or had been reduced by taxis; (2) all cases not controlled by truss; (3) where truss wearing caused pain; (4) where the patient could not be observed regularly; (5) in cases associated with reducible hydrocele or fluid in the hernial sac. Following, in a general way, these indications, he had operated during the past year upon twenty-three cases for the radical cure of hernia in young children. Three cases were under one year of age and three under two years, and the remaining were under four and one-half years of age. There were three cases of strangulation. There was one case of encysted hernia and hydrocele of the cord. In every one of the cases there was some feature of interest and some definite indication for operation. The Bassini method deservedly occupied the first place in the treatment of inguinal hernia, as it dealt thoroughly with both the sac and the canal. If rigid asepsis, absolute hemostasis, and a minimum amount of traumatism to the tissues were carried out this operation would give practically uniformly successful results. Two points he emphasized were: First, in splitting the aponeurosis of the external oblique, the division should be made in the cleavage line and as high above Poupart's ligament as possible. If the division was made directly over the inguinal canal, the lower flap of aponeurosis was so short that it was difficult to put in the two deep rows of sutures without tension and subsequent danger of splitting or sloughing. Where the long flap was used there was no tension on the stitches, and the suture rows were on different levels, thus giving a stronger wall. Second, that Lloyd, in a study of recurrence of hernia after operations, had demonstrated that the relapse was usually at the lower end of the wound and the rupture was of the direct type. His own studies had confirmed this observation, and therefore it was of the greatest importance to accurately coapting the internal oblique and transversalis muscles to Poupart's ligament at the lower end of the wound. After operation patients were kept in bed ten or twelve days and a bandage worn for three or four weeks. Children bore these operations well.

Dr. Neil Macphatter said that the whole secret of the matter was the study of the ring and its formation; this was absolutely necessary for a thorough and comprehensive understanding of the subject. When one considered that the testicle developed from the kidney in early embryonic life, and that the testicle developed behind the peritoneum and was brought down into the scrotum by the gubernaculum testis, being attached in three places, and when one considered the fact that sometimes the gubernaculum became too zealous and a sac of peritoneum was brought down as well, so as to form a nest or bed for the testicle, then one would be aided in their understanding of these hernias. Sometimes this process of peritoneum did not become obliterated, and then we got a congenital hernia. Occasionally one got an infantile variety of hernia covered over at the top and strong enough to resist the descent of the testicle for some time. If the child strains then these strands would give way and hernia develop suddenly.

Dr. Charles N. Dowd said that the question of whether a child should wear a truss or be operated on was a very important one, but the tendency to-day was for radical operation. When operative procedures are carried out the mortality rate was probably from .25 per cent. to .50 per cent. with the rate of relapses practically nil. In Dr. Coley's statistics of 1,400 cases there were eleven relapses, a very small proportion. At St. Mary's Hospital relapses were unknown. A truss could be worn under certain conditions. If the child could have careful and intelligent watching, with the means and inclination for doing it, the child certainly should be given the chance without operation and with a small risk. But when a child was brought to the hospital, coming from conditions and surroundings which made it impossible to follow out the truss treatment, then there was danger in attempting it. The conditions under which a child lived had a great deal to do with the decision of the question.

Dr. A. V. Moschcowitz said that it made all the difference in the world whose bull was being gored or whose corns were being trod on. Personally, he had grounds for serious doubt regarding the curability of herniæ, even in very young children, by means of the truss treatment. If one "cured" these hernia, there still remained potential herniæ. In the typical Bassini operation one closed up the lower part as tight as one wanted to, suturing the combined tendon, the internal oblique, and Poupart's ligament where it was attached to the spine of the pubis. If, therefore, recurrences occurred they must occur where the opening was left for the transmission of the spermatic cord, *i.e.* at the upper angle and not low down. Of late years he had been doing a modified Bassini's operation, not transplanting the cord, but leaving it in its bed, suturing the ligament over the cord. Here recurrences would occur at the lower angle, because there was the point of emergence of the cord.

Dr. Samuel Lloyd said that during the past few years he had looked up a large number of cases, and he found that, in the great majority of the cases, it was the exception to find recurrences occurring through the internal ring; the hernia came through at the lower end, and this he believed to be due to the fact that operators did not succeed in sewing down Poupart's ligament, making it firmly adherent to the symphasis pubis; the result was an extrusion of the gut through the lower end. He called attention to some remarks made by the elder Ford some years ago, when he was surgeon to the Randall's Island Hospital, and when he contracted for truss work. A great many measurements for trusses were demanded and he remembered well a statement by Mr. Ford, "Why not operate upon these babies?" Dr. Lloyd answered that they were too small. Mr. Ford replied, "I am trussing some babies that I began to truss forty years ago."

Dr. C. A. McWilliams said that he had had three cases of undescended testicle, one being accompanied by a strangulated intestine. The intestine was found at the bottom of the scrotum with the testis in the canal. Another case showed the testicle at the internal abdominal ring and a sac of peritoneum went down one-half into the scrotum. In the third case the testis went into the scrotum, but laid on Poupart's ligament outside the external ring and had no sac.

Dr. Moschcowitz asked Dr. McWilliams if the hernia in any case was large; if so, the sac would protrude into the scrotum.

Dr. McWilliams replied that they were all small. The ages of the three children were 8, 10, and 15 years, respectively.

**Subcutaneous Pelvicureteral Implantation, in Lieu of Ureterectomy After Nephrectomy.**—Dr. A. Ernest Gallant asked if removal of the ureter after nephrectomy was advisable, desirable, or necessary, and his own answer to this question was best stated by a recital of the history, method of operation, and outcome of a case which led up to certain conclusions. The following technique was employed: After the kidney had been delivered and the renal vessels securely ligated the kidney was freed from the ureter by cutting across the pelvis about one inch above its junction with the ureter, thus leaving a funnel-shaped opening into the ureter which must be sutured to the lumbar fascia in such a way that the mouth was not exposed on the skin surface, but opened into the subcutaneous fatty tissue. The flaring of the funnel made suturing very simple, the introduction of the drainage tube easy, and the mouth did not contract. When the discharge ceased the skin readily closed over the outlet and buried it, but should pus or mucous reaccumulate a simple incision through the cuticle released the pus and drainage could again be established. Refilling was announced by pain, fever and bulging at the site of the implanted ureter, but by this method there could be no involvement of the retrocolic space or any of the deep structures. This operation avoided the additional risk of immediate ureterectomy and secured free and easy drainage and maintained an opening through which drugs could be introduced to hasten retrograde changes. On the other hand the opening being beneath the skin did not prevent primary union and avoided exposure on the skin surface, and, should mucous or pus accumulate, it could not burrow in the retrocolic space, was easily recognized and released through a small skin incision and a tube inserted for drainage. There was an absence of ligature on the ureter and deep inflammation was avoided. If the ureter must be subsequently removed it could be accomplished without difficulty. The presence of the drainage tube in the ureter, with or without vaginal implantation, did not interfere with the patient in getting out of bed at an early date after operation, nor the exercise of her home duties.

## Chicago Medical Society.

At the regular meeting, held October 25, Dr. Arthur Dean Bevan made some remarks on "Treatment of Actinomycosis and Blastomycosis with Copper Salts." He had found in connection with the treatment of actinomycosis that the iodide salts had very definite and positive effects, and they had been quite successful in curing the circumscribed lesions about the mouth, tongue, and neck with iodide of potassium, and combined with it the *x*-ray, used as had been emphasized by Ochsner in intermittent doses, that is, giving the iodide of potassium for a period, then discontinuing it, and then giving it again. This fact was noted, that although marked impressions were made by the iodide salts on all cases of actinomycosis, the cases of abdominal actinomycosis and of lung actinomycosis were fatal in a large percentage of cases. Probably seventy per cent. of the cases of abdominal actinomycosis were fatal, and about 90 per cent. of lung actinomycosis were fatal in spite of the iodide treatment. In regard to some of the cases the speaker reported last year, one abdominal case had since died with very definite brain lesions. He had no doubt, although the post-mortem was not obtained, that it was a ray fungus lesion of the brain. One of the lung cases had made apparently a surprising recovery, as the patient had now no active evidence whatever of the process. He presented a patient with abdominal actinomycosis, secondary to ray fungus either of the appendix or of the cecum. The patient developed an enormous lesion which filled the entire pelvis. He was operated upon, and the abscess cavity opened, with fistulæ found extending in all directions. The patient was placed upon large doses of iodide of potassium, and in spite of that fact there was suppuration, and fistulæ continued to develop. About six weeks ago he placed the patient on copper sulphate, using it internally and as an irrigation. He began with one-fourth of a grain of copper sulphate, three times a day, then increased it to half a grain, and he had given some of his patients as high as one grain three times a day. It had been determined by French chemists that copper sulphate could be used in doses of from two to eight grains a day for six months at a time, without any deleterious effect to the individual. In the same connection he had used copper salts in two cases of blastomycosis. Iodide of potassium had a very powerful effect, used internally, in these cases. Many of them had been cured with iodide alone. Of the superficial cases the ordinary treatment of blastomycosis had been the combined use of the iodide and *x*-ray. Possibly, as had been shown by some experiments conducted by Prof. Haines and the speaker, the *x*-ray might produce a more powerful effect; that is, the iodide might produce a more powerful effect with the *x*-ray, because free iodine was given off as the result of the *x*-ray in iodide solutions. Some cases resisted the *x*-ray and the iodide treatment, and this was especially so in cases of general blastomycosis. Iodide as a successful means of treating general blastomycosis could not be considered, no matter how successful it had been in the cutaneous cases combined with the *x*-ray. He showed the effect of copper salts in one case of quite extensive blastomycosis involving the entire dorsum of the hand. He had used the copper salts internally in one-quarter grain doses, three times a day, then in half grain doses three times a day, using the copper sulphate as a wash in a one per cent. solution. The hand had almost entirely cleared up. The next patient was a man whom he had treated with copper salts for actinomycosis of the abdomen. At the time the iodide was used, he employed the *x*-ray. There was a large mass filling almost the entire pelvis. The ray fungus could be found in the pus at almost any time. There was extensive infiltration of the recti muscles by process; fistulæ were developing and now this pathological process had almost entirely cleared up under the iodide, so that the patient had gained twenty pounds in weight since the first of September under this treatment. He did not want to create an erroneous impression in regard to this treatment, but submitted it for what it was worth, believing it to be of considerable value.

At a meeting, held November 1, 1905, Dr. Henry Gradle read a paper on "The Efficiency of Salicylate of Sodium in Inflammatory Diseases of the Eye." This agent did not act specifically on any one form of disease, but it shortened the course and reduced the severity of many different types. It required to be given in very large doses, and although distressing, it never caused serious disturbances in large doses. It was best tolerated in the form of tablets. In non-suppurative tenonitis it had always shortened the course. In episcleritis, used only after other less annoying local measures had failed, it sometimes acted promptly, sometimes more slowly. Small sluggish infiltrates in sections of the cornea were usually made to heal rapidly in case the customary local treatment had proven inefficient. Salicylate of sodium might prove of great benefit in those rare instances of phlyctenular disease in which persistent lesions did not yield to the ordinary local treatment. It had influenced very strikingly some of the atypical forms of circumscribed deep keratitis. In diffuse interstitial keratitis the writer had seen no permanent benefit, nor had it affected the course of corneal ulcers. In atypical forms of iritis it had at times a striking influence upon the duration of the disease. In serous cyclitis it proved useless. Its greatest utility was seen in infectious iridocyclitis following injuries. Three cases of sympathetic disease of the second eye were treated from the start with

large and almost continuous doses of salicylate of sodium, and all recovered with perfect sight. Dr. D. N. Eisendrath read a paper on "Early Diagnosis of Acute Abdominal Conditions." He laid stress upon the fact that many of the cases observed by surgeons were not diagnosed as early as they might be if a more careful study of the patient's general and local conditions were made. He suggested dividing the acute abdominal affections, if seen at an early period of their development, into four classes. (1) Those in which symptoms of suppuration appeared early and predominated. (2) Those in which pain of varying intensity was the predominant symptom. It might be followed by signs of localized or diffuse peritonitis, or by the symptoms of intestinal obstruction. (3) Those cases in which the symptoms of intestinal obstruction were the most prominent from the onset. (4) Those in which signs of internal hemorrhage were marked, and were followed by signs of peritoneal irritation. The four classes were discussed at length. Much emphasis was laid upon the local examination of the abdomen, and the general practitioner was urged to make a careful physical examination of the patient's abdomen which should embrace, first, the location of the pain and the direction in which it radiated. Second, the amount of distention, whether local or general, of the abdomen. The third important point in the physical examination was to observe by the gentlest touch possible the amount of muscular rigidity. A fourth point was the detection of superficial tenderness which always accompanied the rigidity. Dr. Thomas A. Woodruff discussed the subject of "Changes in the Retina and Retinal Vessels as an Indication of Lesions in Heart and Blood Vessels."

## Pathological Society of Philadelphia.

At a stated meeting held October 26 Dr. Samuel Leopold read a paper entitled "Report of a Case of Coccygeal Teratoma." Dr. Courtland Y. White presented a communication entitled "Pathogenic Molds." He discussed especially the activity of the aspergillus group and exhibited specimens of birds showing the lesions due to aspergillosis. He pointed out that the aspergillus may be present as the cause of a primary and exclusive infection; or it may be engrafted upon a preexisting tuberculosis; or it may be present as a saprophyte. Similar conditions are observed occasionally in man also. Dr. M. Howard Fussell demonstrated a specimen of "Large Left Cystic Kidney, with Calculus of the Right Kidney." The patient was a young man who had presented symptoms of urinary disorder for some time. Skiagraphic pictures disclosed the presence of calculi in the right kidney. While under observation a large tumor developed in the opposite half of the abdomen and death resulted. On post-mortem examination eight calculi were found in the right kidney, while the left was converted into a large cyst. No cause of urinary obstruction was found in the left kidney or its ureter, and the conclusion was reached that the organ had been a mobile one which from time to time became kinked, so that accumulation of urine took place in its pelvis with the formation of a tumor. It was subsequently learned that symptoms of such a condition had been observed during life. Dr. A. O. J. Kelly presented a communication entitled "The Nature and the Lesions of Cirrhosis of the Liver, with Special Reference to the Regeneration and Rearrangement of the Liver-parenchyma." He considered first the normal histology of the liver, secondly the changes that take place in the parenchyma in cases of cirrhosis and finally the changes in the interstitial tissue. He was able to show that the cirrhotic change begins in the parenchyma of the lobules of the liver, constituting a form of cellular degeneration, and that the increase in interstitial connective tissue is secondary. He objected to the employment of such qualifications as atrophic and hypertrophic as applied to cirrhosis of the liver, and contended that the question of size is incidental and not essential, and that the real disturbance resides in the parenchymatous structures. Dr. Randle C. Rosenberger presented a communication entitled "The Spirochete Found in Syphilis." He had studied the secretions from various syphilitic lesions in some 33 cases of syphilis under diverse conditions and he succeeded by great persistence in finding the spirochete described by Schaudinn and Hofmann in every one. He made a large number of control observations, and while spiral organisms were often present they were appreciably different from *Spirochæta pallida*. The organism can be stained with great difficulty and at times it can be found only after protracted and painstaking search. It must be distinguished especially from a larger spirochete often found under the same conditions as *S. pallida* and staining more deeply, namely, *S. refringens*. Dr. Allen J. Smith presented specimens of extrauterine pregnancy and dermoid of the eye. Dr. C. Y. White exhibited a specimen of melanosarcoma of a horse's tail.

## Philadelphia County Medical Society.

At a stated meeting held October 25 Dr. John H. Gibbon read a paper entitled "The Operative Treatment of Fracture of the Patella," and he exhibited a number of patients illustrating the value of the method. Without delay the curvilinear incision is made through the tissues below the line of fracture, the latter being freely exposed, interposed structures removed, the fragments united by sterile catgut sutures and the wound closed. The results have been eminently satisfactory. Dr. Herman B. Allyn read a paper entitled "Two Cases of Severe General Infection of Obscure Origin." Both terminated fatally, but autopsy was secured in only one. In this, hemorrhagic pleural effusion was found, but in neither was the essential lesion determinable. Dr. W. Wayne Babcock read a paper entitled "A New Method of Surgical Anesthesia." He pointed out the antiquity of anesthesia induced by the administration of drugs, particularly mandrake. In more recent times morphine has been employed for the same purpose, and lately preparations of the belladonna group have come into use. Hypodermic injection of morphine and atropine has for some time been known as a serviceable procedure in advance of inhalation-anesthesia. Within a few years, scopolamine, which is now supposed to be identical with hyoscine, has been employed in combination with morphine for the purpose of inducing surgical anesthesia, and a considerable literature has already accumulated on the subject. An injection of gr. 1-100 of scopolamine hydrobromide and gr. 1-6 of morphine sulphate is made subcutaneously and repeated in an hour if necessary and for a second time in a shorter while if required. Dr. Babcock has modified this procedure by the substitution of apomorphine, gr. 1-10 in the third injection. Anesthesia was induced by this means in 33 cases of widely varying surgical conditions and the results in general were most satisfactory. As a rule the patient is unconscious—occasionally he is not, but generally there is no recollection of pain or operation. Often the patient is scarcely able to believe that there has been an operation at all. There is an absence of nausea and of vomiting. There may be some muscular rigidity during the operation, but respiration is calm and there is practically no disturbance of the abdominal contents in operations within the abdominal cavity. Sometimes there is delirium and motor excitement. The method proved especially applicable to operations about the mouth and upper air-passages, there being a measurable freedom from secretion, and the patient getting rid of blood and discharge by swallowing or expulsion, so that entrance of fluid into the larynx was avoided. The procedure is particularly valuable in cases in which operative intervention is indicated and inhalation-anesthesia cannot be borne. To attain successful results it is essential that a trustworthy preparation be secured and that the first injection be given not less than an hour before the operation.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 25, 1905.

| | Cases | Deaths |
|---|---|---|
| Measles | 326 | 11 |
| Diphtheria and Croup | 310 | 31 |
| Scarlet Fever | 153 | 11 |
| Smallpox | | |
| Chickenpox | 121 | |
| Tuberculosis | 406 | 162 |
| Typhoid Fever | 65 | 9 |
| Cerebrospinal Meningitis | 17 | 7 |
| Typhus Fever | | |
| Yellow Fever | | |
| Cholera | | |
| Totals | 1,398 | 231 |

**Voluminous Tumors.**—De Rouville reports a number of these cases. In 1904 he removed a mixed carotid tumor weighing 2 kilogrammes, 950 grammes. It is interesting to note in this tumor the absence of all malignant tissues. The patient continues in excellent health. A case of very large tumor of the thigh was observed in a woman sixty-five years old. There was nothing noteworthy in either the personal or family history. The tumor, which the patient first noted at the age of eighteen, was very small. It increased in size slowly but continuously, but it never gave any pain, nor did it exercise any unfavorable influence on the general condition. After an attack of influenza the tumor grew more rapidly, and ulcerated. When the writer examined it, it had reached the size of an enormous gourd. It was removed without trouble. It was found to be a lipoma weighing 11 kilogrammes, 800 grammes. Another case is that of a tumor over the sternum. This proved to be a dermoid cyst. It was the size of two large adult fists. The last case mentioned by the writer is that of a large adenofibroma of the breast. The woman was a patient forty-four years old. The tumor after removal was found to weigh 2 kilogrammes, 800 grammes.—*Le Bulletin Médical.*

**A Practical Suggestion Respecting the Removal of Foreign Bodies from the Larynx, Illustrated by a Case of Cockle-Burr upon the Vocal Chords.**—Robert Barclay reports this interesting case describing his method of removing a cockle-burr from the larynx. The great immediate difficulty in a case of this kind in attempting forcibly to remove a foreign body of this character from this position is that of the intense reflex laryngeal spasm which may be excited thereby, against the sharp spines and tentacles of the cockle-burr. The writer first applied a light spray of cocaine to anesthetize the superficial tissues of the larynx. The patient was directed upon the word to take a slow, very deep, forced inspiration; and then at the words, "Say 'A'!" (not Ah) to attempt to phonate that vowel. She was told to prolong this sound, however much it might tax her to do so, at the end of her breath. This proceeding was followed out. The forceps was passed at the proper moment behind the burr, the blades were gently separated, the burr was firmly seized, and the patient was told to say "A." She kept up this sound until she was desperate for air, when she was directed to "Breathe!" The larynx at once relaxed into the position of forced inspiration. A slight wig-wag motion of the forceps brought away the entire burr without the loss of one of its parts, and without wounding any of the laryngeal tissues. The recovery was uneventful.—*The Medical Fortnightly.*

**Clinical Forms of Chronic Rheumatism.**—According to Teissier, chronic rheumatism is an infectious disease, the pathogenic agents of which are multiple and varied in different cases. Chronic rheumatism shows itself in diverse forms. The osteoarticular type includes chronic rheumatism, primary or secondary; certain forms of spondylosis (these cases are rather rare) in which there are noted deforming articular lesions; and certain cases of Heberden's nodes. The serous type includes cases of chronic synovitis and tendovaginitis, certain latent pleurisies, and so on; and generally also such skin phenomena as purpura, erythema multiforme, and erythemanodosum. The fibrous type is observed in the hypertrophy of periarticular organs; in certain cases of Dupuytren's disease; in certain cases of spondylosis with alterations in the vertebral ligaments; and in certain cases of scleroderma. The muscular type is seen in chronic rheumatismal myositis, and in certain cases of spondylosis of muscular origin. Up to the present time the existence of tuberculous rheumatism is merely hypothetical. Tuberculosis appears, nevertheless, to determine in some cases articular disorders which have nothing in common with rheumatism.—*Le Bulletin Médical.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended November 20, 1905:

SMALLPOX—UNITED STATES.

### ON CERTAIN FORMS OF OCULAR TUBERCULOSIS.*

BY CHARLES STEDMAN BULL, A.M., M.D.,
NEW YORK.

IT is now generally admitted by ophthalmologists that as regards the pathogeny of ocular tuberculosis, the eye may serve as a point of entrance of the infection into the general organism, and usually by way of the conjunctiva. We have reason to believe that tuberculosis of the conjunctiva is much more often a primary disease, the result of an ectogenic infection, even in cases where tuberculosis has already developed elsewhere in the body, than of infection occurring through the blood. But, although tuberculous disease of the conjunctiva is not often secondary to tuberculous disease in other parts of the system, yet it is itself liable to be the starting point of general tuberculosis.

An intact normal conjunctiva can, however, never be infected. There must always be a loss of substance usually a traumatic abrasion.

The conjunctival tuberculosis may long remain the sole localized point of infection, and hence the early removal by the knife here may lead to a cure. In certain cases, however, the conjunctiva may be invaded secondarily from the skin of the eyelids, from the lacrimal sac, from the nose, or from the eyeball. In these cases where the miliary nodules are not visible to the naked eye, the bacilli may sometimes be demonstrated in bits of tissue removed from the conjunctiva. Later in the course of the infection, every part of the eye may be invaded.

*Tuberculosis* of the *skin* of the *eyelids* is very rare as a primary disease. The lesion here consists of discrete shallow ulcers, with irregular eroded edges, and a pale yellow granular surface. These ulcers never heal, but extend and coalesce, especially along the ciliary margin of the lid, where they involve the conjunctiva.

*Tuberculosis* of the *conjunctiva* is a rare affection, which may be primary, but is generally secondary to nasal tuberculosis. When primary, an abrasion of the epithelium may furnish the nidus for the growth of the bacillus, which may be introduced from without, by the air, dust, towels, or the fingers. It is a singular fact that of the comparatively small number of cases reported, the majority of them have been in patients at or about the age of puberty. The conjunctiva of the lids is more often involved than the ocular conjunctiva. It is generally unilateral, and as the disease extends the conjunctiva of the eyeball is invaded, the cornea may become involved, and later the interior structure of the eye also. Then the preauricular glands, and sometimes the cervical and submaxillary glands may become involved.

*Read before the Practitioners' Society, November 3, 1905.

Its first appearance is characterized by small miliary nodules in the palpebral conjunctiva, which soon ulcerate and tend to coalesce. The conjunctiva is generally thickened, and in the subconjunctival tissue are found similar nodules, which have not yet ulcerated. The ulcers are ragged and the bottom looks "worm-eaten." The nodules vary in size, and as time goes on they grow and look like the hypertrophied papillæ, being accompanied by an extensive growth of granulation tissue. The eyelid becomes thickened, and there is a scanty mucopurulent discharge. There is usually but little pain.

The diagnosis is not always easy, and the disease must de differentiated from trachoma, chancre, and epithelioma. The bacillus is not always to be found, either in the secretion or in microscopic sections of the tissue, and when not found, inoculation experiments on animals should be instituted, for these will prove the diagnosis when the bacillus has not been found in the tissues. The injection of tuberculin in all doubtful cases is often a decided aid to diagnosis. The course of the disease is essentially chronic. The prognosis, of course, depends on the possibility of the destruction or removal of all the diseased tissue. When there has been total destruction of the conjunctiva, even over a limited area, this is not practicable. The idea has been suggested that tuberculosis of the conjunctiva might act as a focus for the dissemination of a general infection, but we have no absolute proof of this.

*Treatment.*—If a nodule or ulcer is small, it should be extirpated by the knife or the galvanocautery. The writer has tried tuberculin injections, but always without any success. Some cases have been reported where the *x*-ray treatment had been used with success, but the writer has had no personal experience with this method. The reaction from repeated injections of tuberculin in these cases is sometimes so severe, that it is wise, at least in the beginning, to limit the dose to two or three milligrams.

*Tuberculosis* of the *cornea* and *sclerotica* is exceedingly rare, only two cases of the latter having been reported in literature. The cornea, like the lens, seems to be very little liable to the infection. I have never seen a case of primary infection of the cornea, though such are reported. The corneal infection is usually secondary either to conjunctival infection, or to extension of an intraocular invasion from the iris to the cornea. The diagnosis must depend upon the presence of the bacillus in the scrapings and detritus removed from the cornea. The prognosis is unfavorable, and the only treatment available seems to be the galvanocautery. In the writer's experience, the injection of tuberculin, TR, has proved entirely useless.

*Tuberculosis* of the *iris* may occur in two forms, either as disseminated growths, or as a solitary tuberculous mass.

In the first form, small reddish nodules appear

in the iris, which may subsequently flatten and disappear, or be followed by numerous grayish elevations, mainly at the periphery of the iris, varying in size from one to five millimeters. Each is surrounded by a zone of fine bloodvessels, making the base appear red. Sometimes these elevations appear at the papillary margin of the iris. Whether these miliary tubercles disappear or become larger, by coalescing, the entire iris becomes dull, thickened and discolored, and adhesions are formed between the iris and the capsule of the lens, proving the existence of a general iritis, and the entire pupil may be occluded by the growth of the small tuberculous masses.

In a certain number of instances, these disseminated tuberculous nodules are absorbed and disappear, and in these patients the presence of other foci in the body either have not been positively recognized, or, if present, they have been absolutely quiescent. Leber has described these cases as "attenuated tuberculosis," but they must not, therefore, be regarded as offering a favorable prognosis; for they have been known to be followed by meningitis, or acute miliary tuberculosis of the lung, and death. This "attenuated tuberculosis" is not deficient in infecting power, for inoculation of an excised portion of such an iris in the anterior chamber of a rabbit's eye will produce severe local and general tuberculosis in the animal.

The second variety of tuberculous disease of the iris is characterized by a single round or oval nodule of considerable size, arising from the periphery of the iris. This is of slow growth, but may fill the entire anterior chamber, involve the cornea, and end in perforation of the eyeball, and protrusion of the tuberculous mass. The tubercle bacillus may be found in the nodule. This form is unilateral and rarer than the disseminated form. Both varieties usually occur in young adults, who have a family or personal history of tuberculosis, and many of them present other signs of active infection, such as suppurating glands and joint affections. In view of these facts, it is doubtful whether tuberculosis of the iris is ever a primary disease.

The diagnosis depends partly on the character and course of the lesion, and partly on family or personal history. Tuberculin injections are a decided aid to the diagnosis. The disease must be distinguished from syphilitic gumma and from sarcoma. The latter usually appears at a later period of life, and grows more slowly. If a solitary growth is found in the iris, without any signs of inflammation, and if syphilis can be absolutely excluded, the test by tuberculin injections should be made, and, if the reaction occurs, treatment may be begun by tuberculin injections, though in the writer's hands this method has given no satisfactory results. It is not wise in these cases to attempt the removal of the single nodule by iridectomy, on account of the danger of the more rapid spread of the disease. In all cases of multiple growths, the eye should be enucleated before perforation has occurred, provided there is no evidence of the existence of other foci of disease elsewhere in the body. It was formerly believed that tuberculosis of the iris was a primary affection, and as such necessitated an immediate enucleation of the eye, in order to prevent a general infection. But there is now a widespread belief that tuberculosis of the iris is also a secondary infection, and hence enucleation is not always indicated.

*Tuberculosis of the Chorioid.*—Tuberculous disease of the chorioid also occurs under two forms, the so-called miliary tubercles, associated with general acute tuberculosis, and in large masses of infiltration, associated with chronic tuberculosis.

Miliary tubercles of the chorioid are almost always bilateral, and vary in number from one to twenty or more, and in size from one to three millimeters. Repeated examinations are often necessary to detect them, on account of their small size, and they have been found at autopsies, when they were not recognized during life. They are of a yellowish-white color, surrounded by a rose-colored area, scattered all over the fundus, and have been mistaken for patches of chorioiditis disseminata. They are of decided prognostic value in many cases, for they appear shortly before death, some observers affirm only a few days before. They grow from the adventitia of the larger vessels in the deeper layers of the chorioid. They may cause no disturbance of vision, and must often be repeatedly sought for before they are found Some of a larger diameter than three millimeters are occasionally found, but these tend to coalesce into large masses. They may form rapidly or slowly, and their actual frequency cannot be accurately estimated. As a rule, their presence is of diagnostic value as an evidence of general tuberculosis, and of prognostic value, because they are found when the general infection has reached an advanced stage; but their absence is of no significance. They are usually, but not necessarily, associated with similar nodules in the meninges.

The bacilli can, by no means, always be found in these eyes at the autopsy. One additional diagnostic value is that their presence may enable the physician to distinguish acute miliary tuberculosis from typhoid fever, which it sometimes resembles.

According to the most recent statistics, these tubercles have been found in fifty per cent. of the cases of acute miliary tuberculosis and tubercular meningitis, and in ten per cent. of the cases of chronic tuberculosis.

The second form of chorioidal tubercle, the large mass of infiltration or conglomerate tubercle, is usually met with in the subjects of chronic tuberculosis, whose general condition is much more favorable than those affected with miliary tuberculosis. The disease, like the acute form, is secondary to a tuberculous lesion elsewhere. It is usually unilateral, and ophthalmoscopically resembles a chorioidal sarcoma. At first it gives rise to no symptoms, unless occurring in the vicinity of the macula lutea, when, of course, the vision is defective, but it may be characterized by the early appearance of destructive inflammation of the eye, with perforation. It occurs chiefly in children and in young adults. Its appearance, under the ophthalmoscope, is a solitary grayish-white spot of elevation, and it may be distinguished from a sarcoma by the absence of vessels, and from an intraocular cysticercus by its immobility.

As the disease is always secondary, it is bad surgery to advise enucleation of the eyeball in every case, with the object of preventing general infection; but those cases which show a tendency to grow very rapidly and cause perforation of the eyeball, are better removed, in order to save the patient much suffering and long-continued suppuration.

There is a form of chronic tuberculosis of the chorioid, which appears in groups of nodules, and involves the retina, and is therefore, a chorioretinitis, and it has been called by Michel chorioretinitis disseminata tuberculosa. Michel has gone

so far as to say that every case of nodular exudation in the chorioid, which cannot be traced directly to constitutional syphilis or some other equally known cause, must be regarded as tuberculous. Whether we accept this dictum or not, it has been proved that the chronic nodular tuberculous chorioretinitis can exist as an independent lesion, with no clinical evidence of any tuberculous infection elsewhere in the body.

This form of disseminate chorioretinitis may seem an entirely benign course. The groups of nodules are at first yellowish-white, with but little elevation and with ill-defined margins. These may be pigmented or free from pigment. Later, the chorioid in the vicinity becomes discolored. But it must be admitted that the ophthalmoscopic picture of the supposed tuberculous chorioretinitis is difficult to distinguish from other ordinary forms of chorioretinitis disseminata.

Microscopical examination of chorioidal tubercles seems to prove that the nodules which consist solely of epithelioid elements are more difficult to recognize ophthalmoscopically than those consisting of lymphoid elements. The vascular changes in this form of chorioretinitis are not so marked as in the chorioretinitis due to syphilis or arteriosclerosis. In making our diagnosis, we must also depend upon the results of the general physical examination. If tuberculous disease is found elsewhere, and there is no evidence of syphilis or of general arteriosclerosis, then the diagnosis is easy. But it should not be forgotten that even when we cannot demonstrate clinically the presence of tuberculosis, it does not necessarily follow that none is present. It is known that changes in the chorioid sometimes precede the development of tuberculous disease elsewhere. In these doubtful cases the past history of the patient is valuable, as to the presence of other diseases, or of hereditary taint. Schultz-Lehden suggests that the rather benign course followed by this form of chorioretinitis may be due to a less virulent tubercle bacillus, or even to spores, and experiments by Stock have shown that the injection of very virulent tubercle bacilli into the veins of a rabbit's ear almost always causes a tuberculous inflammation of the chorioid of a mild, benign type.

*Tuberculosis* of the *retina* is rare, and may be said never to occur as a primary lesion, and never involves the retina alone. When found, it is usually around the optic nerve entrance, and is accompanied by such intense papillitis, that ophthalmoscopically the tubercles are not recognizable. Under the microscope they are found to occur in the nuclear and molecular layers, and they are always associated with general tuberculous infection of the whole eyeball.

When we come to speak of the *optic nerve*, it may be stated positively that the optic papilla, the intraocular end of the optic nerve, is never the seat of tuberculous disease, unless all the tissues of the eyeball are involved. The optic nerves back of the eye, the optic tracts, the chiasm, are infected in general tuberculosis, but always directly by extension of the disease from the meninges, or by the proximity of tuberculous nodules at the base of the brain. It may be remarked here that visual disturbances without ophthalmoscopic findings in tuberculous patients are not at all uncommon symptoms of tubercular meningitis.

As regards the occurrence of optic neuritis or papillitis, the cause is more often tubercular meningitis than any other variety of meningitis. But the inflammation of the optic nerve is not a specific tuberculous neuritis, and the bacilli are not found in the optic nerve. A tuberculous tumor of the optic nerve is a very rare lesion, of which a few cases have been reported, but it is only found in the extraocular portion of the nerve, somewhere between the eyeball and the chiasm, and is never a primary disease. Hence, if tuberculous deposits are demonstrated or suspected to exist elsewhere in the body, the usual surgical treatment for tumor of the optic nerve, resection of the nerve and excision of the tumor, is in such cases contraindicated.

No *tuberculous* lesion of the *extraocular muscles* has ever been reported, and the cases of muscular paralysis met with occasionally in tuberculous patients are due to intracranial invasion of the nerves supplying these muscles.

*General Conclusions.*—It is doubtful if any case of intraocular tuberculosis is ever a primary disease. In cases of doubt, or of very difficult diagnosis, the injection of tuberculin is an efficient aid to diagnosis. There is a general reaction in at least eighty-five per cent. of the cases, and some local reaction in about fifty per cent. of the cases. As a method of treatment, both the old and the new tuberculin have proved practically useless in the writer's experience. It is a remedy which needs careful watching.

Surgical intervention in intraocular tuberculous conditions of the eye should seldom be done, unless there is considerable pain which tells on the patient's health, because the disease is not a primary one, and hence excision would remove only one focus of the disease.

## DISPLACEMENT OF THE ABDOMINAL ORGANS.

By OTTO LERCH, A.M., M.D., Ph.D.,
NEW ORLEANS, LA.
PROFESSOR OF CLINICAL DIAGNOSIS, NEW ORLEANS POLYCLINIC.

Splanchnoptosis is an affection of common occurrence, causing so many functional disturbances of the abdominal organs, of the heart and lungs, and of the nervous system, frequently presenting a variety of symptoms imitating organic lesions, that it will be always of great importance to the general practitioner. On the other hand, occasionally an entire absence of suffering may be found, even in cases in which the displacement of organs is marked. Virchow showed in 1853 that such displacements were frequently caused by local peritonitis. Relaxation of the abdominal walls seems to be their most frequent origin. I believe that this is the reason why we find the disease far more frequently in women than in men, and that women, usually after childbirth, commence to suffer from the trouble, and young girls are less subject to it.

A dislocation of organs may be congenital, and not rarely we can trace the affection to other members of the family, sometimes through two or three generations, to females and males as well. Slender figure, emaciation, trauma, tight lacing, lifting and straining, and various other causes are justly accused, With the prolapse of the stomach we may find the kidneys dislocated, especially the right kidney, the intestines, especially the transverse colon and iliac flexure, the liver, the uterus, and occasionally, though rarely, the spleen. A displacement of the heart in advanced cases is found occasionally. The disturbance of the nervous system is practically found in all cases, and nervous symptoms presenting the picture

of hysteria and neurasthenia are always present. Such a symptomatology, with the history of good health up to marriage, frequent childbirth, and emaciation often allow a diagnosis almost invariably confirmed by an examination. The nervous symptoms are, therefore, of great interest, and, as the patients frequently present hysterogenous zones the disease has been diagnosed as hysteria. If the dislocation of the abdominal organs were not present such a diagnosis would be correct in many instances. Women are most frequently the sufferers, and ovarian pain and backache are hardly ever absent. The psyche is changed, the patients show the great instability of temper so characteristic of hysteria, are easily irritated, and easily fatigued. Susceptibility to suggestion and forgetfulness, or better, lack of attention, are associated with a train of various other hysterical symptoms. Hot flushes and chilly sensations dermographia, globus, cramps, tremor, pressure points of pain in the usual locations, headaches, hemicrania, and the clavus hytericus, exaggerated reflexes, absense of uvula reflex, and diminished or absent corneal reflex, analgesia and hyperesthesias, palpitation, of the heart, and dyspnea may all be present. Subjective pulsation of the vessels, especially of the abdominal aorta, is always an object of observation and worry to the patient. One of my patients called it her "second heart." All may be found, and to such a picture we may add often an inherited tendency of the trouble. The mother and grandmother, or some other member of the family, are suffering like our patient. It is not strange then that the disease has been and is not rarely mistaken for hysteria. Symptoms of neurasthenia are usually mixed with those of hysteria. The patients are easily irritated, the slightest mental or physical exertion will thoroughly fatigue them, they are unable to think, to read, or do anything. They complain of loss of strength and inability to walk when an examination of the various groups of muscles will show considerable power. They are depressed, complain of dizziness, headache, and sleeplessness; of pain everywhere, of hypochondriac sensations, etc. These are all important symptoms, and frequently will call attention to the real trouble. The downward displacement of the stomach is the usual form, though occasionally we find it in the vertical position. In the congenital displacement of the organs, *situs viscerum inversus*, the stomach is found on the right and the liver on the left side of the body. This is of such rare occurrence that it does not need further consideration. The displacement of the stomach causes digestive troubles, and these vary in character, are rarely alike in two patients, and even in the same patient they may change from day to day, though, on the other hand, a certain complexity of symptoms may be lasting in spite of treatment for days, for weeks, and for months. It is a clinical picture of the digestive troubles of the neurotic, the hysteric, and the neurasthenic, not that of any organic disease, though it may, as these so frequently do, occasionally imitate the latter to perfection. Pressure and fullness after eating, a voracious appetite, changing to complete anorexia, a good appetite with fear to eat, may be seen. Heartburn, waterbrash, and regurgitation of food, paroxysmal pains that frequently amount to crises which have been mistaken for gallstones, the gastric crises of locomotor ataxia, or renal calculi, appendicitis, etc., are frequent symptoms. Vomiting does occur, of food or of gastric juice mixed with mucus, but it is rare and some of the patients state that they cannot vomit at all. Loud belching of odorless gas, swelling and tightness of the abdomen, sometimes after eating, sometimes with an empty stomach, are also symptoms, and sometimes the swallowing of a mouthful of water may cause severe pain and discomfort, and just as the chemical composition of the gastric juice happens to be, food may relieve or cause it. As is to be expected, intestinal function is always disturbed, flatulency and constipation are common, though diarrhea may be found alternating with constipation. Large flakes of mucus are often passed, though their passage does not cause pain in every instance. One patient of mine passed for weeks at a time large masses of jellylike mucus without the slightest pain, and no pain or pressure along the colon, though the appearance of the mucus in the stools greatly affected and worried her. A dislocation of the intestines, which always may be found in these cases, coupled with the disturbance of the nervous system, causing hypersecretion of mucus, explains these peculiar symptoms. Symptoms due to dislocation of organs, whether the stomach, intestines, kidneys, liver, or uterus, are produced by the new position the organ occupies, pressing upon the neighboring structures and pulling and tearing on its own blood vessels and nerves, thus causing reflex symptoms. Pain caused by a dislocated kidney may be a dull, aching sensation in the right side below the border of the ribs, or it may be paroxysmal in character, giving rise to Dietel's crises, often accompanied by nausea and sometimes by vomiting. These crises may last for hours or for days. The urine rarely shows any abnormality in nephroptosis, though during these crises, when the ureter is twisted, it is concentrated, contains a heavy sediment of urates, uric acid, and oxalates of lime; and occasionally blood, albumin, and epithelial casts are found. All the symptoms are relieved as soon as the ureter has returned to its normal position; as a rule, the urine becomes copious and pale after such a crisis. A completely dislocated liver, a floating liver, is not of frequent occurrence, at least I have seen it only twice, once in a young boy following a fall after a severe attack of grip, and prolonged confinement in bed, and once in an old negro who had been a hard worker and had done a great deal of heavy lifting and straining during his lifetime. Minor degrees of displacement of this organ are frequently found with a general ptosis, but do not give rise to particular symptoms outside of a dragging sensation, pain, and heaviness in the right hypochondrium or lumbar regions. Far more pronounced are the symptoms caused by the displaced uterus so frequently accompanying a general ptosis. The patient will often call upon the physician for local examination and treatment of the genital organs, to the disease of which she ascribes all her sufferings. If she is a young married woman she dates back her troubles to the birth of her first or second child, and if she has passed the age of thirty she wants to know whether her suffering is due to an approaching menopause. There, as well as in the gastrointestinal tract, organic disease may follow the displacement. A positive diagnosis in the majority of these cases is, as a rule, not difficult to make. The course of the disease is marked by its chronicity and slow progress. The symptoms are vague to begin with, and, as they are always associated with nervous symptoms, they are frequently passed off as hysteria or neurasthenia, the patients obtaining but little sympathy from the members of their families. They gradually fail in health and lose flesh, so that in the most advanced stage they may suggest tuberculosis or malignant disease. Examing the lungs of these patients I have sometimes been asked by the patient: "Doctor, are you hunting for consumption?" Generally, only after the troubles have become severe a more thorough examination is called for, and in these the emaciation brought about

by the disturbance of the digestive tract facilitates the diagnosis. Bimanual palpation readily discovers a dislocation of the kidneys of the first, second, third, and fourth degree, meaning by these terms, respectively, that the kidney is movable with respiration, a condition not considered pathological, a portion of it can be palpated, the whole kidney can be palpated, and lastly the kidney is dislocated and fixed. Similar degrees of dislocation of the liver may be determined, the third degree being a complete downward displacement of the organ, which can be felt in the abdominal cavity. The dislocation of the spleen is so rare that it only needs mention. The stomach is readily seen in the emaciated standing out like a distended bladder below the thin abdominal walls. The whole organ can be inspected and the space below the ensiform cartilage is found more or less sunken. The upper border of the stomach is found below the fourth intercostal space, and the large curvature below the navel; splashing sounds can be elicited over the stomach area, and the percussion note confirms inspection. Any doubt that may still exist as to position may be removed by distending the stomach with carbondioxide or air in the usual manner, giving a seidlitz powder in two portions, or inflating the organ with air. The last method is preferable, as the exact amount of air necessary to distend the stomach can be gauged, and as this can escape after use before withdrawing the tube. Gastrodiophany is another method introduced by Einhorn to determine the position and size of the stomach, but is rarely, if at all, necessary for practical purposes. Atony of the stomach walls is usually present, and splashing over the stomach area is a constant symptom. The motor function of the organ is disturbed, though, as a rule, the stomach is able to empty itself. The examination of the contents showing an absence of lactic acid, Boas bacilli, yeast cells, and sacrinæ, and frequently an excess of hydrochloric acid, may become of importance in those extreme cases that suggest malignancy. Furthermore, the chemical examination will indicate therapeutic measures. The position and size of the large intestine is conveniently shown by inflating it with air after it has been thoroughly evacuated. This is best done on an empty stomach. Another method advised by Boas, is to prepare the patient as above and to inject 300 c.c. of water. If the colon is distended and dilated, splashing and succussion sounds can be elicited, the position of which will determine the course and size of the colon. In the healthy, 500-600 c.c. and more, are needed to produce splashing, which will show the normal position of the colon. The dislocation of the intestine explains the chronic constipation from which these patients are constant sufferers. The histories of these patients present an interesting study. We find a considerable number of cases with nephroptosis, gastroptosis, and splanchnoptosis in different degrees of advance, up to the most marked without symptoms. In fact, it has been said that a patient with a prolapsed organ will not suffer till told of it by his physician. This, of course, is going too far. The physician will discover the trouble, as a rule, only when searching to find the cause of some obscure ailment. As with any other disease knowledge may aggravate suffering. Quite a number, however, who have been accused of suffering from imaginary troubles, are relieved to find some real cause to grieve over. We occasionally find an inherited tendency to the same trouble in families, and frequently the families from which these patients come are nervous, and anomalies of development are found in a large number. The tall and slender figure, the peculiar form of the chest, high arched palate, infantile uterus, etc., are common features. Nervous symptoms are never absent and are always the same. They present the clinical picture of the functional neurosis and the treatment most benefiting this class of patients without displaced abdominal organs is the treatment best adapted to benefit our patients, and it is just as difficult to treat the latter class of patients as the former. Occasionally the local trouble may become a source of comfort to the patient and be of assistance to the general treatment. These are quite a number of important reasons all pointing one way—that the trouble only can be developed upon an inherited basis. A neuropathic constitution with faulty development, especially insufficient fixture of the abdominal organs, is not sufficient to start the trouble, but a direct cause is needed to produce it, and the various agents that may gradually or at once produce the familiar picture have been mentioned. Relaxation of the abdominal walls after childbirth, emaciation, trauma, tight lacing, emotion, and worry, etc., may cause it. A dislocation of abdominal organs may occasionally be produced without such an underlying cause. The following histories of a few cases taken from my record will illustrate the points discussed:

Mrs. A., thirty-one years of age; has four children, no miscarriages. Her father is fifty-seven years of age and her mother fifty-four. She is weak, has always been so, and is a sufferer from hysteria. One uncle on her mother's side suffers from epilepsy. Five sisters and brothers suffer from nervousness and stomach trouble. Grandmother was a nervous woman and suffered, like all her children, with stomach symptoms. Patient has had measles, whooping-cough, diphtheria, typhoid fever, grip, and several severe attacks of malaria. Appendix, right ovary, and a small fibroid tumor were removed five years ago. When sixteen years of age she commenced to suffer from her stomach, and experienced fullness and oppression after eating, followed by nausea, and occasionally vomiting and hemicrania. These attacks would last for weeks and months at a time with long intervals of apparently good health. The trouble was greatly aggravated later by the various pregnancies, the patient improving between pregnancies. Excitement would also increase troubles. When coming under my observation a few months ago she complained of being unable to eat anything. After taking any food, independent of its character, she feels nauseated and vomits the food with mucus. She suffers from pain in the epigastrium, severe hemicrania, and constipation, the stomach feels tight and swollen. She is depressed and is constantly worrying about something; she is never free from pain somewhere, is easily irritated and fatigued. Weighs 118 pounds, usual weight 120; height, 5 ft. 7 in. Is thin, color good, eyes bright, expression of face mobile. Has cold hands and feet. Complains of choking sensations, tremor of hands and of eyelids, sways with eyes closed. Dermographic, pressure points of pain especially below left clavicle, left nipple, and left ovary. All reflexes are exaggerated. Complete analgesia of right arm and hand. Painful points along spine. Chest organs normal, liver somewhat prolapsed, lower border one finger below border of ribs; right kidney displaced, can be entirely palpated; prolapse of stomach, upper curvature just above navel. The urine, nothing abnormal; the fecal matter contains flakes of mucus. After test breakfast contents of stomach show absence of hydrochloric acid, undigested food, and mucus. The case is typical, and illustrates well the salient features of most of these patients. Neurotic, hereditary history, slender figure and emaciation,

hysteria, and, finally, as a direct cause, the frequent pregnancies of a young woman. She commenced to suffer at the age of puberty, but those attacks were mild and passing in character.

Mrs. B., twenty-eight years; has no children and no miscarriages. Father and mother are living, and are healthy; the mother is nervous. She has had measles, whooping-cough, malaria, typhoid fever, and appendicitis, and states that she has always been in delicate health, but well until about six years ago. She then commenced to suffer occasionally with severe paroxysmal pains in the right side, though she would constantly have a feeling of discomfort and soreness in that side. In the summer of 1901 she commenced to suffer from indigestion and flatulency after eating; the character of the food did not make any difference, everything would disagree. She was then treated by a specialist for ovaritis and appendicitis, without obtaining relief; returned to her home and improved until 1903, when the pains again became severe and she had her appendix and ovaries removed, and the stomach, which was found prolapsed, raised and fixed. The gall-bladder was also removed. No gallstones were present. After the operation the pains became milder, but shortly afterward again returned. When I saw her she complained of the same soreness and pain in McBurney's point and around the navel, and backache, which she has had for years. She is deeply depressed and cries frequently. Her face expresses despondency. She worries constantly about herself, examines her rectum frequently and feels greatly worried if she finds mucus in the stools, as is often the case, or if she has not had a passage. Patient is easily irritated and fatigued, afraid to walk or to do anything. Her appetite is good, digestion poor, she feels full after a meal and belches loudly. She has never vomited, and states that she has frequently tried to relieve herself by putting finger in the mouth, but cannot vomit. Patient is thin and pale, clear skin, five feet eight inches in height, weighs 125 pounds. Weight has been always between 110 and 125 pounds. Chest organs normal, liver and spleen normal, and right kidney can be palpated full length; splashing is present over the stomach area, lower curvature is a hand's breadth below the navel. Contents very acid, excess of hydrochloric acid, undigested food, and some mucus. The urine is normal. The stools are formed and occasionally contain flakes of mucus. "Infantile uterus." This patient presents the neurasthenic type, with hypochondriacal sensations and anomalies of growth—slender figure and infantile uterus. It is interesting to note that the usual complexity of symptoms, though temporarily relieved after the operations, returned after a few weeks to stay.

Mrs. C., twenty-six years of age; one child, no miscarriage. Father died at the age of forty-five, of some liver disease. Mother is sixty-five years of age, living and in good health. Four brothers and one sister living; the sister is nervous. Patient has passed through measles, whooping-cough and mumps, and was in perfect health until birth of child. Three days after birth had a severe cramp, colic, and terrific pain below sternum. From this time she commenced to suffer with severe backache, and during the next few years had similar attacks like the first, but more in right side and above pubis. She felt "as if she was cut open." These attacks became gradually more frequent, finally two, six weeks apart. They are entirely independent of diet, and she never has had any attack during rest or sleep. Excitement has nothing to do with them. The patient is fairly well nourished and weighs 128 pounds. Weight during good health 135 pounds. Appetite and digestion are good, but she suffers occasionally from heartburn. She sleeps well, the bowels are regular. She suffers from severe backache; the chest organs, liver and spleen are normal; the right kidney can be palpated for full length; there is splashing over the stomach area and the lower curvature is three fingers below navel. The uterus is prolapsed.

This case is instructive on account of the almost complete freedom from nervous symptoms and disturbances of the digestive tract. The pains are Dietel's crises. During the crises the urine is high colored, scanty, loaded with urates, and contains traces of albumin. After the crisis has passed the urine is copious, of light color, and specific gravity. The direct cause is relaxation of the abdominal walls after childbirth.

Mrs. H., fifty-seven years of age; has four children and never had any miscarriages. She states that she lives on raw eggs, milk, and rice, and that she does not take coffee, tea, or alcoholics. Her father died at the age of eighty-one years and her mother at thirty-nine, after childbirth. She has had measles, diphtheria, yellow fever, and dysentery when seventeen years of age. She states that she has been a dyspeptic all her life, and does not remember whether her mother was nervous. She was always thin, but during the last two years has lost weight and gotten weaker. She complains of excessive weakness, palpitation of the heart, indigestion, fullness, pressure, pain, and swelling after eating, loud belching of odorless gas, and severe constipation. Her appetite is good, but she is afraid to eat. She sleeps well. Patient is five feet three inches in height, and weighs eighty-nine pounds. Three years ago she used to weigh between 100 and 110 pounds. She has stigmata of hysteria. The lungs are normal. Instanding, heart dullness to the right is increased and the apex near left sternal border is displaced downward. Systolic murmur at apex, not conveyed to left. Has no symptoms of heart disease, no dyspnea, cyanosis, or concentrated urine, swelling of feet and ankles, etc., and never has had any. In lying down heart is normal, the displacement and murmur disappear. The right kidney can be palpated full length, and lower curvature of stomach is a hand's breadth below navel. Contents of stomach show hydrochloric acid in excess and mucus. Two brothers, one sister, and daughter suffer as she does. One sister and daughter are now under treatment. This case is especially interesting on account of the heart displacement simulating disease of this organ. It is useless to give any further histories; they all show the same features. Often an inherited predisposition, "a neuropathic constitution," a direct cause and symptoms that are caused by the displaced organs. The treatment has to be prophylactic, as a relaxation of the abdominal walls is the most frequent direct cause. The abdominal muscles ought to be strengthened by systematic exercise, bending forward and backward, raising from a horizontal position into sitting posture, etc. As soon as such a predisposition is recognized a bandage ought to be advised during and after pregnancy, lifting of the child prohibited, overloading of the stomach avoided, and the bowels kept open.

If these patients call for relief after the disease is fully developed, the first thing is again to direct a suitable bandage and to strengthen the abdominal muscles. The patients are emaciated, at least the majority of them, and it is, therefore, difficult to find a bandage that gives the desired support. Almost every clinician who has given attention to these cases

has designed his own bandages. I have designed a bandage made for me by McDermott & Co., consisting of a piece of elastic, which is fitted above the pubes in front, and held by leg straps and three elastic straps buckled to a second shield across the spine. These straps secure a backward and upward pressure and are easily regulated by the patient so as to be comfortable. The bandage is not cumbersome and gives full support. The second indication of treatment is to replace waste of fat and muscle. This is done by directing rest, a proper diet, varying, of course, in each case according to the chemical composition of the gastric juice, hyperacidity, or anacidity, and moderate exercise short of fatigue. The diet in every case must be designed to counteract the obstinate constipation and to avoid overloading of the stomach, frequent and small meals being the rule. Mild hydrotherapeutic measures are always of advantage. A warm bath, followed by a cold sponge or shower bath and by vigorous friction in the morning, and cold ablutions at night, is to be recommended. A cold sitz bath, in suitable cases, every day or every other day is often of advantage. General massage and special massage, given or directed by the physician, will be valuable assistance in the treatment of these cases. From the Weir Mitchell treatment I have not seen much advantage, but some failure, but this may yield better results in a sanatorium. Judging from my own experience, rest and exercise well suited to each case act best. Drugs can be employed only to assist the mechanic dietetic treatment, and ought to be discontinued as soon as they can be dispensed with. Strychnine and resorcin act well in these cases, raising tone and preventing fermentation. The sulphocarbolates of sodium and zinc are useful where flatulency is a disagreeable symptom and the stools are offensive. Hydrocholoric acid and wine of pepsin may be used where anacidity is found, and burnt magnesia, if necessary, combined with bismuth and soda, given one or two hours after eating where hyperacidity exists. Finally, we have to decide whether an operation is to be advised. An operation may occasionally relieve these patients by suggestion, though ovariotomies performed on hysterics to cure have been very discouraging, and the operation for that purpose has been abandoned. With this class of patients we have to remember that, in the majority of cases, the visceral dislocation forms only a part of the trouble. Organs are frequently found dislocated without causing any disturbance if general health is good; the severity of suffering does not depend on the degree of dislocation and correcting operations have been, in many cases, without any or without permanent result. Under such conditions it requires careful consideration of the cause, on set, and history of the case before operation is to be advised. If the defect to be corrected contributes to the trouble, and medical treatment has failed, an operation is indicated.

---

**A Hospital Car** has recently been built by the Southern Pacific Railway. It is 67 feet long, with a breadth of 9 feet 8 inches. Twenty-six feet of the central body of the car is given up to the operating and dressing-room, and a ward with berths for twelve patients. The rear of the car is built as an observation room, and between it and the hospital proper are staterooms for doctors and nurses. Forward a limited space is given to kitchen, refrigerator, and servants' quarters. Under the car body, stored in pockets reached through trapdoors, is the paraphernalia which goes to make up the twelve berths. Close by is the medical locker room, with closets containing a regular dispensary outfit and sets of surgical instruments.

## FRESH AIR AND REST IN THE TREATMENT OF PULMONARY TUBERCULOSIS.*

By G. R. POGUE, M.D.,

GREELEY, COLORADO.

In recent years much has been written on the subject of fresh air and rest, and their relation to the treatment of pulmonary tuberculosis. Few writers have apparently taken into consideration the individual case, or any certain class of cases, and have simply recommended fresh air or outdoor life, without qualification, ignoring that most important feature that must be considered in any line of treatment, viz., management or supervision of each case, all of which is generally left to the patient's own sweet will. Fresh air and rest, while perhaps the most important factors in the treatment of pulmonary tuberculosis, will prove of little advantage except they be properly administered according to the therapeutic indications, and tempered to suit the individual.

The indiscriminate prescribing of fresh air, outdoor life, and exercise, without proper instructions and education of the patient, together with a consideration of the extent of the lesions present, has led to many unsatisfactory results, and has been the undoing of many a poor fellow who has staked his all on "outdoor life" and who might have had a fair chance for recovery had he had a proper education in the needs and dangers of his particular condition. If there be any part of the treatment of tuberculosis in which the patient needs supervision and education, it is in the line of fresh air, rest, and exercise, and how to apply them to the greatest benefit to himself, and why certain things should be done and others avoided.

A man in the early stages of the disease, with little or no breaking down of tissue, would require different treatment, and could stand more hardships incident to outdoor life, than a frail woman with more advanced lesions. Yet we see all classes of cases, in all stages of the disease, practically put on the same line of treatment, with no regard for the individual, and still feel disappointed that our results are not more uniform.

The history of tuberculosis proves that it is essentially a house disease, that is, it is harbored and spread by overcrowding, unhygienic conditions, and lack of fresh air and sunlight. Knopf and others have done much to educate the laity on this subject, and their efforts will certainly bring their reward and be a lasting monument to their devotion to suffering humanity. Even the little animals that have served us so faithfully in our laboratory experiments, and which are so susceptible to infection when exposed, are seldom or never found to be tuberculous in their native haunts. While lack of sunlight, fresh air, sufficient space in sleeping apartments, together with other unhygienic conditions, may be the surroundings of those unfortunates whose lot in life forces them to live in such habitations, it would be a surprise to us could a canvass be taken of the sleeping and living apartments of the more well-to-do class who have the opportunity and surroundings for the enjoyment of fresh air and good ventilation, and note the number who have a "holy horror" of the "bad" effects of night air, and who, during the day, value the colors in their rugs and carpets above their own health. They practically live day and night shut up in a box, breathing over and over again the same air, and enjoying no sunshine except when they leave the house. The lack of fresh air is often carried to the extreme by the individual who is ignorant of his

*Read before the Colorado State Medical Society, October 5, 1905.

unhygienic mode of life. The other extreme is demonstrated by the physician who carries the fresh air treatment of tuberculosis so far in the opposite direction that his patient is injured rather than benefited.

It is the sheerest folly—but we see it done every day—to place a patient with high fever, chills, and sweats, outdoors all day long in cold weather, and then require him to sleep in an open tent with no provision made for the comforts of life to which he has been accustomed. Before morning he may have his usual night sweat, it may be mild or severe, and on waking he finds himself wet with perspiration, unable to make a change of either night robes or bedding; he must remain in his uncomfortable condition until he dries off or morning brings relief. During his waiting, his cough becomes aggravated from the cold and his own restlessness, and he dare not move or change position, as every move lets the cold air come in contact with his moist body and sends chills to his very heart. By morning he is worn out and haggard from loss of sleep and exposure to cold; yet his friends wonder why he does not improve, as he and they have been informed that "tent life" is the only proper course to pursue in pulmonary tuberculosis.

We also have the same remedy ordered for a patient in the early stages of the disease. There are no modifications or conditions attached. He is simply ordered to live in a tent, and being ignorant of the laws of ventilation, or fearful of the bad effects of night air, he closes up his tent so that no outside air may get in, and virtually spends eight to ten hours each night in a closed, canvas box. Again comes failure. We must first become thoroughly acquainted with the physical conditions of our patients, learn their peculiarities of constitution and temperament, and then their life and treatment can be regulated accordingly.

1. Our patients must be kept outdoors all day long in the open air, and practically the same conditions must prevail at night.

2. They must be made comfortable, and be protected from cold winds, rains, and storms, and, during the summer months, from the direct rays of the sun.

A covered porch, shut in from the north and west, gives ample protection during the fall and spring, while winter weather will require the addition of extra clothing, rugs, blankets, etc. During the summer months it is a matter of shade and comfort during the day, as the hot sun has a lowering effect on the patient's vitality, as well as causing certain digestive disturbances. In the higher and dryer altitudes, with their more even climates and maximum number of days of sunshine, it is much easier to train our patients to live outdoors.

Patients who come under treatment during the late autumn or winter must be gradually hardened to outdoor life. They have previously been accustomed to warm, indoor life, and it would be a great mistake to put such a one outdoors in cold weather and require him to remain out all day at first. He must be gradually tempered to the cold, and ere long he will be more comfortable out than indoors. Especially must we be careful in this line with women and children. They cannot bear much cold to start with, and often become easily discouraged; but when once they have undergone the hardening process, they enjoy the outdoor life, and as a rule are the most obedient patients.

Where the patient comes under treatment during the warmer seasons of the year, there is no difficulty in getting him acclimated to his new surroundings, and by the time winter is at hand he has learned how to care for himself and provide protection accordingly. We have comparatively little trouble in providing good, fresh air during the day, but when night comes we encounter our difficulties. As the vast majority of tuberculous cases are treated by physicians in private practice, each patient must be educated to the needs of air at night as well as day, and it falls on the physician to look after these little details. So many people have an apparent inborn dread of night air, especially in any form of pulmonary disease, that they resort to all manner of schemes to modify or exclude air from outdoors at night.

I make it a practice, when possible, to have my patients sleep in large rooms with two or more windows, which are kept open from the top. The larger the windows the better. Rooms facing the south, east, or west, are suitable, but we should never use a room that faces the north only. A screened-in porch makes a very appropriate sleeping apartment, and has advantages in some cases over an open room, and it prevents meddlesome friends from in any way interfering with the ventilation. The open room has a great many advantages. It is more comfortable and convenient for all classes of patients, especially women and children, who never do well on a purely tent life. For centuries mankind has dwelt in houses, and no matter how well they may do in tents while ill, they sooner or later return to their old house life and discard the habits of tent life, and the lessons learned are forgotten. If they have been taught to live and sleep at night in the open room, they are very apt to continue the practice when they are no longer under the supervision of their physician.

For male patients, especially those with no active or extensive lesions, a tent life properly conducted may prove very satisfactory, particularly during the warmer months of the year; but for those in the more advanced stages, and for any during the winter and spring, the open room and sheltered porch are much more desirable.

That tuberculosis is never cured by any single element with disregard to all other therapeutic laws is a well-known fact. Anything and everything that is applicable to the individual case must be utilized in aiding to arrest the disease and building up the barriers against further invasion, thus laying the foundation of an ultimate cure. That fresh air is one of the essential elements in attaining this end, is admitted by all phthisiotherapists, but we must not rely on fresh air alone, without regard to climate, temperature, humidity, altitude, and general surroundings, and the physical and mental condition of our patient.

"The healthy man sits down to rest because he is tired; the tuberculous man should sit down so as not to become tired" (Brehmer's motto). How many follow it? There is perhaps no part or element in the treatment of tuberculosis that has been more abused and has brought greater disaster to the patient than exercise and gymnastics. For some unknown reason both physicians and laity have become imbued with the idea that if a tuberculous patient does not take lots of exercise he is sure to go the downhill course and his finish is in sight. Patients are sent away from home for change of climate, and about the only instructions they receive are to "get out and rough it." When they get to their journey's end, every person they meet gives them similar advice, at the same time pointing out Jones or Smith, who came here several years ago and has recovered his health by walking, riding horseback, and climbing mountains, but they never tell the poor secker after health of the hundreds who have gone over the "great divide" and have practically been forgotten, who

tried the same remedies. The few who survive this vigorous exercise are but a small percentage of the numbers who employ it. I have been through it, and know whereof I speak. It took me two years to get over one day's duck hunting, which I took on the advice of a physician who has since succumbed to the "exercise cure." I have seen a patient who, under rest, fresh air, and good diet, had gained twelve pounds in four weeks, take the advice of another and go horseback riding; in three days he was in bed, and in less than sixty days he had passed to the great beyond. This is only one case out of many that have come under my observation during the last five years, with similar results.

One of my patients who had improved rapidly and apparently was in a fair way to have her disease arrested, and who had in four months gained over thirty pounds, and all of whose symptoms had disappeared, took some violent exercise, which was soon followed by fever, return of cough and expectoration, tubercle bacilli in the sputum, loss of appetite, chills, and sweats. Examination of the chest showed infiltration of the greater part of the upper lobe, while previously the disease had been confined to the apex; this was due to the rupture of a necrotic focus in the apex, the contents of which were aspirated into the greater part of the whole upper lobe, causing caseous pneumonia, and later a tuberculous infiltration of a new area. It is too recent to give a prognosis, but it is safe to say that her chances of recovery are about one to ten she had before she took her exercise.

Respiratory gymnastics also come under the head of exercise, and are equally pernicious when carried to the extreme, and a tuberculous patient is very apt to go to the extreme with any class of exercise. Forced and deep breathing, together with the accompanying muscular exercise, causes certain metabolic changes, followed by increased absorption.

Rest and exercise must be graduated to suit each individual case, and while there is little fear that the patient will not get enough exercise there is a great fear that he will not get the required amount of rest. As a general thing our patients come to us imbued with the idea that everything depends upon exercise, and so thoroughly do they believe in active exercise that they often disobey instructions and steal exercise and imagine it is the right course to pursue, and is all right if the doctor does not know it. These active exercises are generally followed by recurrences or advances of the disease, which sometimes require months to arrest.

There is not in this broad land a surgeon of any recognized ability who would advise active exercise or motion as a cure for a tuberculous joint. Instead, he would put the parts in an immobile dressing and put the patient at perfect rest, trusting to the recuperative powers of the tissues to arrest the disease and give the patient, if not a perfect joint, a useful limb.

If such absolute rest be required in the treatment of a tuberculous joint, what sane argument can be brought against rest in the treatment of tuberculosis in any other tissue of the body? A knowledge of the pathology of the disease teaches us that rest must be one of the essential factors if we expect to get an arrest of the process, the same as in any other infectious disease, as in pneumonia, typhoid fever, etc. Even in the earliest form of the disease, when the lesions are small, rest is just as necessary as later, and the results are far more satisfactory to both the patient and the physician.

Tuberculosis differs from other microbic diseases in that the tissues in their attempt to destroy the invading microorganisms, build about them a non-vascular structure histologically known as tubercle in the center of which are the imprisoned bacilli, hemmed in by a more or less impervious capsule; but there is always present the danger of a spread of the disease from rupture of the walls during resolution, and it is here that active exercise gets in its deadly work. Should rupture take place into an open bronchus and the contents be carried out with the secretions, little or no harm results, but should the rupture take place into the parenchyma of the lung or into the blood stream, the results would be quite different, viz., an acute exacerbation of the disease, or an acute general miliary tuberculosis.

Exercise favors and promotes the absorption of toxins, while quiet and rest reduce it. In all acute processes the elaboration and absorption of toxins is greater for two reasons: (1) The young and growing tubercle bacilli produce more toxins; and (2) in the young tubercle the walling-up process is less dense, allowing the escape of toxins from the infected centers. The greater the amount of toxins absorbed, the higher the fever with its accompanying destructive influences.

In the face of these pathological facts, we are justified in demanding rest in all cases of active tuberculosis, no matter how minute the lesions, and more especially when even mild exercise causes a rise of temperature.

The injurious influence of fever upon the entire organism, if it persists for any length of time, is of the highest importance. The heightened consumption of albumin and tissue material which the fever induces in an already sparsely nourished body, bring about a loss of weight and strength in ratio to the height and duration of the febrile course. Loss of weight causes an increased absorption, which in turn adds fresh fuel to the fire. The effects of fever in further weakening the heart, together with the loss of strength from sweating which often follows high temperatures, has a very depressing effect on the morale and spirits of the patient; as the heart partakes of the general emaciation produced by toxemia, fever, and malnutrition, it requires rest and nursing so that it may continue to perform its functions without producing further degeneration in its anatomical structure, such as dilatation, fatty degeneration, valvular insufficiency, etc., with coexisting edema.

These are a few of the conditions that may be brought about by exercise in active tuberculosis, which are detrimental to the patient, and I fail to find anything except that which is imaginary, in exercise, whether athletic or the so-called pulmonary gymnastics, that is of any benefit to the individual suffering from pulmonary tuberculosis.

Granting that rest in itself does not add to repair, it surely prevents the occurrence of those conditions that bring about degeneration and destruction of tissue, and it thereby aids the physiological processes that tend to repair and to produce greater resisting power in the economy. In an individual whose tissues oppose a somewhat more sturdy resistance to the advance of the tuberculosis process, there is a greater possibility for an arrest of his disease.

I have the histories of sixty-two patients with tuberculosis in various stages of the disease, seen during the last five years, who took the so-called "roughing it" cure, or active exercise; of these forty-three are dead, and only two show signs of having their disease arrested with a prospect of ultimate cure. Fresh air and rest are only units of the sum total of the therapeutics of tuberculosis, but without them other remedies are of little avail.

In special sanatoria there is little trouble in carry-

ing out the rules for obtaining the best effects of rest and fresh air, but it is in private practice where we get our greatest opposition, not so much from the patient as from the numerous individuals who are always ready to give free advice (in good faith), believing that active exercise is the only means of combating pulmonary tuberculosis, and when the patient breaks down and dies, they have the same consoling answer, "all cases of consumption die anyway, it is only a matter of a short time."

By rest we do not mean actual confinement to bed, except in those cases in which there is a very acute process accompanied by high fever and rapid pulse, together with the other phenomena that accompany such a condition. Under these circumstances, absolute rest in bed is necessary until the acute symptoms have subsided. But even here we must employ the fresh air or open-room treatment.

As the patient regains his strength, I find it much more profitable to get him up and dressed (to suit the climate or season), and have him outdoors, either on a comfortable couch or on a reclining chair. Comfort is the great essential to rest. Worry and excitement have just as detrimental an influence on the patient as exercise, especially if he be of an excitable and nervous disposition. How often have we seen a sudden elevation of temperature after the receipt of bad news, the arrival or departure of a friend, or some minor accident in the family or immediate neighborhood?

It is very difficult in discussing fresh air and rest in regard to the treatment of tuberculosis to leave out of consideration other therapeutic measures, such as nutrition, special medication, etc., but the field is too broad, and authentic opinions are too numerous to enter into at the present time. But I wish to state that all measures that are of value in building up the patient and increasing the resisting powers of the tissues, should be employed in conjunction with rest and fresh air, if we expect to get the best possible results.

Statistics show that the death rate from tuberculosis has been reduced from 14 per cent. to 10 per cent. during the last third of a century, and there is little doubt, that if all cases were recognized early, and the pathological conditions properly appreciated by both physician and patient, with proper management and education, the next third of a century would see the death rate reduced to as low as 5 per cent.

Dr. Norman Bridge, in discussing "some common errors in the treatment of pulmonary tuberculosis," in part says: "Every one of these patients should be constantly supplied with outdoor atmosphere in such abundance that every successive inspiration brings a fresh dose of air into the lungs, and none from previous expiration. Everyone should have long hours of rest—if feverish, the rest recumbent should be almost, if not quite, constant, for exercise increases fever. The digestive powers should be made to do their best under the most careful supervision toward improving nutrition, and possibly also the resisting power of the patient. But we have allowed our patients to stay indoors, without proper ventilation, and breathe a poisoned house air three-quarters of the time. We have subscribed to the popular untruth—as pitiful as it is groundless—that patients in a gentle current of air, called a draught, are in danger of cold and other harm, and so we have kept them breathing over and over their contaminated air. The truth is, one never takes cold in any draught, even a wind, if his body and head be kept warm by clothing. The advice of the profession ought to be, to keep in a draught, never out of it; only it would lessen the business of the physicians, while it would be of incalculable benefit to the people." (*Journal of the American Medical Association*, Vol. XLIV., No. 12.)

In closing I cannot do better than quote the conclusions of Bernheim of Paris, in regard to rest in the treatment of tuberculosis:

"1. In the treatment of phthisical patients the rest cure is the indispensable complement of a sojourn in a salubrious climate and of forced alimentation.

"2. Since the lungs participate in all excessive activity, the effect produced is an active congestion in the region of the tubercular focus, and new tears in old adhesions.

"3. Every organism which fatigues, suffers more abundant organic losses (increased katabolism). These losses are still more augmented in the phthisical subjection who, when overexercised as a consequence of fatigue, mobilizes his bacilli, whence comes a veritable autointoxication which evidences itself by febrile phenomena.

"4. Forced feeding and life in the open air are of profit to a tuberculous patient only when he is placed under conditions of absolute repose.

"5. Furthermore, repose plays another important rôle: it prevents the general localization of the bacillus of Koch.

"6. One should therefore prescribe the rest cure for every phthisical patient who has fever and in whom one observes clinical symptoms of tubercular activity.

"7. This rest cure may be practised in all cases, provided it is applied in a disciplinary manner and with intellectual supervision." (*Journal of Tuberculosis*, Vol. II., No. 4.)

## REDUCTION TREATMENT.

By JOHN W. WAINWRIGHT, M.D.,

NEW YORK.

Old and long-held theories as to the treatment of disease are so often being overthrown, that it is no matter for surprise that views regarding therapeutic measures to reduce obesity have undergone within the past few years a considerable change. Not that there is now by any means unanimity among the medical profession as regards the treatment of obesity, but some time-honored ideas have been strongly assailed, and it would seem that our views with regard to the best means of reducing corpulency must undergo revision.

Von Noorden, who is perhaps the most distinguished authority on the diseases of metabolism and nutrition, has recently published a monograph on the subject of obesity. The work opposes some popular beliefs with regard to the indications for treatment of obesity, but coming as it does from one with the experience of v. Noorden, is at least entitled to respectful consideration. His work is somewhat disappointing in that no means by which superfluous flesh may be reduced are disclosed; it merely treats of the indications for the establishment of these methods, the main points of his teaching being, (1) that the different methods must be suitable to individual cases; (2) that reduction cures should be seldom applied to children and old persons; (3) that rapid reduction cures pursued for a month, and followed by eleven months of self-indulgence are of little benefit; (4) that massage does not, as is popularly supposed, remove local deposits of fat, but rather increases them; (5) that slow methods of reduction are to be preferred, especially in women with a large

amount of abdominal fat, and in young subjects; (6) that the reduction of obesity is often of very great advantage in heart disease, the treatment being best conducted in a sanatorium; (7) in renal diseases obesity can only aggravate the functional disturbance; (8) in chronic bronchitis, chronic rheumatism, chronic gout, diseases of the organs of locomotion, and diseases of the nervous system, obesity may constitute an unwelcome complication, while good results may follow careful reduction; (9) even in pulmonary tuberculosis, the extreme obesity which has sometimes followed the overfeeding and lazy life of a sanatorium, does harm, this result being likely to occur in early or slight cases of pulmonary tuberculosis.

Referring to the principles which should decide a physician for or against a reduction cure, v. Noorden wishes, in the first place, to place himself on record as opposing the view so frequently expressed that reduction cures are a weakening process and constitute in other words, a so-called "weakening cure." He is of the opinion that a reduction cure can always be tolerated under proper conditions without detriment to the patient, and as a rule improves the general functional powers of the organism. He takes occasion to utter some timely words of warning regarding the regulation of diet for obesity. He points to the fact that there are in Germany and elsewhere a number of sanatoria and many physicians who are committed to certain definite methods of dietetic treatment, methods that are usually known by some well-known name; in all such institutions the particular method that is in favor is adopted for the average patient who goes there for treatment, and all physicians who swear by any one particular method of treatment, apply it in each case that comes under their care. Individual idiosyncrasies are ignored, and the old precept that "what is one man's meat, is another man's poison" is not heeded. Von Noorden also criticises severely the schematic method of treating disease so greatly in vogue at the present time, and thinks that when a medical history of our times comes to be written, we shall certainly be accused of having endorsed almost any method of treatment that seemed to contain something new or seemed to present certain special features. In the case of obese, but otherwise healthy people, a strict treatment, and not half-way measures, is the best method to adopt. It should constitute short courses of treatment, lasting some four or five weeks, at varying intervals; the result of these interrupted courses is a loss of weight of a few kilos; after a small loss of flesh has been brought about, the patient should be induced to take advantage of comparative leanness and strengthen the muscles by systematic exercises and at the same time use appropriate measures for improving the condition of the skin. Sanatorium treatment for sufferers from obesity presenting urgent indications for a reduction cure, is to be recommended.

Williams has called attention to the importance of due mastication of food in the treatment of obesity; for, not only does food thoroughly masticated assimilate better, but by long mastication appetite is much more easily satisfied and less food is ingested. Duckworth has pointed out that heredity plays an important rôle in obesity; according to Oertel this influence can be traced in fifty per cent. of all cases. Occupation and habits have, of course, much to do with the condition. Those who lead sedentary lives, eat and drink too much, are likely to be burdened with a superfluity of flesh. Overeating and drinking are potent causes. Osler has said that "the majority of people over forty years of age habitually eat and drink too much," and it may also be said exercise too little.

Bain, at the meeting of the British Balneological and Climatological Society, in April, 1904, discussed the subject from the physiological standpoint. Excessive fat deposition is due either to an abnormal production of fat or to a diminished oxidation. Fat formation is chiefly linked with carbohydrate metabolism. As regards treatment he said that the essential elements are regulated exercise, the restriction of the carbohydrate and fatty materials of the food, living an outdoor life, accelerating heat loss, and combating any tendency towards anemia. Barnes considered that to elucidate the question of obesity it was desirable to study the conditions of race, climate, and food. He had been struck with the extreme leanness of the Arabians of the working class, most of whom were extremely active and fed mainly on vegetables. Clippingdale referred to the frequency with which a state of obesity was found in persons of high intellectual capacity, contrary to the usual belief, giving several instances in the present and past times, and referred to Julius Cæsar's well-known dislike for thin persons.

Symes-Thompson pointed out that as life assurance experience showed how dangerous to life obesity was, it behooved us to utilize to the utmost spas and climate treatment, to encourage exercise, to promote metabolism, and to raise the health level of the patients. Morison maintained that undue mystery had been cast around both adult and infant feeding. The principles of nutrition were clearly known and their application was sufficiently indicated by each case considered on its own merits. He pointed out the importance of separating obese cases from those with and those without anatomical organic disease. In the former the general force of the patient must be improved before his fat reduction by restricting diet was commenced. Bezly Thorne drew attention to the fact that Bouchard placed obesity in the class of affections which he had denominated "l'arthritism," that it was common to the subjects of gout and rheumatism in which venosity was a recognized concomitant, as well as in those who were deficient in hemoglobin or had suffered from prolonged loss of blood. He recalled the fact that the obese were specially liable to angina pectoris and to death from syncope and to apoplexy consequent on atheroma. Such considerations in his opinion pointed to a potent cardiovascular factor in obesity, and emphasized the danger of treating that condition on lines of arbitrary dietary restriction. Ewart alluded to the distinctions between physiological stoutness, which ran in families and needed no treatment, and that which was pathological. The latter was generally admitted to depend upon relative deficiency in oxidation. Baynes said that he had found high frequency currents on alternate days with galvanism speedily reduced the most corpulent, and quickly relieved the dyspnea due to fatty heart. Sunderland considered it to be necessary to warn patients who showed signs of commencing pathological corpulency, to begin to take the requisite precautions against its increase in the early stage; there would then be seen fewer cases of excessive

stoutness, the reduction of which was sometimes attended with much risk. He referred particularly to the abuse of thyroid gland extract, with which some people dosed themselves without medical advice.

Treatment should be conducted on preventive lines. Strict temperance should be observed as regards food and drink, and activity of life, both mental and physical, should be a main feature in the treatment. General principles to be observed, so far as dietetic measures are concerned, are the restriction of fats and carbohydrates and a no less certain increase in the proteids. Increase in water drinking between meals and in some cases treatment by spa waters. The sea air is generally beneficial as a means of reducing obesity. The fact must always be remembered that obesity cannot be successfully treated by the same or similar methods in every case. Corpulent persons, who are otherwise healthy, by careful dieting, plenty of exercise, baths, and other rational means may reduce their superabundant adipose deposit, or at any rate may prevent an increase. But on the other hand, obesity in disease is but a symptom, and the treatment of the obesity alone may, and probably will, have an injurious effect upon the patient's general condition. The cause must be treated and the attempts to reduce the flesh must be governed by the disease from which he is suffering. As v. Noorden truly says, we possess so many physical means of treatment and such a large variety of dietetic schemes, that in deciding on a method of reducing fat the peculiarities of each individual patient can, without difficulty, be considered and included in the calculation. In numerous cases, it is true, the choice of the matter is more or less indifferent and we may be permitted to exercise considerable latitude, may in fact allow the patient to determine the method he wishes to adopt, according to the requirements of the external circumstances obtaining in each case; in others, again, the success of the treatment and the feasibility of instituting a reduction cure at all, not to speak of the well-being and very life of the patient, may depend on our choice of method.

The Harvey-Banting was the first method of dieting in the treatment of obesity, which gained general recognition. Harvey of London initiated this form of treatment, and used it with much success in the case of Mr. William Banting. Animal food is not restricted, but the amount of carbohydrates is reduced, and little or no fat is given. Water is permitted in large quantities. The Oertel method combines mechanical and dietetic treatment. Fluids, fats, and carbohydrates are all restricted. The second part of the treatment consists of systematized exercise, walking, and hill climbing. The Ebstein method consists of increase of fat foods, reduction of carbohydrates, while the amount of proteids remain unchanged. The Schweninger method somewhat closely resembles that of Oertel. No water at meals and less than a pint in the course of the day. Hot baths and massage are important features in this treatment. Duckworth recommends as a diet for the obese: 12 to 14 ounces of meat daily; 6 to 8 ounces of bread, 4 to 5 ounces of green vegetables, 1 to 1½ ounces of butter and fat, and 30 to 35 ounces of fluid.

The reduction treatment of obesity, to be successful, must be left wholly in the hands of a competent physician, who will recommend whatever form of treatment he may think advisable.

H. C. Wood divides corpulency into two divisions; the anemic, with little muscular power, and the plethoric and robust. It is plain that a treatment which afford a measure of relief in one of these conditions would not avail in the other; in fact, that a line of treatment pursued in the plethoric and robust type would be extremely hazardous in the anemic and weak form.

In the robust type the tendency is sometimes hereditary, but more often the condition begins with an overindulgence in food and alcoholic beverages, especially malt liquors. Once the tendency is fairly started, however, the quantity of food partaken of is of lesser moment; in fact, an aggravated obesity is often accompanied by a pronouncedly small consumption of food. Sedentary habits, lack of the proper amount of exercise, are also potent factors in the tendency to obesity.

The theory of the excessive indulgence in carbohydrates being mainly at fault is no longer tenable, as we know that these products are converted into water and carbon dioxide. That they interfere, however, with the oxidation of the albuminous elements of the food, and thus interfere with complete metabolism, is conceded. A rigid diet may be prescribed for the plethoric and strong, but would prove inoperative for the anemic and weak. A more complete oxidation is the object to be attempted, and this is measurably secured in various ways. Baths, particularly the Turkish or Russian bath, or a combination of the two, exercise such as walking, horseback riding, work with the various apparatus to be found in gymnasiums, rowing and massage are the most beneficial, but these must be accompanied by a restricted diet, especially of the albuminates, such as animal foods, to a lesser degree the farinaceous and starchy foods. The quantity of water consumed, if it has, previous to the commencement of the treatment, been large, should be restricted. Alcoholic beverages should be proscribed, excepting occasionally a Moselle or Rhine wine mixed with an alkaline carbonated water. In these cases saline cathartics may be rather freely indulged in to the extent of keeping the intestinal canal free from all accumulations, and this is an important part of the treatment. Carlsbad salts or water taken before breakfast in hot water, or Rochelle salt will answer admirably, the dose being regulated according to the individual needs of the case and the response to its administration; but this should be used in connection with the other methods indicated.

The thyroid gland has been recommended, as it hastens the oxidation of the carbohydrates, but its effects should be very carefully noted, as the continuous use is followed by shortness of breath, weak, rapid pulse, and a general nervous condition.

With the anemic and weak, the problem is more difficult. If the measures suggested above for the plethoric and strong are adopted, they must be carefully watched. Heroic treatment in those cases is injurious. Exercise, mild at first, gradually increased, will prove useful. Iron in some form is often indicated.

Poultry, game, fish, eggs, toasted bread, fresh vegetables, and fruits are allowed in moderation in obesity, while soups, especially the heavy soups, containing fats, milk, unless thoroughly skimmed, farinaceous foods, puddings and pastries of all kinds are to be forbidden.

Dietary lists might be given, but it is not thought that any form or quantity would meet

the indications in all, or, in fact, very many cases. Each case must be carefully studied and the diet as well as amount and character of exercise and the medical treatment must be adapted to the individual.

Williams declares that obesity is not only not a disease, but occasionally it is not even, strictly speaking, pathological, inasmuch as its presence is apparently essential to the ordinary physiological working of certain individuals. In the commoner forms, obesity is due to a want of balance between intake and output. Too much food is eaten or too little is oxidized. The ingested material may be excessive in quantity. This is frequent in the case of those who have been athletic in youth. That class of women patients, too, who think they need "supporting" habitually takes more food than can be assimilated. The practice of drinking fluid with meals is another cause of the ingestion of too much food. This fluid not only seems to increase the appetite, but by enabling the food to pass more rapidly out of the stomach than it would otherwise do, it makes it possible for the patient to eat more. Insufficient mastication leads to the ingestion of a great deal of unnecessary food. Excess may be a matter of quality. The quantity itself may be moderate enough, but the excess may reveal itself in the relative quantities of fat-forming or fat-saving principles. The starches, sugars, fats, and alcohol, are most readily converted into adipose tissue.

As to the oxidation of food, the chief agent in effecting this is muscular exercise. Ordinary obesity probably never occurs where circumstances allow this agent full play. When obesity is already established, there are substitutes for ordinary exercise which may be used, such as massage, electricity, Swedish movements, and Zander exercises. The nervous system plays a part in the oxidation of food. Mental anxiety may give rise to an extreme degree of emaciation. The obese patient must have mental and physical energy forced upon him. Hot baths for ablutionary purposes by the young and healthy are most undesirable, except when they are immediately followed by cold affusion and vigorous toweling, as are the Russian or Turkish bath. The prevalent vice of overclothing is still more important. The wearer of flannel undergarments, as far as his skin is concerned, lives in a moist climate, relaxing in its effects. A preservation of the activities of skin and lungs, bowels and kidneys, is very important.

## THE PRINCIPLES OF ETHICS OF THE AMERICAN MEDICAL ASSOCIATION.

By A. L. BENEDICT, A.M., M.D.,

BUFFALO.

A short time before the last meeting of the New York State Medical Association, the President of the Medical Society of the State of New York sent to his fellow members a circular letter asking them to prepare themselves to vote intelligently on the acceptance or rejection of the principles of ethics of the American Medical Association. As it has transpired, this action was evidently in anticipation of the favorable vote of the State Association to amalgamate with the State Society.

The Principles of Ethics of the American Medical Association thus become a live issue for the profession of the Empire State. In attempting a discussion of such a topic, it becomes the duty of each writer to acquaint his possible readers with his viewpoint, since, however fair one tries to be, his mental picture varies according to perspective and position. The present writer, therefore, in no egotistic mood, but merely to allow a discount of personal prejudices, would summarize his personal bias as follows: Graduated about five years after the split in the New York profession, member of the State Society, but mainly because of its relative antiquity, a member of the American Medical Association from 1897 until 1902, when, along with certain other members of the State Society who were unwilling to be on both sides of the fence at the same time, he was turned out of the A. M. A., a disbeliever in sectarianism in medicine or anything else, unless actually demanded by practical conditions, and yet not refusing consultation with homeopaths or any other conscientious and ethical practitioners of medicine, hostile to "politicians" of all kinds, but especially to manipulators of the medical profession.

The derogatory and ridiculous spectacle of two antagonistic State organizations of the "regular" medical profession, who can meet on a common ground not only at the bedside, but in other medical societies and who, as individuals, may even belong to both opposing organizations, has required explanation and apology during the whole period of its existence.

While the history of the schism scarcely needs to be repeated to medical readers, it may not be out of place briefly to recapitulate the conditions. A little over twenty years ago, the New York State medical profession, which had for some time been trying to secure a higher standard of medical education, became convinced that it could do so only by combining with the Homeopathic and Eclectic organizations of the State. Such a combination necessitated more or less professional recognition of the standing of sectarian physicians, and an abandonment of insistence on ethical qualifications for medical licensure since, in the first place, it would be impracticable to frame a law which would make such a requirement, or to pass it if framed, or to execute it impartially if passed, and since, in the second place, the Eclectic organization consisted mainly of advertising physicians, and, indeed, existed as an organization rather on account of dissatisfaction with ethical than with scientific and clinical views held by the regular profession. On the contrary, the homeopathic schism was almost solely on account of therapeutic differences and not on account of differing general conceptions of the professional customs of physicians.

Not because it favored advertising nor because it believed in homeopathy nor because its members were influenced by sordid motives with regard to consultation fees, but because, on the whole, these matters seemed insignificant in contrast with the annual graduation and licensure of ignorant and imperfectly trained physicians, the Medical Society of the State of New York voted to make the necessary combination with the Homeopathic and Eclectic organizations and, necessarily, thus to cut loose from the code of ethics of the American Medical Association, and its delegates were excluded from the latter body, at its next meeting. It may be questioned, as it has frequently been, whether a more general appeal to the profession in other States in advance, or a more diplomatic attitude of the delegates would not have averted the actual separation of the mother—the State Society—from the daughter—the National Association. Very likely, if the delegates had submitted to suspension or had demanded a postponement of radical action for a year, the bond would have been strained, but not broken. However, it is unwise to

censure action so long past, especially since, at the time and subsequently, the need of a national organization was not realized, and the American Medical Association has only recently assumed a leading position in scientific medical thought. Even so recently as 1900, when the writer unsuccessfully tried to induce the Medical Society of the County of Erie (Buffalo and vicinity) to memorialize the State Society to take action looking toward reaffiliation with the American Medical Association, one of the most prominent members of the society asked, in all seriousness, "Who gives a —— for the A. M. A., anyhow?" So rapidly, however, did opinions change that in 1902 there was a very nearly unanimous sentiment in the State Society that reaffiliation was urgently to be desired, and the mere fact that the meeting of the A. M. A. took place in New York State in that year was confidently regarded as indicating that such reaffiliation would be speedily and readily accomplished. This expectation was too sanguine, and, in one way or another, medical union has been delayed, but it now seems warrantable to expect that the desired harmony will be reached within the coming year.

Meantime, curious inconsistencies have prevailed. The members of the State Society have certainly demonstrated that their dismissal of the code of ethics was not a prelude to the adoption of quack methods, nor even to any inordinate desire to run after homeopaths. On the other hand, the State Association members have, in many instances, met with homeopaths, both at the bedside and in the discussion of sanitary and other general topics of interest to medical men. The Association has freely admitted members of the State Society, and a few homeopaths who have stated that they have not relinquished homeopathy. Other State organizations have followed closely the method of the New York State Society, to secure legislation in regard to educational requirements of prospective physicians, and in no case has this action resulted in their exclusion from the American Medical Association.

In 1903, partly to pave the way for the readmission of the New York State Society, partly in recognition of the impossibility of governing individuals by a formal code of ethics, the code was simplified, abbreviated, and reduced to the status of "Principles." Over a year ago the committee on conference of the State Society adopted the resolution that "The principles of medical ethics of the American Medical Association, being suggestive and advisory, shall be the guide of members in their relations to each other and to the public." Aside from the verbal blunder, this emasculated resolution can arouse no hostility, although its half-hearted spirit is scarcely satisfactory to either party. For that matter, the Principles of Ethics are a compromise between the adherents of the old code and the radicals who consider that the Golden Rule, or even the instincts of a gentleman, ought to suffice for guidance.

The Principles of Ethics are divided into three chapters, dealing with the duties of physicians, respectively, to patients, to other physicians, and to the public. The first and last chapters strike one as rather musty platitudes. An uncharitable layman would perhaps say that there is too much said as to cheerfulness of demeanor, realization of duty, and advisability of making visits frequently and of not abandoning cases that cannot be cured. If such matters are mentioned at all, it might be well to qualify them with warnings not to place the patient under obligations for unnecessary services. Objection may also be made to the reiterated policy of reserving unfavorable prognoses from the patient and of communicating them only as a last resort, and, then, preferably through a member of the family. Under older conditions, when treatment was largely expectant, and when all physicians were general practitioners, much could be said in favor of such a policy, although even under such conditions there are obvious religious or, perhaps we should say dogmatic grounds for informing patients of an unfavorable outcome, while they are still in possession of their faculties; and in a great many instances the physician is better qualified than a distracted member of the family to convey such information. The language of the Principles seems to imply that the preference for the member of the family is because the patient will be less likely to take the information seriously, and this is exactly the reason why the physician ought not to shirk his painful duty. There are also obvious business reasons why patients should prepare for death by putting their earthly affairs in proper condition.

In this age of specialism and of divergent methods of treatment, there are very practical reasons why an intelligent layman may rightly feel that he is, in a sense, purchasing not merely relief from symptoms or even treatment directed toward radical cure, but also an intelligent and clearly-stated opinion as to his case. In many conditions, the conception of seriousness of a case carries with it one line of treatment to one physician, another to another. Often there is a choice between medical and surgical treatment, between treatment designed to prolong life and that which stakes full recovery or immediate death upon a single throw of the dice. Again, even when there is no choice of this sort, one physician may have his own theory as to the proper treatment of a disease, while others, equally expert, may have others. Sometimes, in diseases whose various treatments have proved unsatisfactory, a physician has arrived at an idea the execution of which is purely experimental, and perhaps involving foreseen or unforeseen dangers. At other times the patient can be influenced to yield himself to needed treatment only by a full realization of the extreme gravity of his case. All things considered, the writer would lean to the view that the rule should be perfect candor as to prognosis, and that exceptions should be made in the case of patients of highly sensitive and apprehensive natures, or who are not thoroughly compos mentis, or who may well be spared disagreeable knowledge for a certain time. Be this as it may, there certainly is enough to be said on both sides of the question, so that it should not be decided as a matter of ethical principle, in one direction.

If a chapter, even a brief one, be devoted to the discussion of the duties of physician to patient, it is a serious omission to emphasize how the doctor should comport himself and how often he should make his calls, and to say nothing as to his prime duty to maintain, by proper preparation and continued application, a reasonable degree of scientific skill, and to secure for the patient supplementary care when, for any reason, his own skill is inadequate. In this practical age it is more important to examine the urine and the blood than to preserve a cheerful demeanor, and, in many instances, a doctor might much more humanely "abandon a patient because deemed incurable" than fail to call the proper counsel. All of us can recollect cases which we have cured after they were deemed incurable, as well as cases which seemed hopeless to us and that proved to be curable by some one better fitted to deal with them. It may seem uncharitable, but it is a cold fact that an aggregate of hundreds of human beings die every year because physicians of good ethical standing do not abandon them to others who might cure them.

Chapter 2, on the duties of physicians to their pro-

fession, is quite lengthy, and, perhaps, may be criticised as going into too many details. For example, the successive steps in organizing individuals into county societies, these into State societies, and the latter into the American Medical Association, though highly desirable under most circumstances, hardly constitute a principle of ethics.

Article 3, regarding consultations, like the first chapter, is behind the times in failing to recognize specialism. The true consultation is no longer a council of war of men of essentially equal standing, in which differences of opinion are to be decided by majority vote or by mere weight of individual experience or seniority. There are certain localities and certain cases in which such consultations must persist, but they have long since given place, in practical importance, to consultations in which one or more experts, rationally so considered, are summoned to give opinions rightly considered as decisive. If, for any reason, and such reasons often develop, the consultation does not assume this phase, it is recognized that the result is not ideal. Many of us would frankly confess, from various standpoints, as attendant and consultant, as general practitioner and specialist, often to have violated the explicit "principle" of ethics that differences of opinion developed at a consultation should not be divulged either to the patient or his friends. This policy was proper enough half a century ago, but it is contrary to ordinary principles of business ethics to-day, when consultations are called and paid for, largely because the patient and his friends on the one hand, and the attending physician on the other, realize the possibility of such differences of opinion. When a consultation was called of neighboring physicians, to decide how long a patient would live, whether he had had enough, too much or too little calomel, or bleeding, whether one tonic should be substituted for another, etc., such a dictum was proper. Nowadays, the matter is very different. If the patient's disease is called a cancer of the pylorus by one consultant and gastric catarrh by another, it is a matter of operation or very different methods of treatment. Differences of opinion as to climatic changes, adbandoning business, grounds for divorce, suspension of reproduction, interruption of pregnancy, commitment to asylums, submission to gradual failure of vision or risk of eyes in the hope of securing practically rejuvenated sight, questions as to whether an intermittent fever is to be treated with quinine or by draining a possible hepatic abscess or supurating gall-bladder, do not appeal to us as proper for final settlement by majority vote or by the dictation of supposedly superior judgment or admittedly longer experience. It is unfortunate that they should be left to the decision of the laity, and yet, in many cases, the laity are paying for just such a frank submission of disagreement and, under modern conditions, by yielding to their explicit or implicit demand, we are not asking the laity to settle abstruse problems as to which learned doctors have disagreed, but are enabling them to cast a vote from the standpoint of other considerations which they can intelligently entertain, or to seek further advice from experts. Thus, in general, it seems to us that any radical difference of opinion at a consultation should be submitted to the patient or his representatives, and that, ultimately, the interests of patient, attendant, and consultant are best subserved by this policy. The vital defect in this "principle" is the implied conception of medicine as an infallible and mysterious art, rather than an application of natural, scientific principles to bodily ills.

The essential weakness of the document of the "Principles of Ethics" is that it attempts to codify rules of conduct of physicians, without reference to existing problems. Among these problems, we have already mentioned education and specialism. These imply other problems with regard to medical colleges, hospitals, dispensaries, sanatoriums, open and covert advertising, selfish or altruistic use of positions of trust and honor, subversion of public or private benevolence to personal, scientific, if not pecuniary, advancement, etc. Then, too, problems present themselves with reference to the relation of the medical profession to prospective members, and to official and sanitary control, to allied professions, as of dentistry, nursing, pharmacy, etc., pharmacy alone being touched upon and very briefly in the "Principles." Very delicate problems also present themselves as to the harmonious relations of private physicians and those in institutional practice, in the employ of various branches of the government, etc. A live issue is the licensure as limited by State and national boundaries. Many others will present themselves to those studying the situation carefully.

As has been stated at the outset, the principles of ethics, in their present suggestive form, are not an obstacle to the reunion of the medical profession of the State of New York. Yet, like most compromise measures, the "principles" cannot prove satisfactory. Without reference to special points of disagreement, a very large minority of the medical profession favor a "code." In other words, they hold that if a matter of professional policy is really a principle, it ought to be binding. The present "principles" are too detailed and too codified for a general preamble of professional ideals, too arbitrary in some particulars to secure universal approbation, even as a suggestive guide, too incomplete for the practical demands of the present age. In their present form, they cannot be viewed complacently, except as a rough draft for future revision, which must take one of two diametrically opposite directions. Either they must be abbreviated to a very general application of the Golden Rule to medicine, or they must be amplified and perfected so as to cover the ethical details governing modern physicians. In either case they must be so far restored to the position of the old code that their spirit shall be binding on the profession, and that departures from the principles enunciated shall be allowed only under exceptional conditions.

156 West Chippewa Street.

## UNCERTAINTIES AND FALLACIES IN SCIENTIFIC MEDICINE.*

By HENRY BIXBY HEMENWAY, A.M., M.D.,

EVANSTON, ILLINOIS.

One of the first lessons I learned in the use of the microscope was: Keep both eyes open, but ignore everything not seen through the microscope. Unfortunately many of our younger graduates in medicine seem to have learned this lesson so thoroughly that they ignore as unscientific everything which they do not discover by the aid of chemistry or the microscope. In a recent discussion on typhoid fever, before the Kalamazoo Academy of Medicine, Dr. Simeon Belknap, one of the leading practioners in southwestern Michigan, called attention to the greater fatality of the disease at the present time than formerly, and expressed the opinion that, if the time which is spent in looking through the microscope studying the germs were used in watching the patients, more would recover. There is more truth than poetry in his remark.

An interne told me some time ago that in the

*Read before the Evanston Branch, Chicago Medical Society, October 26, 1905.

laboratory he learned thoroughly that salol has practically no antiseptic influence. He also learned that typhoid fever is a general, not an intestinal disease. When, therefore, in the hospital, he was told to give a typhoid patient salol he protested, but he finally agreed to give to some patients salol, and compare those cases with others in which the treatment was, as he thought, "more scientific." The result was that he was thoroughly convinced of the clinical efficiency of salol.

I have no doubt of the fact that the pneumococcus is the cause of pneumonia, and I believe in the general truth of serum therapy, but there is something more required to-day in the treatment of this disease. Why is it that pneumonia is now so much more fatal than formerly? That it is so is well known. Why is it that eminent men in the profession have said that treatment of this disease is useless? The doctor of forty years ago studied his patient. He imagined that he was engaged to pilot the craft through a dangerous channel. He wanted to know the materials of which the craft was constructed. Heredity and hereditary characteristics play a much more important rôle in disease than the recent graduate is likely to realize. Some time ago I was surprised and horrified to hear a prominent specialist urge that in a case of pneumonia the entire chest should be examined thoroughly at least twice every day. After that advice I was not surprised to hear him say of treatment that there is little one can do. The old-fashioned idea was that the patient must be kept quiet, his strength must be saved, he must not be exposed to draughts, and the chest should be enclosed in a meal poultice. Perhaps early in the case the patient might be bled. The recent graduate smiles sardonically at those old fogey ideas, but, strange to say, the old-fashioned treatment is as successful to-day as it was fifty years ago. Some of the modern specialists certainly bleed the patient's pocketbook, but through their curiosity they turn the patient into the undertaker's hands. Respiration, temperature, and pulse are sure guides as to the progress of the disease. Is it mere accident that one doctor loses half or three-quarters of his pneumonia patients, while another scarcely a set of his? These facts ought to open the other eye of the laboratory doctor, but unfortunately, in his self-satisfaction he asserts that the other fellow must have made an error of diagnosis.

In diphtheria we ordinarily have a mixed infection. The diphtheria antitoxin is theoretically efficient against the Klebes-Loeffler bacillus only. It has been of undoubted benefit, but it should not be used exclusively. Why neglect the streptococcus infection?

Some time ago I read with much pleasure an article on a simple method of obtaining definite percentages in modifying cow's milk for infants; but the article was spoiled for me because, when it came to the application, it did not differ from the rules laid down half a century ago. Each case must have the milk modified to meet its individual requirement. Some children demand an increase of cream, some of water, and others of milk. No account was made of the fact that the casein of Jersey milk differs clinically from that of Holstein, and that most mothers do not know the meaning of the percentage. So long as the indications for use are inexact, so a great display of accuracy in prescribing seems to be done chiefly to impress the patrons.

Every movement of troops from the south northward in the war in 1861 was followed by an increase of fevers. People coming from the Ohio river to the Lake region, or from Southern Michigan to the Lake Superior region, are frequently troubled after a week or two with what are familiarly called bilious symptoms. It is far too common that the drinking water is unjustly blamed for these conditions and the following fever. In fact that water may have absolutely nothing to do with the case. It is easy to assume a wise air and, *ex cathedra* as it were, condemn the water supply; but what are the facts? Take Evanston for example. I doubt if any city of its size in America has a better supply. "The proof of the pudding is in the eating of it." Compare the amount of sickness here with that in other cities; especially compare the amount of intestinal disorders here with that in other places, and the contrast is remarkable. It might almost be said that we have no such troubles. If the water were bad we should have these disorders, particularly in the summer time. Yet there are some well meaning doctors who are constantly urging that all the water be boiled. Why? Because chemical analysis may show the presence of albuminoid ammonia. Is that of itself harmful? Not so far as is known. It may show the presence of sewerage, but that is harmful chiefly, not entirely, on account of the presence of pathogenic bacteria. Nonpathogenic bacteria are nearly always present in an open water supply, and they are necessary for the purification of the water. The presence of pathogenic bacteria I believe is exceedingly rare in our public supply. But note the inconsistency of the "boil the water" doctors. They do not condemn our sola fountains, though the water there is not boiled. They often endorse the use of well water, though the well may more easily become contaminated than our public supply; but especially they permit and even recommend the use of salads, though the lettuce, cress, radishes, and celery are washed and often soaked in this same unboiled water. The semi-gelatinous outside of the celery or lettuce makes a fine culture ground for bacteria. Notice the "rust" on the stalk of celery, or the spots of decay on the tender lettuce leaf that has been kept a day or two. If the drinking water must be boiled, the salad should be cooked also.

Don't misunderstand me—too great care cannot be taken of our water supply. The Emerson street sewer* should be diverted to the south as far as possible and as soon as possible, certainly before the opening of the drainage canal. Now occasionally it is best to take extra precautions. For example, as in the past week, when after a period of calm a northeast wind drives in the surface of the lake, and the returning undertow washes out the filth that has accumulated along the shore. So, too, when after a dry spell the sewers are flushed by heavy rains. At such times the water is oily. At any time when the intestinal tract is in an irritated condition it is wise to avoid every possible source of infection, whether it be water, fruit, or salads. But do not let us lose our heads. I know of a man who refused to drink his coffee because it had been made of water which had not been filtered, though perfectly clear, yet at the same time he eats freely of salads.

The Widal test and Diazo reaction are of undoubted value in the diagnosis of typhoid fever, but he who depends upon either, is sure to overlook important symptoms. The Diazo reaction for example has been noticed in tuberculous and simple

*Evanston is supplied with water taken from Lake Michigan, about a mile from shore. The Emerson street sewer empties into the lake about one mile south of the waterworks. The current of the lake is southward on this shore. An extension of the Drainage Canal will pass through Evanston and open into the lake about a mile north of the waterworks. The opening of this branch of the canal may affect the current in the lake.

meningitis, septicemia and other conditions, aside from typhoid fever. I have previously reported a case of supposed cancer of the stomach in which the diagnosis had been made after the most careful examination of test meals, and made by competent observers. I told the family that what we to-day regards as facts the future may prove to be false, and that, though I believed the diagnosis correct, I should work on the supposition that it was not. To our surprise the patient recovered.

The causative action of a few germs has been demonstrated in some diseases, but even in those cases—diphtheria for example,—there are other influences at work. Disease is not an entity, but an abnormal condition, and generally speaking we name it according to the most prominent abnormality. The action of the pneumococcus in a plethoric patient is very different from that in a person of the nervobilious temperament. Disease therefore must not be treated by name.

The body is a complex mechanism, and "if one member suffer, all the members suffer with it." The fact that the peculiar germ of a disease or its toxin is found in the blood or in the various parts of the body, does not prove that that disease is essentially general. Tropical anemia is general in its results. Smith has recently proven that the uncinaria may enter the body through the skin of the wrist, yet here, as in other cases of uncinariasis, the use of intestinal anthelmintics cures the disease.

Again: When diphtheria or pneumonia is present in the community the specific germ may be found in the fauces of perfectly healthy individuals. The presence of the germ is then not sufficient ground for a diagnosis. The healthy animal organism has power to overcome and destroy bacteria. You may not properly speak of a bed of radishes until the seeds begin to grow. They may decay before germinating. You do not have a case of diphtheria before the germ has begun to develop and produce its toxin. Where the bacillus is present without disease, the patient is really threatened with the disease. When by medication we aid the system to conquer an incipient attack of diphtheria or typhoid fever, I see no impropriety in saying that the disease is aborted. Tuberculosis is frequently aborted, and why not typhoid fever?

All remember about the French professor of the practice of medicine who always closed his clinic by hoping they might be present at the autopsy of the patient. When we are called by our patrons it is to avoid an autopsy. It is our duty to get them well with the least possible delay. To do this we must sometimes use remedies which experience has proven good, even though our reason says differently.

Let us, therefore, use both eyes and have minds open to receive truth from every source. Centuries ago one wrote the good advice: "Be not wise in your own conceits."

---

**Some Anomalous Cases of Locomotor Ataxia.**—F. H. Edgeworth calls attention to cases of locomotor ataxia which differ from the ordinary type of this disease. In certain instances there is noted the absence of ordinary features, in others the presence of rare ones, in still others the coexistence of diseases which modify the general clinical picture of this affection. It is known that absence of the knee-jerks is an almost constant symptom of the malady. However, in certain cases they are present. The writer describes a case of tabes in which the physical signs were absolutely negative. The patient had had both primary and secondary syphilis and had suffered for a year from attacks of intense shooting pains in the muscles of the legs. Aluminum chloride was administered three times a day, and antifebrin was given during the attacks. Six months later considerable improvement was noted; the physical signs were, however, still negative. In another case the gastric crises were so characteristic that the diagnosis of tabes was made even in the absence of physical signs. Morphia, given hypodermically, was the only drug which controlled the attacks. Romberg's sign which developed was the only physical evidence of tabes. This man had had a hard chancre. Another case showed an interesting combination of symptoms—ocular paralysis, gastric crises, and loss of knee-jerks. This patient was a married woman twenty-seven years old. She had suffered from symptoms very suggestive of syphilis five years before. Iodide was administered and the ocular paralysis disappeared in two months. The other symptoms persisted. The writer states that the knee-jerks, if lost in tabes, may return in consequence of an attack of hemiplegia. He further declares that an arthritis does not bring back the knee-jerks. He concludes this paper by citing the case of a man thirty-four years old in whom peripheral neuritis complicated tabes. Treatment consisted of large doses of iodide, massage, and electricity. Almost complete recovery took place in two months, but the physical signs of tabes did not change.—*The Bristol Medico-Chirurgical Journal.*

**Subcutaneous Fixation of the Omentum.**—Narath has obtained satisfactory results in cases of cirrhosis of the liver with ascites by the following modification of the Tahua operation. A small incision is made in the median line just above the umbilicus under local anesthesia. Through this incision the abdomen is emptied of ascitic fluid as thoroughly as possible by pressure and by drainage through heavy metal catheters introduced into the pelvis and hypochondrium. A thick finger of omentum 12 to 15 cm. long is then drawn into the wound, and secured by sutures at its base. The portion of omentum selected should have a rich blood supply. Under further local anesthesia a subcutaneous pocket is formed by blunt dissection to the left of the umbilicus, and the selected projection of the omentum fastened in it. If the pocket is not too large sutures are not essential to hold the omentum in apposition with the abdominal wall. Traction upon the omentum must be as slight as possible to avoid displacement of the transverse colon. This is the only danger in the operation, but even where the intestine has been drawn into the wound no clinical symptoms have resulted. The abdominal incision is closed without drainage. Transient edema of the abdominal wall from infiltration with ascitic fluid is occasionally observed. Dilatation of the paraumbilical veins indicating the formation of anastomoses is usually apparent at the end of a week. The advantages of this method are, (1) the rapid and extensive formation of venous anastomoses; (2) the substitution of local for general anesthesia in debilitated subjects.—*Zentralblatt für Chirurgie.*

**The Motility of the Stomach in Pregnancy and the Puerperium.**—Giuseppe Fossati calls our attention to the fact that in pregnancy the motility of the stomach is increased, and the secretions are increased in the amount both of pepsin and of hydrochloric acid produced. Hence the good appetite shown during the last months of pregnancy. To test the rapidity of peristalsis and of absorption of materials by the stomach the author administered iodopina, a combination of iodine with the oil of sesame, which is absorbed in the intestine, being unchanged in the stomach. By noting the time between the ingestion of the iodine and its appearance in the urine, he determined the rapidity of the motor action of the stomach. The experiments were made on women in the last three months of pregnancy, and a few in the first ten days after childbirth. The author's conclusions are as follows: (1) The gastric motility in pregnancy is above normal at the seventh month, and is at its acme in the eighth and ninth month. (2) In the first four days of the puerperium, it is below normal; it then rises again above normal, but not to so high a degree as during pregnancy. (3) Primiparity or multiparity has no influence on the motility of the stomach.—*Annali di Ostetricia e Ginecologia.*

New York, December 9, 1905.

## THE HABITUAL USE OF PURGATIVES.

IN dealing with a malady so widespread as constipation, and so susceptible, in its most prominent manifestation at least, of easy medicamentous relief, it is not surprising that therapeutic abuses should be almost universal, and that among the laity and the profession alike measures leading to symptomatic alleviation rather than to radical cure should be oftenest applied. The orthodox dietary régime is frequently irksome or inconvenient to follow, fresh air and exercise may be luxuries difficult of attainment, and still more so the special gymnastic, electric, and hydrotherapeutic measures that are usually the privileges of the well-to-do. It is so much simpler to take at bedtime a spoonful of this or that, or some pet pill, then to carry out the hygienic program dictated by a more rational, but less convenient system of therapeutics, and the result is often the acquisition of a highly undesirable "purgative habit." The advantages attending a smoothly functionating intestinal tract have been so thoroughly impressed on the popular consciousness that a special type of neurasthenics and hypochondriacs has been fostered, amateur scatologists who make a fetich of the water-closet and view with dismay any putative diminution in the matutinal output of waste material, or regard an occasional omission of the function as a signal for instant recourse to the medicine bottle. The difficulty is that it is not sufficiently well recognized that while it is customary for most individuals to empty the lower bowel once in twenty-four hours, this is largely a matter of education, and perfectly good health may be maintained even though the act of defecation is performed only at much longer intervals. Habit and idiosyncrasy play a large part in the establishment of periodicity in this regard, and what constitutes constipation for one person may not be at all unnatural for another. The advocates of restricted dietary and thorough insalivation, like Sir Michael Foster, Chittenden, and Horace Fletcher, have shown that infrequent defecation may be quite consistent with good health. The literature of proctology is indeed full of phenomenal, but we suspect apocryphal, cases in which defecation regularly occurred at intervals of weeks or even months without apparent impairment of the general well-being.

Jürgensen, in a contribution to the "Ewald Festschrift" of the *Berliner klinische Wochenschrift*, points out that the multiplicity of available purgatives has led to a haphazard, stereotyped manner of their use which demands serious censure. The daily administration of such agents is wholly unwarrantable and is distinctly pernicious. Under these conditions the intestine is deprived of all occasion for spontaneous action, and no opportunity is given for any estimate of its intrinsic capacity. The question of the normal interval between movements is still unsettled, but is after all of secondary importance, for in determining whether or not constipation exists the nature of the stools, their consistency, amount, etc., are of greater significance than their frequency. The usual statements of habitually constipated persons to the effect that unless a daily movement is secured by the aid of drugs all sorts of disagreeable symptoms result may, according to Jürgensen, often be disregarded, and he thinks the alleged general consequences of the condition are in many cases much exaggerated. The distinction between permissible and non-permissible laxatives must be drawn with greater care. Ewald has stated that only those laxatives are satisfactory that produce mushy, non-watery stools, without any discomfort, such as griping or tenesmus. Jürgensen goes still further and avers that such agents intended for routine use must act without giving rise to any unnatural collateral effects whatever, that is, without even disturbing the normal consistency of the movement. Another point of importance is the matter of dosage. Laxatives must never be prescribed in a fixed dose if intended for repeated use. The amount to be taken must always be determined by experiment in each case, and the minimum quantity which will produce a perfectly comfortable, formed stool is the proper dose. Many cathartics, perhaps most of them, exhibit only the two extremes of action, and either are without any effect at all or, if the dose be increased by even a very little, cause liquefaction. If no golden mean can be obtained such agents should be discarded from the treatment of chronic constipation, and only those that can be made to exhibit a more nearly natural action should be used. The various mechanical, electrical, and dietary measures are termed by Jürgensen the hygienic purgatives, while those belonging to the realm of pharmacology, he says, are distinctly anti-hygienic. Of the latter class he mentions as suitable a decoction of the European buckthorn bark, a weak infusion of senna leaves, and, finally, medicinal "teas" containing combinations of several simples, such as linden, elder, and German camomile flowers, peppermint leaves, valerian root, arnica flowers, mullein flowers, etc. These latter, on account of their mild action, he considers especially satisfactory and he recommends them for further trial.

The same subject is approached from a somewhat different standpoint by A. Schmidt, of Dresden, who has already done much toward advancing the study of the feces. In the *Münchener medizinische Wochenschrift*, No. 41, 1905, this author states that most writers in attempting to explain the nature of chronic constipation regard it as dependent on a primary defect of the motor apparatus of the intestine, *i. e.* its nerves and muscles. He believes, however, as the result of observations, mainly on the feces produced while on a test diet, that this theory is insufficient to explain many cases, and suggests an entirely different view. This is that in chronic constipation the food is exhausted to an extreme degree as compared with the normal conditions, so that the

residue is hard, dry, and too small in amount. This abnormality of digestion is the primary element, the deficient motor activity of the gut being the secondary factor. This is dependent on the fact that owing to the small quantity of débris from the food fewer bacteria develop, and consequently smaller amounts of decomposition products to irritate the intestine into activity are formed. Strassburger has actually found that the feces of constipated individuals contain much less than the normal proportion of bacteria, and Lohrisch has shown that the feces of such persons give evidence of increased digestive capacity for cellulose. Furthermore, the stools of chronic constipation do not usually show evidences of decomposition, but are almost odorless, neutral in reaction, and when tested in the incubator undergo little fermentation or putrefaction. Schmidt's idea is that if the cause of the constipation is the, so to say, overdigestion of the food, an effort must be made to render the amount of residue greater. This is usually attempted by the addition to the diet of coarse articles of food, such as whole wheat bread, nuts, fruit, etc., often without much effect. Wholly indigestible materials such as sawdust, bran, and sand have also been tried, but although they may render the intestinal residue more bulky they do not cause it to be softer or moister, which are the essentials for easy evacuation. A substance which fulfills both conditions and increases not only the actual volume of the stools, but also their moisture, while without being in any way injurious or irritating, is the agar-agar of the bacteriological laboratory. This absorbs water freely and then swells up, but is practically indigestible. Schmidt has found that if small amounts of this (10-20 g.), finely chopped, are added to the food the consistency of the feces is altered for the better to such an extent that many cases of chronic constipation may be relieved in this way. Another agent that has a similar but somewhat less effective action is vaselin, and often a combination of this with the agar is more satisfactory than either alone. In some cases, he admits, the increase in bulk and moisture effected by this means is insufficient alone to produce the desired result, and a small amount of some laxative, such as cascara, must also be given, to serve as an irritant stimulus to the intestine; but this need never be as large as would otherwise be the case.

Whatever practical value this suggestion will be found to have there is no doubt that it, like all other plans of internal correction, will be most likely to prove successful if the greatest stress in the treatment be laid on what Jürgensen terms the "hygienic purgatives," and of these proper diet is probably the most effective. The tendency of the laity to self-medication is always a source of danger to the public health, and the risk is certainly less if the therapeutic endeavors of the populace have as their inspiration the bill-of-fare instead of the pharmacopeia.

---

**Another Cancer Cure.**—According to the newspapers, Dr. James Fenwick of Accrington, England, has hit upon a new cancer cure. Like Behring, he declines to reveal the exact nature of the remedy, but asserts that he has cured nine patients in nine years—a rather poor showing for an infallible remedy.

## CHRISTIAN SCIENCE AND THE CHURCH IN ENGLAND.

The Bishop of London, who, undoubtedly, is the most progressive and, in many respects, the most able of the English Protestant Church prelates, has made recently a considerable commotion in both church and lay circles by the delivery of a remarkable address in regard to Christian Science. The occasion was a meeting of the Women's Diocesan Association, held in London on November 11. The title of the Bishop's address was "The Truth and Error of Christian Science." In the course of his remarks the speaker admitted that the teaching of the Christian Scientists embodied a great truth. Up to a certain point they were perfectly orthodox. There was in us all a deeper personality which had a power over us. In times of sickness an appeal might be made to that deeper personality in such a way that the sick might be strengthened even to recovery. The Bishop then related an instance in which he had been the means of exerting so great an influence over a sick person that she had come out of a state of collapse and had been enabled to undergo an operation which had cured her. The speaker said that "to a great extent there was truth in what the Christian Scientists taught. But when this truth was distorted and exaggerated, as it was, one was changing it deliberately into a gigantic heresy." The Bishop further declared it to be his firm belief that some persons possessed the gift of healing, and he laid down the following rules for those thus endowed: First, those who thought they had these special gifts must never attempt to exercise them apart from the medical profession. In the second place, they should make it clear that they looked upon the healing art as in itself a sacred thing. Thirdly, they were to maintain the equal rights of the Christian minister and the doctor in the sick room.

Christian Science is making considerable headway in England, which, no doubt, was the main reason for the Bishop's discourse. The cult, however, has by no means the vogue that it has in the United States. Of course, it is an undeniable truth that the mind has a powerful influence over the body, and it is due to this fact that Christian Science has had a large amount of success in treating certain forms of disease. Indeed, what is known as autosuggestion has a distinctly curative effect on certain functional affections, as, for instance, on some forms of headache, on hysteria, and on imitative chorea. A Dr. Moll of Berlin wrote a pamphlet a few years ago in which he endeavored to trace the connection between Christian Science and Occultism, and concluded that there was an intimate relation between the two. The writer freely admitted that Christian Science treatment might improve symptoms even when serious anatomical changes were present, but he proceeded to point out that so might also ordinary psychotherapy and suggestion. It is manifestly absurd to term the cult Christian Science, for there is but little Christianity in connection with it, and there is most certainly no science. *The Lancet* some few years ago referred to this religious craze as "unchristian nescience," which phrase, if it be analyzed, will be found to be far more apt than the name given by the founder. That there are earnest and good Christian Scientists is assuredly true, but the so-called religion is based to a great extent upon fallacious reasoning.

If the Christian Scientists were not to go beyond the treatment of the thousand and one petty ailments which have their origin in the mind rather than in the body, nothing would be said against their efforts; but when, as the Bishop of London remarked, the truth is distorted and exaggerated, it is changed into a gigantic heresy—he might have said fraud. As, however, has been pointed out in the MEDICAL RECORD on many occasions, one of the most unpleasant features of the Christian Science fad is that it is in so large a degree a money-making scheme, engineered by wonderfully keen business brains. The people of education and culture who have joined the sect have been attracted probably by the craving, inherent in most people, for something new. It may also be noted that the majority of Christian Scientists are women of queer nervous constitution, when not strictly on the make.

## PHYSIOLOGICAL ACTION OF THE ELEMENTS.

EXPERIMENTS have determined that the physiological action of the elements corresponds to their motion and vibration, and that of the molecule upon the preponderance of a single component. Thus carbon has a paralyzing, hydrogen an exciting, and oxygen an indifferent action. The more carbon and the less hydrogen in a compound the greater its paralyzing effect, and vice versa. In groups which contain hydrogen and nitrogen, the exciting action of the former preponderates over the weakly paralyzing action of the nitrogen. In this way the hydrocarbons are paralyzing groups because of the overpowering influence of the carbon. In the hydroxyl groups the hydrogen has an exciting action because of the indifferent oxygen.

The experiments above mentioned marked an attempt to establish a connection between chemical constitution and biological action. Schmiedeberg followed up these interesting investigations and determined that the absorbability of a substance plays a most important part in its action; that which cannot be absorbed being clearly inert when taken into the animal organism. Further, volatility at body temperature will modify the action. The narcotic action of the alcohol groups is conditioned upon the number of oxygenations contained in the molecule. Combinations of the alcohol groups containing two or more oxygenations with a hydrocarbon group become largely or entirely inefficient. Very poisonous atomic groups lose the intensity and original character of their action upon the substitution of a hydrocarbon of the fatty series, while the efficacy of the hydrocarbon groups is weakened or abolished by combination with other atoms or complexes. The introduction of hydrogen into the cyclical bases will strengthen the physiological action and increase the toxicity.

Many poisons are rendered inert by the introduction of acids. This is explained by Nencki, chemically because of differences in oxidizability, but Ehrlich rather thinks that it is one—oftentimes at least—due to physiological conditions. For instance, all cocaines in a chemical sense cause the same pathological changes in the mouse's liver, but the anesthetic effect is limited to the benzoyl group, which is anesthesiophoric, while the methyl group is only anesthesiogenic, and herein is explained the synthesis of new remedies in the body. First, it is necessary to select a group which has an affinity for certain tissues, and in these substances to introduce various other groups which exert a toxic or therapeutic action. The recognition of the varied relations of different active series follows upon the study of the possibilities under which they act, especially upon the physiological and chemical study of substances which act in small quantities and chiefly on organs or tissues.

### SPIROCHETES IN YAWS.

AN interesting observation has recently been published by Dr. Castellani, who has done much work on the etiology of various tropical diseases. In a communication to the *British Medical Journal*, relating to parangi or yaws, which he is at present studying at Colombo, Ceylon, he announces that he has been able to demonstrate in the lesions of the disease several varieties of spirochetes, one of which is very delicate and closely resembles *Spirochæta pallida*. In preparations from ulcerated lesions various spirochetes are present, one form being identical with the *S. refringens* of Schaudinn. Two other types may be recognized and for these the author proposes respectively the names of *S. tenuis obtusa* and *S. tenuis acuminata*. In non-ulcerated lesions there may be found a spirochete which Dr. Castellani believes is identical with *S. pallida*. A significant feature is the fact that no spirochetes are observed in lesions which are healing. Of eleven cases of parangi examined seven revealed the presence of spirochetes, and in four cases peculiar oval, chromatin-containing bodies were seen which the author suspects may be a developmental stage of some possibly specific protozoon. Dr. Castellani states that he submitted one of his first specimens to Professor Schaudinn, who reported that he could differentiate three varieties of spirochetes, one of which resembled, but was not identical with *S. pallida*. While Dr. Castellani is not yet prepared to ascribe an etiological significance to the occurrence of these organisms in yaws, the observations he records are certainly of importance and will prove equally interesting to those who attribute purely saprophytic properties to the spirochetes, and to the adherents of the view that yaws and syphilis are related diseases.

### RADIOTHERAPY IN CHRONIC INFECTIOUS DISEASES.

THE report of a positive cure of three cases of leprosy, presented by Dr. H. B. Wilkinson to the Manila Medical Society, an account of which is contained in our special Philippine correspondence in another column, is interesting from more than one point of view. The fact of a cure, at least of the disappearance of Hansen's bacillus from the tissues, seems to have been demonstrated beyond gainsay, and it affords a promise that at last a means of arresting the course of this hitherto hopeless disease has been discovered. But it has possibly another and even deeper significance. If the theory advanced by Dr. Wilkinson of the manner of cure in these cases is substantiated, it is possible that radiotherapy will prove to be curative in other constitutional infections with superficial lesions. He assumes that the action of the *x*-rays is to attenuate or kill the bacilli present in the rayed lesion; these then become the prey of the phagocytes, and in the lytic process an excess of protective substance is formed which effects the destruction of the active bacilli elsewhere in the body, thereby establishing an immunity. If this is so other affections, notably syphilis in certain of its stages, may be amenable to a similar mode of treatment.

## News of the Week.

**Medical Society of the State of New York.**—The meeting of the Medical Society of the State of New York, which is to be held on the last day of January next and the two days following, being the Centennial meeting will be so largely devoted to papers written especially for the occasion, that the opportunity for the usual volunteered papers will be limited. Any members who wish to read communications of this sort should, without delay, make application for a place on the program, to the Business Committee, Dr. L. H. Neuman of Albany, Dr. A. T. Bristow of Brooklyn, Dr. H. U. Williams of Buffalo, or to any of the officers of the society. Those applying first will probably be assigned a place.

**Tuberculosis Exhibition.**—It has been decided on account of the increasing interest shown by the public in the tuberculosis exhibition in the Natural History Museum, to keep the exhibition open on Sunday, December 10, instead of closing on Saturday night. The attendance last week averaged 2,000 in the afternoon, with an increase in the evening, when lectures were given. The trades unions of New York held a convention on December 2 in the Natural History Museum to discuss tuberculosis and how the unions can aid in preventing it. Addresses were made by Health Commissioner Darlington, Herman Robin, secretary and official delegate of the Central Federated Unions, Prof. Graham Taylor, and J. W. Sullivan of Typographical Union No. 6, who said tuberculosis was the scourge of the printing trade. Thirty per cent. of the compositors die of tuberculosis, and thirty-two per cent. of the number are under thirty years of age. A circular of facts and statistics about consumption has been approved by the Committee on Sanitation of the Central Federated Union of New York, and is to be sent out to the various unions for distribution.

**New Free Bath Opened.**—The new city baths at 133 Allen street were opened on November 29, and are ready to furnish opportunity for cleanliness, free to all comers, who provide their own soap and towels. The building, of brick and granite trim, occupies two city lots, and cost $92,000. The hours are from 6 A. M. to 9 P. M., and a daily attendance of about 5,000 is expected. There are in all, 165 showers and dressing rooms and 16 tubs. Two new baths on East Eleventh street near First avenue, and East Seventy-sixth street near the John Jay Park, will be opened about the end of next month, and one on Sixtieth street near Eleventh avenue, will be ready about the close of January.

**Louisiana State Board of Health Resigns.**—After a more or less prolonged and unedifying series of accusations and recriminations on the part of the press and members of the board, the latter tendered their resignations to Gov. Blanchard on December 2. This action was taken on account of the popular expression of loss of confidence in the board, due to its failure to keep out the yellow fever. An appeal, headed by Lieut.-Gov. Sanders, has been made to the Governor to call an extraordinary session of the Legislature to confine itself exclusively to health matters.

**Illiteracy in the United States.**—A recent bulletin, issued by the Census Bureau, shows that about 100 out of every 1,000 persons in the United States, more than 13 years of age, are unable to write. The proportion for native white population is 46, foreign born whites 128, and negroes 445 in every 1,000. This shows a marked improvement over the conditions existing ten years ago, for in 1890 the illiterates of the United States numbered 133 per 1,000 for the total population; 62 for the native whites, 130 for the foreign born whites, and 568 for negroes, Indians, and Mongolians. International comparisons, restricted as far as possible to corresponding classes of the population, are, on the whole, favorable to this country, although the United States is still far behind Germany, Sweden and Norway, Denmark and Switzerland. Illiteracy is more prevalent among females than among males in the United States, the proportions being 112 for females and 101 for males per 1,000. There has been a greater gain in literacy among females than among males since 1890, when the figures for the sexes were 144 and 123 respectively. Commenting on this feature, the bulletin says: "Changes which are in progress point to the coming of a time when females of all ages will be less illiterate than the males. They also point to the coming of a time in the more remote future when illiteracy for all classes will have practically disappeared, and equality of the sexes in this respect will thus be restored in a millennium of literacy." Curiously enough there are fewer illiterates among the children of foreign born parents than among those of natives, and this is believed to be due to the fact that most of the former live in cities.

**Disinfection of Railroad Cars.**—In an editorial note in the MEDICAL RECORD, published a few weeks ago, reference was made to the urgent necessity for greater thoroughness in the disinfection of railway coaches. It was stated that an occasional cleansing was insufficient and that the cars should be purified at the end of each run. The Erie Railroad began week before last to sterilize the cars of the Chicago Limited after each trip with formaldehyde gas. The process will soon be extended to all the through trains. A deodorizing apparatus, which has been in use in about fifteen cars for several weeks, has also been devised and is placed under the seats over night. All the passenger cars will be fitted with it, though we must admit that the value of this innovation is probably more apparent than real. The laws of Texas and Kentucky require the sterilization of railroad cars, and an agitation for similiar laws is now going on in Ohio.

**Medical Organizations in Savannah.**—Working under the reorganization plan of the American Medical Association for only one medical society in each county of each State, the Georgia Medical Society and the Chatham County Medical Society, the two Medical Societies of Chatham County, came together a month ago and effected temporary organizations. At a subsequent meeting officers were elected. At the next meeting all these officers resigned and their resignations were accepted, owing to the fact that some members of both societies complained that they had no notice of the purpose of the meeting, and consequently had no voice in the election. While it appears that there is no disinclination on the part of the members of either society to amalgamation, the details of the process are giving rise to differences of opinion which were not reconciled at the last joint meeting, held on November 24. It is likely that one or more separate meetings will be necessary before a satisfactory plan of action can be decided on.

**Yellow Fever at Havana.**—The total number of cases under treatment on November 28 was 15. There have been 5 deaths. Five cases have been discharged as cured, making 27 cases to date.

This does not include 2 patients who died before their disease was recognized as yellow fever, and who were taken sick before the present outbreak. No new cases had been reported on December 1, though several suspects were under observation. Much adverse criticism has been caused by the fact that the health authorities at the request of certain local business elements have ceased publishing the names of patients or of the buildings from which they are taken.

**Patent Medicine Ruling.**—An order has been issued by Commissioner of Internal Revenue Yerkes and forwarded to all collectors of internal revenue, stating that peddlers who go about the country offering for sale patent medicines and other liquids containing alcohol, will, hereafter, be required to pay a special tax at every separate place where they make any sales.

**Thumb Imprint System.**—The New York city police officials have decided to introduce the thumb imprint system of identification into the methods of the police department. The detective sergeant, who is at present in charge of the Bertillon measuring system, is to be sent to Paris to study the French plan of finger-print registration, and will then instruct the local officers in its application.

**Essex (Mass.) South Medical Society.**—This society celebrated its one hundredth anniversary at Salem, on November 21, by a banquet, which was very largely attended. Dr. Frank Holyoke of Holyoke, read a biographical paper, relating to his own great-great-grandfather, Dr. Edward Holyoke, the first president of the society, and the first physician upon whom Harvard conferred the degree of LL.D.

**Tri-State Medical Association.**—At the twenty-second annual meeting of the Tri-State Medical Association of Arkansas, Mississippi, and Tennessee, held in Memphis in the last week of November. The following were elected as officers: *President*, Dr. Allen E. Cox of Helena, Ark.; *Vice-President*, Arkansas, Dr. Dickson of Paragould; *Vice-President*, Mississippi, Dr. E. J. Johnson of Yazoo City; *Vice-President*, Tennessee, Dr. F. J. Runyan of Clarksville; *Secretary*, Dr Richmond McKinney of Memphis; *Treasurer*, Dr. Marcus Haase of Memphis.

**Prize for an Essay on Epilepsy.**—The national Association for the Study of Epilepsy offers a price of $300 for the best essay on the Etiology of Epilepsy. Physicians in any country may compete for this prize. The award will be made in November, 1906, but all essays submitted must be sent in by September 1 of that year. Details as to conditions governing the award may be obtained from Dr. Spratling, Superintendent of the Craig Colony for Epileptics, Sonyea, Livingston County, N. Y.

**Demonstration of the Spirochæta Pallida.**—At Dr. Bulkley's lecture at the New York Skin and Cancer Hospital recently, Dr. Lapowski demonstrated under the microscope several specimens of the *Spirochæta pallida*, and gave a short résumé of the work that has been done to prove the etiological relationship of this organism to syphilis. This was, we understand, the first public demonstration of the *Spirochæta pallida* in this city.

**Removal of the "Illinois Medical Journal."**—The Council of the Illinois State Medical Society contemplates removing this journal from Springfield to Chicago in 1906, and it is said that the press work will be done at the office of the *Journal of the American Medical Association*.

**West Side Clinical Society of New York.**—The first meeting of this Society was held Friday, December 1, at the residence of Dr. Charles R. Jackson. Dr. George P. Shears discussed the subject of "Dystocia from Unsual Size of the Fetus," and Dr. J. C. Taylor that of "Salpingitis."

**Southern Surgical and Gynecological Association.**—The eighteenth annual session of this society will convene at Louisville, Ky., December 12, 13, and 14, 1905. Dr. W. O. Roberts is chairman of the Committee of Arrangements, and Dr. W. D. Haggard of Nashville, Tenn., is the Secretary of the association. All railroads will give one and one-third fare on the certificate plan. Membership blanks may be had upon application. Titles of papers or corrections should be sent at once to W. D. Haggard, Secretary, 148 Eighth Avenue, North Nashville, Tenn.

**The Report of the Evanston (Ills.) Hospital Association** shows that during the fiscal year 85 free patients were admitted, or more than 25 per cent. of the total number of patients received during the year. Twenty-two patients were admitted in the Children's ward, 14 of whom were free patients.

**The Illinois Commissioners of Public Charities,** in their quarterly report, ended September 30, gave the following as the per capita cost of the various State institutions: Illinois Western Hospital for the Insane, $26.21; Illinois Eastern Hospital for the Insane, $30.05; Illinois Hospital for the Incurable Insane, $30.32; Illinois Central Hospital for the Insane, $31.27; Illinois Southern Hospital for the Insane, $35.13; Illinois and Northern Hospital for the Insane, $38.67, and Illinois Asylum for Insane Criminals, $50.43.

**The Chicago Medical Society** has been asked by the Commissioner of Health to appoint a committee on nomenclature and classification of causes of deaths and the registration of vital statistics, authorized by the Society, to make a study of the methods and work of the department in these subjects, and if any defects are discovered to suggest remedies therefor.

**Bequests to Hospitals.**—By the will of the late Joseph E. Gillingham of Philadelphia, the sum of $50,000 is bequeathed to the Pennsylvania Hospital, $5,000 to the Maternity Hospital, $5,000 to the Bryn Mawr Hospital, $5,000 to the Charity Hospital, Norristown, and $5,000 to the Hospital of the Church of the Good Shepherd near Rosemont. The sum of $50,000 is devised to the Veterinary Department of the University of Pennsylvania, and $5,000 to the Women's Medical College of Pennsylvania for providing and maintaining a free scholarship.

**New Hospital Dedicated.**—The Chicago St. Bernard (Hotel Dieu) was recently dedicated by Archbishop Quigley. It has accommodations for 280 patients. Five operating rooms have been arranged for. The emergency room is to be on the first floor. Four operating rooms are on the fourth floor. There are five large wards, four small wards, and five wards for children.

**Dr. W. M. Late Coplin,** professor of pathology and bacteriology in Jefferson Medical College, has been appointed by Mayor Weaver of Philadelphia, Director of Public Health and Charities, in succession to Dr. Edward Martin, recently resigned.

**The Chicago Urological Society** elected the following officers at its annual meeting: *President*, Dr. Wm. L. Baum; *Vice-President*, Dr. Gustav Kolischer; *Secretary*, Dr. J. Allen Patton.

The society will hold its meetings on the last Thursday of each month, excepting July, August, and September. All regular practitioners in Cook County, who are in good standing, and who are interested in medical or surgical urology, are eligible to membership.

**A New Urological Society.**—On November 22 the New York Reno-Vesical Society was organized, for the purpose of studying the diseases of the bladder and kidneys. The officers for the ensuing year are: *President*, Dr. Ramon Guiteras; *Vice-President*, Dr. Winfield Ayres; *Secretary*, Dr. Robert R. Hollister. The meetings are to be held monthly. Membership is limited to fifty.

**American Electro-Therapeutic Association.**—The fifteenth annual meeting of this society was held at the New York Academy of Medicine on September 19, 20, and 21, 1905. The following officers were elected for the ensuing year: *President*, William Benham Snow, M.D., of New York; *Vice-Presidents*, William J. Herdman, M.D.,LL.D., of Ann Arbor, Mich., and Henry Finkelpearl, M.D., of Pittsburg, Pa.; *Treasurer*, Richard J. Nunn, M.D., of Savannah, Ga.; *Secretary*, Albert C. Geyser, M.D., of New York; *Members of the Executive Council*, Emil Heuel, M.D., of New York, and M. W. Brinkman, A.M., M.D., of New York.

**Presbyterian Hospital Report.**—The thirty-seventh anniversary of the Presbyterian Hospital was celebrated on December 2, in Florence Nightingale Hall, the school for nurses attached to the hospital. The annual report was made public and shows that during the fiscal year ended September 30 last 47,936 patients were treated in all departments of the hospital, an average of 606 a day.

**Dr. William J. Hammer**, who has been for the past few years First Assistant Physician at the Loomis Sanatorium, at Liberty, N. Y., has recently been appointed Resident Medical Director at St. Joseph's Sanatorium, Silver City, New Mexico. He will assume the duties of his new office at once. St. Joseph's is a young institution established a few years ago by the Sisters of Mercy.

**Neuralgic Grip.**—From the cabled reports it appears that this year epidemic influenza in Europe is largely of the neuralgic type. It is stated that attacks of neuralgic headaches and facial pains are now enormously prevalent in London.

**Plague in Japan.**—The plague is spreading in the vicinity of Kobé, and the authorities report that four districts are infected.

**Rockingham County (N. H.) Medical Society.**—The election of officers at the annual meeting of this society, held in Exeter, on November 9, resulted as follows: *President*, Dr. William H. Nute of Exeter; *Vice-President*, Dr. A. B. Sherburne of Portsmouth; *Secretary*, Dr. Walter Tuttle of Exeter; *Treasurer*, Dr. Alice M. Chesley of Exeter.

**Second District (Ohio) Medical Society.**—At the meeting of this society, held in Dayton, on November 21, the following officers were elected: *President*, Dr. John M. Buckinham of Springfield; *Secretary*, Dr. Daniel B. Conklin of Dayton; *Treasurer*, Dr. C. H. Minor of Springfield.

**Obituary Notes.**—Dr. Ambrose L. Ranney of New York city died suddenly on December 1. He was born in Hardwick, Mass., on June 10, 1848. He was graduated from the New York University Medical College in the class of 1870, and was one of six brothers, who were physicians. Dr. Ranney held chairs of anatomy and nervous diseases in several colleges and wrote a good deal on medical subjects.

Dr. Kate L. S. Sterling died on December 1, in the New York Hospital. She was graduated from the Woman's Medical College of Pennsylvania in 1886. Dr. Sterling had a clinic for some years in the New York Infirmary, in Livingston street, and served on the staff in the Babies' Hospital, Lexington avenue, and the Hospital for Ruptured and Crippled. She was a member of the Medical Society of the County of New York.

Dr. Augustus Choate Hamlin of Bangor, Me., and one of the best known men of the State is dead. He was widely known as an author, artist, and as an authority on tourmalines, of which he is said to have owned the best collection in existence. He was a nephew of Hannibal Hamlin, Vice-President of the United States during the Civil War. He was born in Columbia, Me., on August 28, 1829, and was the son of Elijah Livermore Hamlin. He was graduated from Bowdoin College in 1851 and from Harvard Medical School in 1855. He was attached to the Second Maine Infantry as assistant surgeon in 1861, and was made brigade surgeon the following year, attaining the rank of Lieutenant-Colonel and Medical Inspector of the United States Army in 1863. He served during several battles. After the war he practised medicine in Bangor. From 1882 to 1886 he was Surgeon-General of Maine. He had been Mayor of Bangor twice. He was the author of a book on Andersonville Prison and of numerous other works, many of them of a scientific nature.

Dr. John B. Sterley died at Reading, Pa., on November 24, at the age of sixty-nine years. He was graduated from the medical department of the University of Pennsylvania, in the class of 1857.

Dr. N. R. Jones of Norton, Kan., died on November 17. He was a graduate of Rush Medica College, Chicago, and came to Norton just twenty years ago. Dr. Jones was a member of the State board of medical examiners.

Dr. William A. Burns, a well-known colored physician of Dayton, Ohio, died on November 18 of typhoid fever. He was the only colored member of the Dayton Medical Academy, and is said to have accomplished much for the advancement of his race.

Dr. Michael Scannell of Worcester, Mass., died on November 16, at the age of forty-one years. Dr. Scannell was born in England, but came to this country when a young man. His family settled in Lawrence and Dr. Scannell entered Harvard college from that city, graduating fourteen years ago. He came direct to Worcester after graduating.

Dr. J. N. Reece of North Liberty, Ind., died on November 18, at the age of fifty years. He was graduated from Rush Medical College, Chicago, in 1888, and for many years served as president of the North Liberty board of education. He was, in 1898, elected representative of the lower branch of the Indiana legislature.

Dr. H. A. Bartran of Green Bay, Wis., died on November 22, at the age of sixty-seven years. Dr. Bartran was born in the town of Barton, N. Y., and was a graduate of the University of Michigan. He took an active part in State and city affairs, having been a member of the legislature of Wisconsin in 1873 and 1874, was mayor of Fort Howard shortly after, and was also county and city physician for twelve years. He was the oldest physician in Green Bay city, having practised there for upwards of thirty-three years.

Dr. Edmund Bennett of Barnegat, N. J., died on November 23 of heart disease. He was a native of Cape May Court House, where he was born in 1831. He moved to Barnegat in 1856, and had completed not quite half a century of active practice in this village.

Dr. F. W. Blair of Farmington, N. H., died on November 19, at Portsmouth, N. H., at the age of thirty-one years. He was graduated from Bowdoin College in the class of 1895 and from the Bowdoin Medical school in the class of 1898. After his graduation he began practice in Farmington, N. H., where he remained until obliged to give up work on account of a malignant tumor, which caused his death.

Dr. Benjamin Myers of Ashland, Ohio, died of pneumonia on November 28 at the age of sixty-four years. He was graduated from the Jefferson Medical College of Philadelphia in 1869, and began to practise in Ashland. He was prominent in politics and was at different times State representative, probate judge of Ashland County, delegate to the Democratic national convention, and mayor of Ashland.

## Correspondence.

### THE ROENTGEN-RAY TREATMENT OF LEPROSY.

(From Our Special Correspondent.)

Manila, P. I., October 19, 1905.

The regular monthly meeting of the Manila Medical Society was held at Saint Paul's Hospital at 8:30 P. M., October 12, 1905. An informal talk was given by Dr. Stitt, Lieut.-Commander, U. S. Navy, upon: "The Methods of Work, and Recent Work in the European and Colonial Schools of Tropical Medicine." Dr. Stitt recently visited the principal laboratories of Europe and America, as well as those of Cairo, Egypt, and gave a brief summary of his experiences, the essence of which may be found in recent literature.

The next number on the program was a paper by Dr. H. B. Wilkinson, physician in charge of the San Lazaro Leper Hospital, upon "Some Observations on Leprosy in the Philippine Islands, with an Account of its Treatment with the X-ray." It will be remembered that the results obtained by this method of treatment have been mentioned from time to time in these columns, since last December. He stated that the number of lepers in the Philippines were variously estimated from five to ten thousand, and that it was impossible to state whether leprosy was increasing or decreasing, nor was it possible to draw any conclusion as to the duration of the disease in any given individual that had come under his observation, because they did not come to the hospital early enough. In the classification, he divided leprosy into an atrophic and a hypertrophic variety, instead of tubercular and anesthetic, because he thought the latter terms caused confusion. Of the 230 cases which he reported, 97 were hypertrophic, 47 atrophic, and 92 mixed. Of the 230 cases confined at the hospital, the lepra bacilli were found in the skin scrapings of 213. The remaining 26 cases were repeatedly examined microscopically, with negative results. However, in several cases the lepra bacilli were found post mortem in the nerves that supplied the atrophic lesions. He began the treatment of leprosy with the *x*-ray during January, 1904, with a ten-inch spark machine, with which he used a bifocal tube. That portion of the patient which presented the greatest amount of infiltration was exposed to the direct rays of the tube at a distance of about ten inches. The exposure lasted about ten minutes and was repeated at intervals of several days. His object was to approach as nearly as possible to the burning point, without actually producing a burn. He called particular attention, however, to the fact that a cure resulted in the two cases which were accidentally burned. After two or three successive treatments, a blushing of the skin is often observed, which is later followed by scar formation. A tabulated statement of the thirteen cases treated showed that three were cured, seven improved, and three not improved.

He reported one case more or less in detail, because it was the first in which an apparent cure was made: Domingo Panol; male; Filipino; medium size; age 37; admitted July 29, 1904, to the San Lazaro Leper Hospital; clinical diagnosis, hypertrophic leprosy, confirmed microscopically by the Bureau of Government Laboratories, and by examination made by the author. Right side of face showed marked thickening of skin and superficial tissue, elevation being from ½ to ¾ inches. The thickening was so great that the right eye was nearly closed, and right ear about three times normal size. Large nodule over chin, about the size of a horse-chestnut. Many smaller nodules scattered over face and head. *X*-ray treatment was begun August 11 and repeated seven times between the latter date and August 23, when it was found that infiltration had disappeared somewhat, and the right eye could be partially opened. Owing to a burn on the right ear treatment was discontinued until September 4. September 8 treatment was again discontinued on account of burns. October 15 gradually improving; scar tissue becoming apparent on face. Pus taken from nodule on chin shows lepra bacilli. January 12, 1905, abscess detected in right groin and 8 ounces of pus evacuated. No lepra bacilli found in latter. Leprous lesions much improved but general health poor. February 2, microscopical examination of skin scraping from right cheek showed few apparently broken-up lepra bacilli. July 1, 1905, appearance normal so far as leprosy is concerned, but has considerable scar tissue on face. Microscopical examination of skin scrapings taken from previously affected area was negative, so far as lepra bacilli were concerned. Has general anasarca, with anemia and albumin in the urine. July 11, patient died of atrophy of the liver. Autopsy was made by Dr. Herzog, pathologist of the Bureau of Government Laboratories, who reported fatty degeneration of the myocardium and kidneys, with interstitial nephritis. Advanced atrophic cirrhosis of the liver, purulent abscess in anterior abdominal wall. Sections were prepared in Zenker's fluid and stained with hematoxylin, from the left side of the face, from the previously affected ear, from the kidneys, spleen, liver, heart and several peripheral nerves. No lepra bacilli could be demonstrated. In conclusion, Dr. Herzog stated that "the histological and bacteriological examination of this case furnished no evidence that the patient, at the time of his death, was suffering from leprosy, either cutaneous or internal."

In the next case reported as cured, the duration of the disease was two years. The patient received 52 treatments between January 7, 1904, and June 7, 1905, and is alive and well to-day. Repeated microscopical examinations made up to the present time have always been negative.

In the third case reported cured, the duration of the disease was two years and the patient received 14 treatments between May 8, 1905, and June 7, 1905. Microscopical examination made August 3, showed several doubtful acid-fast objects which appeared to be broken-up and degenerate lepra bacilli. Examinations on August 11 and 16 were all negative.

The author is inclined to believe that the cure takes place by the lepra bacilli in the lesion being "killed and their bodies absorbed by the system, thereby producing an immunity against the living organism." In support of his theory, he states:

"1. The treatment of one leprous spot on a patient produces improvement in spots at a distance from the one actually treated.

"2. The cure in the distant spots seems to progress parallel to and to be just as complete as that in the one treated.

"3. The best results seem to be obtained only when treatment is pushed to the point of killing or beginning to kill the tissues, which would also probably be to the point of killing the organisms.

"4. Cases in which there are massive localized leprous deposits as in case No. 5, are most rapidly improved, as in these cases we have an abundant culture on which to operate and thereby produce immunity more rapidly.

"5. In diffuse general involvement of slight degree or atrophic character where there are only a few scattered organisms we have had little success.

"6. In two well advanced cases where the amount of new leprous tissue was excessively great, the improvement was marked and rapid, but followed by loss of general health and rapid physical decline. This may be an over dosage, so to speak."

### OUR LONDON LETTER.

(From Our Special Correspondent.)

THE COLLEGE OF SURGEONS' MEETING—EXOPHTHALMIC GOITER—THE PARATHYROIDS—FITZPATRICK LECTURE—INJURY TO FEMUR—TEMPERANCE APPEAL TO THE PROFESSION.

London, November, 17, 1905.

Yesterday was again presented at the Royal College of Surgeons the farce which is officially called the annual meeting of the Fellows and Members. The gathering numbered 64 and the Council presented a report. But the meeting had no power to accept it or reject it. A resolution was moved in protest against the repeated neglect by the council of resolutions passed in previous years and declin-

ing to have the report laid before the meeting. It was said that parents with sons entering the profession would be well advised to avoid the college. An amendment was moved, but after a conversation with some councillors near him, the president declared both resolution and amendment out of order. Nevertheless he put the motion, as he said he "did not wish to appear discourteous." It was lost by the councillors voting against it, which a member called "a dirty trick" but withdrew the expression at the request of the president. Is it not a farce? Two dozen Councillors elected by 12,000 Fellows, refusing any form of representation to about 18,000 Members? The members ask but little —too little. They will get nothing until they organize themselves on new lines. A hint from trades unionists might help them—say a refusal to meet in consultation or refer a patient to any surgeon on the Council until the rights filched from the members are restored.

The Bradshaw lecture at the Royal College of Physicians was this year delivered by Dr. Geo. Murray of Newcastle, whose previous work excited expectation on the announcement of his subject—Exophthalmic Goiter. You may remember his Goulstonian lectures a few years ago were devoted to the Pathology of the Thyroid Gland, and as he devoted one of them to the pathology of Graves's disease it was only natural to expect he might have something of special interest to communicate concerning it. His present lecture is, from a clinical point of view, based on 180 cases that he has observed. Of these 170 were in women and only 10 in men, a relative frequency of 17 to 1. There was some enlargement of the thyroid in 172. In 5 there was none when first seen, but a history that there had been. In only 3 was there no evidence. Probably if all cases could be observed throughout their duration goiter would always be found, although some observers have reported a much larger percentage of its absence. A slight degree of enlargement may be unnoticed by the patient and is often found to her surprise for the first time by the doctor looking for it on account of other symptoms. On the other hand, it may be the first symptom the patient notices, often on account of some slight constriction or fullness about the neck which leads her to examine it by the looking-glass. Both the size and consistence of the enlargement vary. In 63 of the cases a murmur was heard over the thyroid, in 41 systolic, in 19 a continuous venous bruit which in 10 became louder at each systolic or was accompanied by a systolic murmur.

The tachycardia is very variable, may hardly excite the patient's attention, or may come on quite suddenly. It ranges from 90 to 200. In 101 of Dr. Murray's cases it varied from 120 to 150; in 47 from 140 to 150. Irregularity of the pulse occurred in only 12 cases, the action of the heart being such as is produced in a healthy person by violent exertion. Diffuse pulsation is visible all over the cardiac area, and the impulse on palpation extends further than usual.

The exophthalmos is often the most distressing symptom to the patient. In 170 of the cases it was present in 120, in 3 it had been present but had disappeared, in 47 there was none. It usually affects both eyes, but in a few cases only one. The extent varies from slight fullness to so marked projection that the eyelids cannot be brought together and the eyes remain open during sleep, and the conjunctiva is liable to attacks of inflammation in consequence.

The nervous condition is very marked. Dr. Murray described the mental state as one of subdued excitement, such as is seen in a person undergoing a trying ordeal. Some exhibit the restlessness of mind described by Russell Reynolds as "chorea of ideas." A few have hallucinations, visual or auditory. Actual insanity may occur, but is regarded as a complication rather than a part of the disease. Only 3 cases were noted in the 180. Some patients were quite optimistic, others melancholy, and all variations of temperament may be noticed. Intellectual work can be carried on in most cases, and one lady under Dr. Murray's case occupied herself by learning the Turkish language. The fine tremor of the hands which is so generally noticed was present in 163 cases, in 7 absent, and in 10 not recorded. It is often present in the legs: 21 of these patients complained of it, 5 of them could not walk on account of it, but fell down on attempting.

The moist state of the skin was observed in 113 and actual sweating in 92 of the cases. Pigmentation in 42.

Some alteration of appetite was noted in 20 cases, increased frequently of defecation (not diarrhea) in 20, but attacks of diarrhea are quite common. Intermittent albuminuria is now and then met with. In 30 cases tested it was found in 6. In 3 sugar was detected. Menstruation was affected in 45. Some loss of weight was marked in 67 cases.

Treatment naturally claims great attention, and Dr. Murray's experience in regard to this is less promising than some observers have asserted. It is easier to supplement a deficiency of thyroid secretion than to control excess. The general line adopted by most is confirmed, rest at times, outdoor life, and attention to the nutrition, with avoidance of undue mental effort or physical exertion. The faradic current has given much satisfaction when persevered with, and patients easily learn to apply it themselves in the way suggested by Victor Horsley. X-rays have been disappointing. Of drugs arsenic is one of the most useful. When the pulse is over 100 convallaria can be added in preference to digitalis or strophanthus. If nervousness is prominent bromides may be given for a few weeks. Iodides are unsuitable and often aggravate the symptoms, so does thyroid extract, which is still sometimes given under a mistaken view, and does harm. Suprarenal and thymus tablets have been of some service. The application of red iodide of mercury ointment of half strength benefited some cases.

Dr. Murray gave an account of the several sera that have been employed, but his own experience is not encouraging, although, as he acknowledges, it is limited.

With regard to rodagen (the dried milk of goats after excision of the thyroid) he related a case in which the patient, while taking drachm doses, became suddenly collapsed, cyanosed, with a systolic apical bruit, and a pulse fallen from 160 to 32. At a later period this patient took half-drachm doses with apparent benefit.

Dr. Murray has also experimented by preparing an antithyroid serum from rabbits and goats. In 2 cases in which he tried it he considered that some improvement occurred, but not more than under general treatment, and no special effect could be traced to the serum.

The risks of surgical treatment are so great that he does not consider it advisible.

The conclusion arrived at by Dr. Murray from the important facts he communicated is that at the present time the best results are obtained in most cases by the general hygienic treatment combined with the use of the faradic current and a few drugs, and that no serum offers us better results than these older methods.

Dr. Laurence Humphry of Cambridge this week contributes to *The Lancet* an important article on the parathyroid glands which appears very opportunely just after the Bradshaw lecture on Graves's disease. It is true that our knowledge of these little bodies is very limited, although many experiments have been made on animals by the physiologists. Dr. Humphry's object is to ascertain if there is evidence of any pathological change in the parathyroids in Graves's disease, particularly in the acutely fatal form. He relates 2 cases in which changes were found, chiefly extensive infiltration of fat, and remarks that to ascertain the significance of such changes it is necessary to examine the parathyroids in persons dying from various causes. He has himself dissected out these glands in 26 cases—no easy task considering their minuteness and the way in which they are usually imbedded in fat. He gives directions as to the best method of finding them. To make sure of their identity the microscope should be employed. Dr. Humphry has examined microscopically the parathyroids in 18 cases of death from various causes in addition to 4 of Graves's disease, of the 18 well-marked fatty infiltration was seen in 4 and some degree in another case—a girl of 14 who died from burns. In Graves's disease no sign of compensatory hypertrophy was discovered, nor any evidence of specialization by forming colloid. The hypothesis that these bodies are merely compensatory to the thyroid is certainly losing ground and Dr. Humphry remarks that the facts that they develop chronologically in advance of the thyroid, have an epithelial structure which somewhat resembles the suprarenal, and removal in the hands of most observers gives rise to definite severe symptoms suggest that they should be regarded as an independent essential gland. They may have some specific function in relation to the thyroid and its secretion. If it should be shown that pathological changes in the parathyroid are usual in death from Graves's disease, it would be important in reference to the acute toxic symptoms.

Dr. Norman Moore delivered his first FitzPatrick Lecture at the Royal College of Physicians on Tuesday afternoon. He took for his subject John Mirfield and Medical Study in London during the Middle Ages. Johannes de Mirfield, a contemporary of Chaucer and Bede, was described as laborious and high-minded, anxious to do all he could for his patients, and to instruct others. John de Paris wrote of him as an elegant scholar. He began study at Oxford when about 16 years old, probably went subsequently to Paris and Montpelier. Later he represented St. Bartholomew's Convent at inquests, and eventually became one of the Canons Regular. His principal work "Breviarum Bartholomei" treated of various diseases and injuries. He regarded leprosy as incurable and thought that bad seasons when crops were blighted and birds deserted their nests were conducive to epidemics and plague. He thought sea air injurious, and parts far from the coast best. He advised smelling of musk and aloes in cold weather as preservatives. In hot seasons he prescribed oils of sandalwood and roses, camphor, citric acid, and sour milk. Sweets made

with honey he disapproved, and advised fowls and partridges to be eaten with lettuces and vinegar. He recommended small quantities of warm new bread (rye or barley) and in default of it toast. He condemned gluttony in vigorous terms, counseled temperance in all things, and favored gymnastics with ropes fixed to the ceiling.

A comparative study of outbreaks of typhoid fever formed the subject of an address by Dr. Christopher Childs before the Medical Officers of Health last Friday.

He submitted as a conclusion that a community may use a grossly polluted water supply for a long time with impunity until by some combination of circumstances, little known, specific germs are introduced under favorable conditions for infection, and an explosive outbreak follows. He advocated exhaustive investigations, not merely into the primary cause of an epidemic but into the origin and relations of the cases by a specially trained staff of experts. Bacteriologist, chemist, and sanitary inspector, organized by an epidemiologist of high repute should form a section of the staff. In ordinary times this staff should assist in systematically investigating and stamping out endemic typhoid wherever it prevailed, and in an epidemic it should on short notice, if requested, visit the locality and assist the health officer.

Mr. Muirhead Little has reprinted from the Medical Society's Transactions his case of traumatic displacement of the lower epiphysis of the femur backwards, with an additional note. From this it appears that the fortunate youth can do everything he used to do before the accident. But there is some hallux rigidus on the opposite side which he thinks he hurt at the time of the accident. Mr. Little advises the routine use of the *x*-rays in such injuries to afford the opportunity of immediate proper treatment.

Professor Sims Woodhead has issued, by request, a weighty appeal to the medical profession on the objects of the British Medical Temperance Association of which he is the able and energetic president. In the address he says we doctors have a duty as regards the physique of the nation, and though we cannot give a man brains we can advise him how to give such as he has the best possible chance and can tell him that a brain, however weak, will work better without alcohol, and, however strong, will derive no benefit from its use.

## Progress of Medical Science.

*Boston Medical and Surgical Journal, November* 30, 1905.

**A Case of Diabetic Coma with Recovery Under Alkaline Treatment.**—The patient of G. N. Sears was a boy of thirteen years with the usual diabetic symptoms. When seen by the author he presented the usual comatose conditions incident to his disease. His breath smelled so strongly of acetone that the odor could be detected outside the door of his room. Urine in the first twenty-four hours after admission amounted to 156 ounces and contained over five per cent. of sugar. He was given stimulants, and eight ounces of sterile salt solution containing bicarbonate of sodium almost to the saturating point was injected under each breast. A teaspoonful of bicarbonate was dissolved in a glass of water which was given up to the limits of the patient's capacity. Large quantities of this solution were taken. His stupor rapidly decreased, but he remained drowsy for several days. Convalescence was interrupted by anemic convulsions, but the patient finally weathered the storm. In spite of large doses of alkali the urine remained persistently acid throughout. Sugar continued in the urine in varying amount. Suppuration occurred at the site of the hypodermic injections, and healing was slow. The author has collected a series of sixteen cases in which recovery from diabetic coma has been obtained and in which alkalies and various other remedies have been employed. Alkalies seem to have yielded the best results; generally the bicarbonate has been used. The intravenous route is undoubtedly the safest, and the stimulant effect may be of great advantage.

**Rupture of the Intestine.**—Nineteen cases of this class of injury are reported by F. B. Lund, they all having occurred at the Boston City Hospital. He thinks that rupture of the intestine from accident is caused by the catching of the bowel between the body causing the blow on the abdomen and one of the bony structures forming its posterior wall. The abdomen must be, as it were, taken unawares, delivered a rapid, violent blow before the muscles have time to contract, and the intestine compressed between the impinging body in front and the vertebræ or pelvic bones behind. There is no question but that the actual pinching of the intestine between the body which causes the blow and the bone may rupture it. There is also the probability that the catching of a distended coil of the intestine between the impinging body on the outside and the vertebræ or pelvic bones behind may suddenly cause the gas in that coil to burst out through the intestinal wall, thus rupturing the intestine in another way. Of the nineteen cases reported, fifteen were operated; in four the diagnosis was not made. In one there was no history of an injury, but autopsy showed that such an injury must have occurred. Of the fifteen mentioned seven recovered and eight died. All that recovered were operated on within fifteen hours of their respective injuries. The author's experience has been that the rupture is usually found directly under the spot where the blow was received. At this point there is an abdominal contusion and possibly a hematoma. The author contends that if there is a slight contusion to indicate where the blow was received, we should incise over the spot instead of in the median line. Blows below the umbilicus are, in the light of collective experience, more liable to rupture the bowel because the bony pelvis and spine offer counterpoints for compression.

*New York Medical Journal, December* 2, 1905.

**Sarcoma of the Undescended Testes.**—The patient of J. A. Wyeth was a man of thirty years. His left testis had never been felt on the inguinal canal, while the right had descended a short distance and had been complicated with an indirect inguinal hernia. A few days after marriage he was seized with a severe pain, accompanied by a swelling in the right inguinal region. The swelling was about the size of a hen's egg, was located in or anterior to the internal abdominal ring, and was tender to pressure. It was accompanied by a slight elevation of temperature which lasted for two or three days. Cold applications, with rest in the recumbent posture were prescribed, pain was relieved, and no further trouble was experienced until some four months later, when a similar attack came on with deterioration of the general health but without any distinct cachexia or other evidence of malignant neoplasm except the presence of the tumor occupying in part the pelvis and the right side of the lower abdominal cavity. Wyeth was convinced that the tumor was in the undescended testicle of that side, and performed a laparotomy for its removal. Upon opening the peritoneal cavity a mass which was oval in shape was encountered and easily brought up through the incision. Strong catgut was tied around the spermatic cord, which was divided close to the ligature. Further exploration revealed the presence of a second mass of the same general shape, occupying the floor of the pelvis upon the left side, resting upon the sigmoid flexure of the colon. This was removed in the same way. The covering of each tumor was white and smooth and was composed of the tunica albuginea. Examination showed both masses to be large round-celled sarcoma. Four months after the operation the patient was in the best of health.

**A Case of Acute Lymphatic Leukemia, with Consideration of the Pathology.**—The case is reported in detail by W. Mendelson and F. E. Sondern, their patient being a woman of thirty-five years, first seen by them sixteen days before death. Notable symptoms were swollen cervical lymph nodes, swollen tonsils, enlarged spleen, swollen gums, slightly enlarged liver, and buccal hemorrhages. Prostration was very marked, fever was irregular, pulse was rapid, but the respiration was not notably affected. The blood findings are given in full. The author's note that observation of such a case convinces them that some overpowering poison lies at the bottom of this malady. What it is we have as yet no means of knowing. Light on this point can come only from increased knowledge as to the histogenesis of the blood and the interactions which occur between the different bodily organs. With our present knowledge the most one can do is to ameliorate the sufferings of the patient by anodynes and meet the various indications as they arise. In this particular instance arsenic and bone marrow were given, but without appreciable effect. As to diagnosis, we must rule out typhoid, scurvy, the severe forms of purpura, and the morbus maculosus of Werlhof. Our decision must hang on the differential blood count. In chronic lymphatic leukemia the appearances of the blood are similar to those of the acute form, but the clinical history easily differentiates the two diseases, aside from the fact that in the chronic form the small lymphocytes predominate, while in the acute the large form is the more abundant.

**The Diagnostic Significance of Headache in Diseases of the Ear, Nose, and Throat.**—This subject is discussed by S. J. Kopetsky. Severe temporo-occipital headache may be due not only to acute middle-ear disease but also to chronic affections of this kind. Some ear cases cause reflex pain, appearing frequently as migraine. Nasal cases may be due to pressure on the lymph channels of the nasal mucosa, connecting as they do with the subdural lymph spaces and to a secondary interference with the removal of certain products of tissue metabolism from definite areas of brain tissue. Pathological conditions of the teeth may be expressed in pain in different regions of the face and head. Tendency to headaches occurs in

general hyperesthesia of the nasal mucosa. Inflammation of the inferior turbinate may cause unilateral headache. Sinus disease may cause a typical hemicrania. The pain from this general cause may be at times neuralgic or again diffuse. The former occurs for the most part in acute exacerbations of chronic sinusitis or in acute sinusitis. It often comes on daily at the same hour, but no cause for this periodicity has yet been discovered. The diffuse pains occur mostly in chronic cases. There is no reliable scheme for localization of pain for the respective sinuses. All such schedules are of relative value only. The author reproduces two schematic drawings showing regions of greatest intensity of pain in headaches due to ear, nose, and throat diseases, and in general and nervous affections.

*Medical News, December 2, 1905.*

**Etiology, Gross Pathology, Symptoms, and Surgical Treatment of Pyosalpinx.**—J. E. Carmaday gives a general description of this malady and summarizes the features of his own cases, thirty-eight operations with no deaths. He notes that so far as symptoms are concerned, chill, fever, and sweating run riot. In the acute stages the general systemic disturbances are pronounced. Nagging pain and general malnutrition are characteristic features of the chronic types. A careful study of symptoms makes diagnosis easy. The importance of gonorrhea as an etiological factor is due to the great frequency of that disease and to the rarity of cures in the male. The protective conservation of plastic peritonitis and the systemic and generally depressing effects of the disease are marked features. While complete enucleation and vaginal drainage are not by any means advocated as routine measures, the final results of those procedures are excellent, there is seldom a recurrence of the trouble, and if the work is carefully and skillfully done the mortality is low.

**Headache.**—J. N. Upshur calls attention to the headache "habit" and to the fact that large amounts of nostrums are sold to its victims. Many persons gradually become victims of chronic poisoning from the coal tar products which form the basis of all these remedies. He then notes the features characteristic of headache from some of the more common causes. Thus the headache from eye strain is situated over the brow and is persistent, extending in aggravated cases to the top of the head. Proper glasses continually worn give relief. The headache from gastric disturbances is diffused over the cranial vault, being most intense over the brow, gives a sense of tension and causes a distressing throbbing. Dizziness may result and there may be acid eructations. An emetic and free purgation relieve all symptoms. Renal headache presents a dull feeling over the entire cranium with more or less tendency to drowsiness, after scanty urine. Indications are plain. In acute lithemic states the pain is located in the temporal region, more commonly the left, the eyeball is sore to the touch and on movement in the orbit. The indications for treatment are dietetic and hygienic. Reflex headache from uterine and ovarian diseases is very common. It comes on during the latter part of a period or after the flow has stopped. The location of this form is in the occiput and down the back of the neck. The clavus hystericus located in the parietal region and more often on the left side is one of the intractable forms of headache. The area of pain is limited. Relief comes with the cure of the local uterine condition to which the pain is due. The climacteric is often characterized by a sense of fullness, tension, sense of weight on the cranial vault, and a condition of unusual nervous irritability. Headache from various blood conditions is very common. The outcry of the nervous system for more nutrition in cases of anemia causes pain in the head, persistent but not intense, extending all over the cranium, and disappearing finally when the condition of the blood is improved. The specific headache of syphilis is intense, boring in character, and nocturnal in period of occurrence; the history of syphilis aids materially the diagnosis. It may be due to bone caries, or the development of gummata; in the former the boring character of the pain points to the bone involvement; in the latter, when they have sufficiently matured, we have evidence of irregular paresis.

**Studies in Agglutination in Tuberculosis.**—From a limited experience with this reaction as a diagnostic agent, M. P. Ravenel and H. R. M. Landis do not believe that it is available as they obtained it in healthy individuals. Their phthisical cases included some treated with maraglianos serum, some advanced cases and some ordinary sanatorium patients. Their general conclusions are: (1) That the agglutination test is not available for diagnostic purposes. (2) The more advanced the disease the lower is the agglutinating power. (3) A low agglutination is of unfavorable prognostic significance. (4) That cases under favorable conditions, as at a sanatorium, have the agglutinating power distinctly increased.

*American Medicine, December 2, 1905.*

**Results of the Open-Air Treatment of Surgical Tuberculosis.**—W. S. Halstead reports a number of cases illustrative of the splendid results which can be obtained by the continuous out-of-door treatment in cases of surgical tuberculosis. Dr. Halstead is convinced that in these cases recovery will occur if the patients give a fair trial to the open-air treatment. He has the greatest confidence in the efficacy of massage in cases of surgical tuberculosis, but advises against over-feeding. Tuberculin, which for nearly fourteen years has been the main reliance for diagnosis, has never been of assistance in deciding when to discontinue fixation and to permit use of the affected joint. A definite reaction would probably be obtained to-day in all the "cured" cases. In no instance has there been failure to get this reaction when crutches were about to be discarded, and in two individuals it was prompter on release from the treatment than at its institution.

**Action of the Rontgen Rays Upon the Blood—An Experimental Study.**—Roger S. Morris studied the more immediate effects of moderately long exposures (three to five hours) to the Röntgen rays upon the blood of rabbits and rats. After reviewing the work of previous experimenters and detailing his own results, he arrives at the following conclusions: 1. The Röntgen rays cause a marked diminution in the absolute number of leucocytes in the peripheral circulation. 2. Preceding the leucopenia there may be a moderate rise in the number of leucocytes eight to twelve hours after the exposure, the increase being due largely to the greater number of polynuclears. 3. The lymphocytes are especially susceptible to the action of the rays. 4. Alterations in the histologic characters of the lymphocytes and polynuclear amphophiles may be found in the rabbit, similar to those described in the lymphoid tissue and bone marrow. 5. The harder the tube the more pronounced the changes produced. 6. No changes in the red blood cells or hemoglobin take place within the first few hours following moderately long exposures.

**Speech Training as a Factor in the Development of the Feeble Minded.**—Hudson-Makuen says defective speech is both a physical and a mental sign of feeble-mindedness, but it is by no means a pathognomonic sign, and it may be a cause and not a result of feeble-mindedness. Reference is made to the case of a boy who was thought to be feeble-minded, and who is now a successful business man, as a result of the removal of some mechanical obstructions to the normal development of the organs of speech and the correction by training of the faulty mental and speech habit. A child's educability depends more than anything else upon his desire to be educated. The desire to speak is inherent in every normal person, and if this desire is not gratified the desire to be educated will be diminished or blunted. Reports are given of five cases illustrating the difficulties of diagnosis and prognosis.

**Aseptic Management of the Umbilical Cord.**—J. Thompson Schell advises the following method for aseptic management of the umbilical cord: As soon as the child is born the umbilical cord is clamped with a hemostat about three inches from its abdominal attachment; another hemostat is then placed a short distance from the first one toward the placental end of the cord, and the cord is then cut between. The cord and abdominal wall immediately surrounding it are carefully washed in 1 to 4,000 mercuric chlorid solution. The hemostat is then grasped in the left hand, and a pair of scissors in the right hand follows the skin amniotic junction until this is severed completely in its entire circumference. Care must be taken not to cut too deeply, as the vessels of the cord are usually very close to the amniotic covering. So soon as the vessels have been exposed, the amniotic covering and the Wharton's jelly is stripped away in a direction from the abdominal walls and a ligature consisting of a piece of very fine (No. 0) sterile catgut is then thrown around the vessels, and the cord is severed close to the ligature. The stump is washed in mercuric chlorid solution, dried with a piece of sterile gauze, and dusted with any good antiseptic dusting powder. The baby should not be put in the tub for about a week, but should be given a lap bath; the stump must be washed frequently in a boric acid solution, and a small amount of dusting powder used with the usual sterile pad and the abdominal bandage.

*Journal of the American Medical Association, December 2, 1905*

**Pelvic Measurements in Women.**—Effa V. Davis analyzes and discusses the pelvic measurements of 150 women, 105 American and 45 foreign born. Over 82 per cent. were normal in their measurements, and somewhat over 17 per cent. (26) were deformed. Her general conclusions are: "Deformity occurs often enough to make pelvimetry a practical part of the examination

of pregnant women. Generally contracted pelves form by far the most common deformity in American women, though the rachitic pelvis is often present in those who have been artificially or imperfectly breast fed in infancy. Inebriety in the parents is the most constant element toward degenerate types in the deformities studied. The size of the infant can be regulated by diet and exercise if this be carried out strictly for a proper time during the last three or four months of pregnancy."

**The Non-Insane Phychoneuroses.**—J. Punton proposes the name "psychosomatasthenia" for a large class of morbid mental conditions, including certain hysteric, neurasthenic, and various other neurotic manifestations, which, often occurring after exhausting bodily ailments, fall under the care and observation of the general practitioner rather than that of the specialist, and the importance of which is liable to be misunderstood. He considers these as the forerunners of insanity, differing only in degree. Their fundamental nature he considers to be the same, a pathological lack of inhibitory control of the higher mental directive forces, with consequent nutritional cellular instinctive and physical defects, which seriously mar the power of the will, weaken the judgment and intellect, as well as excite or depress the emotional attributes in all degrees of intensity." Their causes are similar, being both congenital and acquired, while heredity, stress, and toxicity are the chief factors of each. The psychopathic manifestations dominate, direct the prognosis, and most urgently call for treatment. They are curable in their incipiency, but become incurable when neglected.

**Hypospadias.**—J. Coplin Stinson describes his method of operating for hypospadias anterior to the scrotum in the following steps: First, he performs an external perineal urethrotomy and inserts a large tube into the bladder so that all the urine will be drained away, permitting the later plastic operations to heal primarily. Next he corrects the incurvation by dissecting up the urethra and dividing all constricting fibrous bands by transverse incisions so as thoroughly to straighten the organ. The third step is to form a new urethra by taking flaps from the mucous membrane and submucous tissues of the glands, and if necessary from the skin and subcutaneous tissues also. To cover the raw surfaces thus left on the glands and body, the hood is utilized. Lastly, the hump and transverse constriction on the upper surface of the body is corrected by making an inch long incision backward through the skin and subcutaneous tissues in the median line. This incision is at right angles to the transverse one made in separating the hood, and is made long enough so that when its angle is dissected it can be drawn forward and sutured in the same line and continuous with the stitching of the preputial or transverse incision. This eliminates the convexity by diminishing the anteroposterior measurement of the penis and overcomes the existing lateral constriction in this region by increasing the transverse measurement to the normal condition. Each of these steps is described in detail, and the advantages claimed are: the surgery is done at one sitting, and takes but a short time, healing is durable in two to four weeks, the new canal retains its normal caliber and its coverings remain in their new positions. The preliminary urethrotomy and bladder drainage allow the plastic surgery to heal without the least trouble, and the results, Stinson claims, are better than those of any operation hitherto described. The deeper structures are sutured separately and accurately with buried absorbable sutures so as to get perfect union. Sterilized catgut is used for the buried sutures. A short account is given of the first operation thus performed and each step is illustrated.

**Cholesterin Stones in Brain and Cord.**—E. E. Southard reports an interesting case of a man aged fifty-six, suffering from general arteriosclerosis and cardiac disease without presenting during life any symptoms directly referable to the nervous system Death occurred unexpectedly after an apparent slight improvement in his cardiac symptoms. The autopsy revealed small masses of pure, or almost pure, cholesterin crystals in several parts of the cortical and central ganglionic gray matter and in the white matter of the cord. The largest of these, two centimeters in diameter, was found in the middle of the left lenticular nucleus and one or two others of considerable size were found in the gray matter of the temporosphenoidal and frontal convolutions. The deposits in the cord were not so obvious, attention was called to them by the findings in the brain. The masses were enclosed in thin capsules, due to fibrillary overgrowth of neuroglia. The author remarks that the case can hardly be unique and that a more careful examination of the spinal cord may bring out in other cases similar miliary or larger glioses in which the cholesterin may have been dissolved away, as seems to have been the case in some of these. The relation of cholesterin to miliary glioses in the spinal cord may readily escape attention.

**Blackwater Fever.**—F. C. Wellman remarks on a case which he reports, of fatal blackwater fever supervening on amebic dysentery and presenting malarial parasites in the blood, that it is the thirty-fourth case he has studied, five of them fatal, and the only one in which death occurred in a first attack. He thinks the dysentery brought about an explosion of latent malaria, and the two conditions combined were able to produce the physiological depression and hypotonicity of the blood that invited the intercurrent hemiglobinuria. He believes that there is a relation between blackwater fever and malaria, but that its precise nature has not yet been ascertained. In southern Angola, as he has previously shown, the geographical distribution of *Myzomia funesta*, Giles (the principal carrier of *Hæmamœba præcox* in West Africa), severe malaria and hemiglobinuric fever closely coincide.

**Climatic Treatment of Circulatory Disease.**—Louis Faugères Bishop finds the climate of the lower Maine coast especially beneficial in cases of secondary low arterial tension, even when accompanied by such accidents as hemiplegia. The climate of the lower Maine coast, he says, has a remarkable combination of dryness with sea air and low temperature in summer. It is beneficial in all cases of physical exhaustion and to patients who require a restoration of vitality after disease, but not to those suffering from purely functional nervous affections requiring rest. It is too stimulating for such cases. Still patients with a tendency to melancholia and depressed conditions are much improved. The physical effect of the change from the climate of New York to that of the lower Maine coast is remarkable, and many persons find a stay of over six weeks too stimulating, and therefore go inland for a few weeks during the middle of the season. His observations were made at York. Three striking cases of benefit from the climate in the conditions mentioned are briefly reported.

*Berliner klinische Wochenschrift, November 6 and 13, 1905.*

**The Relative Small Size of the Heart, and the Predisposition to Tuberculosis in Excessive Growth.**—Bouchard studied the relations of bodily size and the dimensions of the heart in a large number of cases of various diseases. He also compared the average size of the heart as determined in healthy individuals and those suffering from pulmonary tuberculosis, taking into consideration in each case the individual's height, thoracic measurements, weight, etc. As the result of these investigations he arrives at the conclusion that small size of the heart is particularly characteristic of tuberculosis, excepting only certain types of chlorosis. In some pathological states the heart may have normal dimensions, in all others excepting only tuberculosis it is enlarged either through hypertrophy or dilatation. Relative small size of the heart may be caused through errors of development such as the excessive growth that follows typhoid fever in young persons. In them the bones and muscles grow and attain a size out of proportion to the viscera, which do not take part in the sudden development. The heart and blood vessels therefore remain inadequate to subserve the bodily functions, so that the individual is pale, easily out of breath, prone to fatigue and with slight resistance to disease. Such persons easily succumb to a tuberculous infection, which in others might have been recovered from.

**Bilateral Empyema.**—Hellin states that this affection is not as rare as is usually supposed, and gives the outlines of 114 cases that he has discovered in the literature. The statistics show that children under ten years of age are most often affected, and 66.6 per cent. are males, as opposed to 33.4 per cent. of females. No notable difference existed in regard to the side which was first affected. The average time of illness was sixty-four days, though extremes of sixteen days and twenty-two months were noted. The mortality was 30.1 per cent., whereas that of unilateral empyema is given as 22.4 per cent. In reality the difference in mortality is greater than it appears, for usually only the cured cases of double empyema are reported. Taking the figures of the four authors having the largest number of cases, twenty-nine deaths are noted in thirty-seven cases, a mortality of 78.4 per cent. A double pneumonia often preceded the lesion. The time of opening the second pleura varied up to the one hundred and fiftieth day, and several cases of spontaneous absorption of the exudate have been reported. A double operation, consisting of aspiration or resection alone or the two combined was performed in a number of cases with excellent results. Both local and general anesthesia were employed, without perceptible difference of result. The shock of opening the second pleura is often less than that of opening the first, when both are done at

one sitting. The author concludes that bilateral empyema is commoner than is generally supposed, and the involvement of the second side is often overlooked. He also describes a case of his own in which recovery resulted.

**Experimental Observations on Cancer.**—Bashford, Murray, and Cramer in the last two and a half years have carried out 10,000 transplantations of malignant growths. The material used was obtained from twelve spontaneous and four transplanted mouse carcinomata, as well as from fourteen different spontaneous malignant growths from rats, dogs, cats, and horses. Although over nine hundred attempts with the other growths were made it was found that only carcinoma from mice was transmissible. Quite a number of instances of transplantation of malignant tumors from other animals have been reported in the literature, but the authors believe that in view of recent developments these observations cannot be regarded as trustworthy. Two sources of error are noted. One is that most observers have been unaware of the fact that the age of the animal is without effect on transplantation, so that the conditions favoring persistence of a growth must be distinguished from those necessary for its spontaneous appearance. Most workers have taken old animals for their experiments, with the idea of providing a more favorable culture ground, with the result that they have run the risk of being led astray by the spontaneous appearance of tumors in the animals which have simulated successful inoculations. Another source of error is the fact that in some animals growths occur that are infectious in nature and closely simulate malignant tumors, but are not really so. One of the observations made by the authors was that the mice tumors exhibited fluctuations in their transplantability and rapidity of growth, and they succeeded in plotting a curve for these factors which they found reached its maximum about once in two hundred days.

**The True Double Apex Beat.**—Doll believes that the phenomenon of double apex beat may occur under the most varied conditions, and be the result of a number of causes. Its presence, therefore, does not permit of generalizations, but is of significance only when judged in connection with the other attendant features of the cardiac picture. He also thinks that the condition is commoner than is generally supposed, and that it will be oftener detected if one makes a practice of simultaneously palpating the apex beat and radial pulse. Two cases are first described in which the phenomenon appeared temporarily in hearts that were organically sound and did not exhibit any subsequent evidence of damage. In another case the onset of double apex beat after overexertion was the first indication of a cardiac degeneration which in a comparatively short time led to the death of the sixteen-year-old patient. The author takes the stand that one of the causes of this form of disturbance of cardiac rhythm is some irritation of the left auriculo-ventricular junction. Strong evidence in favor of this view was afforded by observations on a classical case studied in 1882 in one of the Munich clinics. This woman's heart had been denuded in the course of an operation for a chondroma of the ribs, and after the skin had healed over the wound she was made the subject of numerous investigations on the physiology of the heart. Among other things it was noted that pressure over the left auriculo-ventricular septum caused a double systole.

*Münchener medizinische Wochenschrift, November 7 and 14, 1905.*

**A Case of Double Sepsis.**—Staubli in studying this case discovered what he considers a hitherto undescribed bacillus, which is, he believes, the smallest yet cultivated. He suggests that its discovery proves the possibility that various diseases which are now considered non-bacterial may be caused by similar organisms which have so far eluded observation by their minuteness and difficulty of cultivation. The patient was a man of twenty-six years who was supposed to have typhoid fever, and for a time he gave a Widal reaction at a dilution of 1 to 200. After about three weeks of illness, during which the picture of extreme sepsis was presented, the patient died, with a hemoglobin content of 20 per cent., 1,200,000 red cells and 13,000 leucocytes. Blood cultures showed the *Streptococcus longus*, and in addition a tiny gram-negative bacillus measuring only 0.4 μ., growing on ordinary media at first only in the depths, afterwards also on the surface, but always only in small numbers. Its first appearance in the plates was so much delayed that the author says that the plates of a blood culture should always be watched during at least six days, even if one germ has already been identified. The case also points out the unreliability of the Widal reaction, which the author considers is to be regarded only as a symptom and not as pathognomonic. The patient exhibited ten days before his death retinal hemorrhages which were apparently due to toxic degeneration of the walls of the blood vessels. The author believes that the unknown germ was the cause of the infection and that the streptococcus was a secondary commensal.

**Cytorrhyctes Luis.**—Jancke examined sixteen fresh placentas for the presence of the cytorrhyctes of Siegel. Ten of the cases were syphilitic and the others came from healthy women. The organism was found in every one of the ten syphilitic placentas and not at all in the others. The material was studied in the living condition, in spreads, and in sections, most of the examinations being on the latter sort of preparations. Apochromatic lenses of especially high quality, yielding a magnification of 2,250 diameters, were used. The author describes the precautions he took to eliminate all possible sources of error from artefacts, and states that it was hardly possible to differentiate the organisms with the ordinary immersion lenses. The size, shape, refractive power, mode of motion, and nature of the nuclei are pathognomonic of the cytorrhyctes.

**Suture of the Lung.**—Tiegel made a series of experiments on dogs in order to evolve if possible a method of suture which should prove practical for use in wounds of the lung or other friable organs, such as the liver, spleen, or heart. After numerous trials he hit upon a plan which appears to fulfill the two chief requisites of being firm enough to avoid secondary hemorrhage and air tight so as not to give rise to pneumothorax. Ordinary interrupted sutures are apt to be deficient in both respects, because the lung tissue is so friable, but if the sutures are passed around two deep sutures of some stiff material running on either side of the wound at right angles to the interrupted sutures, the latter may be pulled quite tight and will furnish efficient closure of the wound. Silk worm gut, catgut and wire were employed for the supporting sutures, but were found open to the objection of causing large stitch canals in the tissue, owing to the fact that a needle was necessary for their introduction. A perfectly satisfactory material for the purpose was finally found in magnesium wire. Arrows of this could be pushed through the lung without the aid of a needle, and wounded lungs sutured in this way could be inflated up to the normal distention without any leakage of air. It was found advantageous to saturate the suture material with ferric chloride solution just before use. The method would find its greatest applicability in cases in which the Sauerbruch pneumatic cabinet was used, but would also be of service in ordinary operating.

**The Ferments of the Placenta.**—Bergell and Liepmann investigated the ferment content of the human placenta. For this purpose they took fresh portions of the tissue, put it through a chopping machine, and expressed the juice, in some instances after a preliminary trituration with sand, by means of a Buchner's press. The fluid obtained was precipitated with alcohol, the resulting powder purified by washing with alcohol and ether, and dried. It was found that a diastatic ferment of considerable strength was present, though the iodine reaction did not altogether disappear. There was some evidence of a milk sugar splitting ferment, but there was no pronounced action resembling that of lactase, and it was certain that no saccharifying ferment was present. Evidence of glycolytic action could be demonstrated, and it was discovered that large quantities of an albumen splitting ferment existed in the placenta, as tyrosin was obtained from pepton solutions by the agency of the placental preparation. Ferments splitting fat or lecithin were not found. Other methods of investigation gave corresponding results. The authors conclude that there are contained in the placenta active ferment-like substances, which produce catalysis, but that synthetic process also probably takes place. These changes deserve closer investigation both as regards the physiology of the fetus, and maternal pathology.

**The Scopolamine-Morphine-Chloroform Narcosis.**—Roith reviews the literature of this subject and says that he believes about 4,000 cases of the use of this form of anesthesia have now been reported. Of the eighteen deaths noted he believes the majority were either wrongly attributed to the anesthetic combination or else were due to the use of too large doses. He advises the administration of either .5 mg. of hyoscine and 1. to 1.5 cgms. of morphine one-half to one hour before the operation, or .3 to .4 mg. of hyoscine and 1 mg. of morphine one and one-half and one-half an hour before. The action of the small divided doses is rather better than that of a single larger quantity. The patient's ears should be plugged with cotton and he should be disturbed as little as possible before the administration of the ether or chloroform is begun. The amount of chloroform needed is greatly reduced, the effect on ether being less marked, but in either case the author considers that the chief advantages of the method consist in the fact that the induction of anesthesia is facilitated and that the post-anesthetic sequelæ are nearly always absent. When carried out according to the method described there is

no risk; it is just as dependable as any other plan, but like all similar procedures it does not invariably yield ideal results. The principle is one that requires no practice to apply, and every one may obtain good results with it. The addition of the hyoscine is a distinct advantage, for the effect is much better if it is used than if the morphine be given alone.

*Deutsche medizinische Wochenschrift, November 9 and 16, 1905.*

**Observations on the Bactericidal Power of Serums.**—Bail says that it is generally accepted that in the process of bacteriolysis two especially developed substances take part, the thermostabile immune body, and the thermolabile complement. The first combines with the bacterial cells and then renders it possible for the second factor, the really active agent, to unfold its power. As doubts have been expressed as to the accuracy of this view, especially as expressed in the form given to it by Ehrlich, the author investigated the subject anew. The result of his work with cholera vibrios leads him to believe that a somewhat new point of view must be adopted. Both the theory of Ehrlich and that of Bordet postulate a direct action of the alexin or complement in the process of bacteriolysis, after the heat-resisting portion of the serum has paved the way. This, of course, involves a consumption and ultimate disappearance of the former. The author has found, however, that this disappearance is only apparent and that the alexin is not altered in any appreciable way. Certain phenomena take place which temporarily inhibit its action, but as soon as these are removed, the old properties return. The author's experiment in its simplest form consists in saturating a certain quantity of serum with bacteria, which are then centrifuged off. The serum will then be found inactive, presumably according to the current belief, owing to the consumption of all the immune body and complement, yet that this is not so is shown by the fact that if a fresh amount of immune serum be added the original strength of the serum is restored and may even be heightened.

**The Treatment of the Functional Psychoses.**—E. Mendel says that it is the duty of physicians to carry out the prophylaxis of mental diseases by restricting the marriage of those whose heredity in this respect is bad. Care must be taken, however, to analyze the conditions with sufficient care to determine the fact that the congenital taint really is present, and that outbreaks occurring in some distant member of the family were not dependent on ulterior causes. No person of unsound mentality should even be allowed to marry, and caution is necessary in permitting matrimony to one who was formerly a patient of this sort. The prophylaxis also involves particular care of the children of mentally weak parents, and in their education and choice of a calling reference must be made to their inherited tendency. If the existence of mental disease has been established the question of confining the patient must be considered. If the patient is violent, threatens his own life or that of his attendants, refuses nourishment, or commits acts prejudicial to the interests of others he must be confined, as also in many cases this measure is necessary for his better treatment. In carrying out the removal it is better to tell the patient he is to be taken to a hospital, but the necessary assistance should be at hand in case he should offer resistance, for it is better to act at once, using force if necessary, rather than to postpone the attempt and leave the patient in a state of dread and anxiety. Deceit is only rarely necessary, and if resorted to, those who are to have the future care of the patient should take no part in it. In carrying out plans of treatment one should avoid the error of attempting to elaborate a program, for many of the psychoses terminate in spontaneous recovery, and their course is but little affected by therapeutic measures.

**Cystoscopy and Lithotripsy in Different Positions.**—Ringleb recounts various conditions such as sacculation of the bladder, prostatic hypertrophy, intravesical bleeding, etc., which often render it difficult to obtain the results for which some procedure such as cystoscopy or lithotripsy is being attempted. The bottom of the bladder is frequently almost inaccessible to inspection under ordinary conditions, yet by suitably changing the position of the patient's body a great deal can be accomplished. It is always an advantage to have the patient rise from a reclining to a sitting position after the instrument is in place, and frequently by turning him from side to side, elevating the pelvis, etc., better views may be obtained, especially if there be a stone present which must be caused to roll to one side. The principal innovation introduced by the author is, however, his recommendation to conduct the examination with the patient lying on the abdomen. This is made possible by the use of a special table constructed so as to allow the genitals to hang down through a rounded gap at the end of the table, while the knees are supported in adjustable holders. The act of catheterization in this position is naturally difficult, but the author describes it in detail and states that the advantages secured by the maneuver in certain special cases more than compensate for the disadvantages.

**Acute Poisoning of the Oral Mucosa by Tincture of Iodine.**—Witzel who has already reported one death from this cause reiterates his warning against the local application of tincture of iodine as a remedy for toothache. There are certain cases in which the dilatation of the vessels of the gum acts beneficially in causing a corresponding depletion of the congested pulpa, but the haphazard recommendation to the laity to resort to this treatment is very dangerous. A case in point is described, in which the family physician gave this advice to a woman suffering from toothache and told her to consult a dentist. The iodine did good at first, so she thought she could complete the cure herself and kept repeating the applications. After three days the mucus membrane became necrotic, filling had to be removed, and finally an alveolar abscess developed, the whole constituting an inflammatory condition of no slight severity.

**Experimental Observations on the Influence of the Emotions on the Secretion of Gastric Juice.**—Bickel first rehearses the results of the classical experiments of Pawlow in feeding a dog with an esophageal fistula, the object of the demonstration being to show that the emotions, *i. e.*, appetite, may produce a great increase in the amount of gastric juice secreted. He then describes the effect produced when a very excitable Pawlow dog was infuriated by being teased with a cat in a cage before or after he had received his apparent meal. If the dog was angered before the stimulus of food was applied practically no gastric juice was secreted; if he was angered after the apparent meal and while the secretion of gastric juice was in full swing, its production was almost completely arrested with great suddenness, and only some time after the animal had become calmer did the secretion once more commence. It was only the quantity of the juice, however, and not its quality that was affected. The author considers this as a valuable demonstration of the fact that one psychical stimulus may entirely neutralize the effect of another.

*French and Italian Journals.*

**Vaginal Cysts.**—Voituriez reports a case of this nature. The patient, a woman twenty-five years old, had given birth three months previously to a well-formed child. The labor was normal. A month later the presence of a small tumor in the vagina was discovered. On inspection it was found that the vulvar orifice was filled up with a rounded swelling. The growth was semi-transparent, of a red color, and the visible part was as large as a nut. The base of the tumor was attached to the anterolateral wall of the vagina. The tumor was sessile. Under general anesthesia the cyst was removed. It proved to be the size of a pigeon's egg. The writer in giving a résumé of the characteristics of such growths states that they are generally found in young women after delivery. They probably develop during pregnancy. However, they have been observed in small children. The cause is generally attributed to the renewal of vital activity in the débris of the Wolffian body. These vaginal cysts are single or multiple. At times they are bilateral. The form is often elongated, accommodating itself to the axis of the vagina; these growths are always behind the vulva but they may project outside. The size varies greatly. There is discomfort in walking, and during labor the vaginal cyst presents an obstacle. There is no real pain except in cases in which the cyst is inflamed and suppurating. Diagnosis is made by direct examination. The patient often believes that she is suffering from prolapsus uteri.—*Revue Française de Médecine et de Chirurgie*, October 30, 1905.

**Pancreatitis in Relation to Mumps.**—M. B. Auché reports two interesting cases of this kind. The first patient was a boy twelve years of age. There was nothing of special interest in either personal or family history. The child contracted mumps during an epidemic of this disease. The pancreatic complication was evident on the fifth day. The patient complained of pains in the epigastric region. These pains were constant and severe, and at times they culminated in paroxysms which caused the child to cry out. Vomiting began about an hour after the pain was felt. The vomitus became bilious in character. The pain was localized between the umbilicus and the xiphoid cartilage, and under the left costal border. The rest of the abdominal cavity was not painful. Pressure in the region of the pain caused it to become very sharp. The stools and urine were normal. In five days the pain had ceased and recovery took place without further incident. This pancreatic complication, according to the writer, generally appears from the third to the sixth day after the beginning of the parotid swelling.

The most important symptom is pain. It manifests itself most often spontaneously. Its beginning is often brusque. Its intensity is variable. Nausea and vomiting are very important symptoms. The occurrence of pancreatitis in relation with mumps appears to be infrequent. The prognosis is favorable. *Journal de Médecine de Bordeaux*, October 29, 1905.

**Pneumonic Pseudo-Appendicitis.**—Méry observed this patient, a child ten years old, which was carried to the hospital with a diagnosis of appendicitis. The child complained of pain at McBurney's point. But this pain increased toward the diaphragm. There was no muscular rigidity, the abdomen being soft. The temperature was higher than that noted in appendicitis. In this case it was from 40° to 41° C. The facies was not typical of any abdominal trouble. On examination the presence of generalized bronchitis and pneumonia were detected. The face was red. When the diagnosis of pneumonia was made the treatment for this disease was instituted and the child soon became convalescent. The writer calls attention to the necessity in such cases of paying careful attention to the leading symptoms. A high fever, absence of muscular rigidity, and a congested facies ought to put the physician on his guard. Careful examination of the lungs will clinch the diagnosis, and the physician will avoid gross errors in the treatment of the case, for there are cases of this nature on record in which operation for appendicitis has been performed.—*Journal des Praticiens*, October 28, 1905.

**The Treatment of Joint Tuberculosis.**—Among the conclusions presented by A. Bier as a result of his experience in this line of work are the following: Articular tuberculosis is an affection essentially curable. Systematic ablation of tuberculous foci is an absurd method of treatment. Treatment of the general condition plays a certain role in the amelioration of the local lesion. Immobilization is one of the best local measures. Iodoform, tuberculin, ignipuncture, and chloride of zinc are useful adjuvants. The method of passive hyperemia by venous constriction is the most efficacious and simple means of conservative treatment. Even in open tuberculous lesions the method of hyperemia should always be tried. The cold abscess should be evacuated by incision, puncture, or aspiration. The following are counterindications to hyperemia: Amyloid degeneration, severe pulmonary tuberculosis, and vicious attitudes which after recovery will give a worse result than resection. Hyperemia allows the ambulatory treatment of patients. The average duration of treatment is less than nine months. The writer has made use of this method for fourteen years.—*Archives Médicales Belges*, October, 1905.

**Clinical and Histological Studies of Endothelioma of the Pleura.**—Giuseppe Siragusa has made an exhaustive study of tumors of the pleura. He states that primary tumors of the pleura are much more frequent than has been supposed. In some cases the tumor is limited to the pleura, in others it is diffused to the lung. The difficulties in diagnosis are not only clinical but anatomical. The best clinical criteria are involvement of the neighboring glands, irregular dilatation of the thorax, narrowed intercostal spaces, and enlarged veins; marked thoracic resistance, boardy resonance, especially on the right; hemorrhagic exudate and presence in it of neoplastic elements; rapid reproduction of the pleural liquid after removal. The most frequent form of tumor is endothelioma, arising from the endothelium of the lymphatic spaces. It is accompanied by small-celled infiltration, new formations of veins, and gives rise to glandular metastases as well as those in other organs.—*Giornale Internazionale delle Scienze Mediche*, October 15, 1905.

**Alterations in the Urine After Operative Traumatisms.**—Guidolerda examined the urine of 265 patients, sick with febrile and afebrile diseases, and subjected to bloodless or bloody operations, either with general or local anesthesia. His purpose was to add to literature a certain number of correct observations of the reaction of the urinary organs in such cases, and to separate as far as possible the results of anesthesia from the other results of operation. A rigorous asepsis excluded post-operative sepsis. The anamnesic and somatic conditions were taken into account, especially the condition of the heart and kidneys, age, nature, and duration of the operation, etc. Kidney diseases were excluded. The urine was examined as to quantity, specific gravity, albumin, reducing power, hematic and biliary pigment, and urobilin. A certain number of cases had the microscopic examination of the sediments made. Two hundred cases were under narcosis by chloroform, and sixty-five cases were operated on under five centigrammes of cocaine hypodermically. In 167 cases of afebrile diseases, after operation there was a diminution of urine secretion, increase of specific gravity, acidity, and pigment. Urobilin was frequently present. In 15 cases there was albuminuria. In 20 cases examined microscopically six showed granular casts and four of them had albumin. In 23 febrile patients, eight albuminous before operation the albumin was increased. The increase of albumin in febrile patients is noteworthy. —*Ospedale Maggiore di Torino 1905*.

**The Antitoxic Power of the Thyroid.**—Daniele Bajardi, in order to demonstrate whether thyroidectomy is sufficient to modify the resistance of animals to experimental intoxications, and whether there is any foundation to the theory that the thyroid exercises a neutralizing function against poisons of both endogenous and exogenous origin, began a series of experiments on animals. He injected toxins into the thyroid substance; injected a mixture of toxins and poisons with thyroid juice; gave contemporaneous injections of toxins and thyroid juice; injected a mixture of toxins and poisons with nucleoisotonics of the thyroid; and lastly, gave injections contemporaneously of toxins and nucleoisotonics of the thyroid in different parts of the body. He concludes that we cannot attribute to the thyroid any antitoxic function for exogenous poisons, whether bacterial or chemical. The hypersecretion of the thyroid in infective diseases is purely reactive.—*Giornale della Regia Accademia di Medicina di Torino*, Vol XL., fasc. 5–6

**Cysts of the Vagina.**—Alessandro Vaccari presents the histories and microscopical examination of four cases of cyst of the vagina, observed by him in order to show that there are reasons for believing that these cysts are not always of embryonal origin. He does not exclude the possibility of the origin of these cysts from embryonal remains, but believes that this is not the usual manner of origin. Much more frequently there is an adhesion of folds of the mucous membrane of the vagina, due to a true pathological process, the result of traumatism or of mechanical agents producing a more or less deep desquamation of epithelium, or to the sinking in and isolation of a portion of the mucosa of the vaginal wall, which, endowed with a certain proliferative activity, goes on growing in the substance of the wall.—*Annali di Ostetricia e Ginecologia*, August, 1905.

**The Genesis of Pulmonary Lesions in the Tuberculous.**—Vallée has recently made a most important communication concerning this subject. He declares that in an animal with discrete tuberculous lesions of the intestine or of the mesentery the predominance of pulmonary lesions does not authorize one to admit that the affection was not contracted through the digestive tract. This opinion which the author already held in 1903, he has confirmed to-day by new experiments on twenty tuberculous calves. Twelve of these animals were infected through the nasopharynx, two by intratracheal inoculation, and the others through the digestive tract or by direct inoculation of a mesenteric ganglion, or of a branch of the mesenteric vein. Of all of these modes of infection, that of the intestine was the one which resulted the most quickly and the most surely in the infection of the ganglia connected with the lungs. The penetration of the intestine by the tubercle bacillus may be effected without producing apparently appreciable lesions of the intestinal mucosa or of the mesenteric ganglia. It must be admitted then at least from the experimental point of view, that the ingestion of tuberculous material plays a most important role in the development of the disease; and that a tuberculous adenopathy may exist without the least lesion of the corresponding viscera. Tracheo-bronchial adenopathy in particular may be due to the direct invasion of the ganglia by the bacillus of Koch. It is not a necessary consequence, at least from the experimental point of view of pulmonary tuberculosis.—*Gazette des Hôpitaux Civils et Militaires*, October 10, 1905.

**Spirochæte Pallida and Syphilitic Infection.**—A. Risso and A. Cipollina draw attention to the spirochete observed in syphilitic cases, a spirillum, very motile, having a length of 4-10, and difficult to stain. The authors have carried out a series of examination in syphilitic cases of different kinds, and especially of the glands. The glandular juice was examined in each patient derived from the inguinal glands, seven observations having been made. Two of them presented typical ulcers and enlargements of the glands, but had not yet had any secondary symptoms. The other five were in the secondary period, and one had already had mercurial treatment. Four other patients had inguinal syphilomata, and one had tertiary manifestations. The spirochetes were found in the glandular juice in five out of seven patients. The examination of various mucous patches showed this typical form of spirochete, as did also a papulohypertrophic condyloma. They were not found in two initial lesions, nor in an ulcerated gumma of the leg, or the fluid from a closed gumma of the forehead. Two facts that have been demonstrated go to show that this germ is the specific cause of syphilis: their presence in the swollen glands of the secondary period, and in the internal organs of infants suffering from hereditary syphilis. At the same time, it has not been demonstrated in the blood in secondary cases. Yet this blood is contagious.—*La Riforma Medica*, August 26, 1905.

# Book Reviews.

Medicine and the Public. By S. Squire Sprigge, M.A., M.D. (Cantab), London: William Heinemann, 1905.

This work was for the most part published in the form of a series of articles in the *Lancet*. As Dr. Sprigge states in a preface to his book, in the first instance the intention has been to place before the medical profession its present position in regard to the general public, more especially with respect to the present conditions of society, and secondly to interest the population at large in the same question. It is pointed out that although the people generally are directly concerned in the quality of their medical service, yet the ordinary individual takes but a languid interest in medical practice, regarding it, except on those occasions when he himself has need of a medical man, as outside his province; and he fails to grasp the undoubted fact that the higher the standard of medical education and training, and consequently the status of the physician, the better must it be for all. Dr. Sprigge contends, and rightly, so we think, that legislation might greatly aid the medical profession, if only the public would take an intelligent interest in the matter and insist upon the right remedies being applied. Of course, the conditions in regard to the medical profession in America are widely different from those in Great Britain. However, they have these points in common, that the public in both countries regards medical practice with apathy, and that until the population at large becomes interested in the subject the scope of medical endeavor and the status of the physician cannot be advanced. Dr. Sprigge (who is an editor of the *Lancet*) strongly insists upon the above points, and as the general tenor of his remarks apply with almost as much force to the situation in America as in Great Britain, his book should amply repay a perusal in this country.

International Clinics. A Quarterly. Edited by A. O. J. Kelly, A.M., M.D., Philadelphia, U. S. A. With the Collaboration of William Osler, M.D., Oxford, and others. Volume II. Fifteenth Series, 1905. Philadelphia and London: J. B. Lippincott Company, 1905.

The contributors, beginning with Bellin, the Paris otologist, and ending with Wilson of the Philadelphia General Hospital, form a list of well-known names. Among the many interesting articles are Acute Nephritis in Children, by Morse; Adrenalin in Pulmonary Hemorrhage, by King; Neurasthenia, by Edes; *X*-ray Treatment of Tinea Tonsurans, by Sabourand; The Plague, by Williamson of India; Enlargements of the Testes and Epididymis, by Eisendrath, etc. The general fields of medicine and surgery are covered by able writers, as usual, but there is missing the abundance of good illustrations of former days.

Currents of High Potential of High and Other Frequencies. By William Benham Snow, M.D., Professor of Electro-Therapeutics and Radiotherapy in the New York School of Physical Therapeutics. New York: Scientific Authors' Publishing Company, 1905.

On running over the pages one is at first struck by the cheap inadequacy of the full-page illustrations. On reading the text, one finds the author a firm believer in his subject and adequately equipped to handle it. The use of the *x*-ray has given a wonderful stimulus to medical electricity in general. The truth about its worth is coming to be known. Too much is apt to be claimed by enthusiasts. The author has given in the main a temperate statement of the methods as they exist from his standpoint. He gives as a synonym of convective discharges the *effleuve* of the French, and throughout the book it is always thus spelled. Scientific accuracy would seem to require that even such details receive attention.

A System of Physiologic Therapeutics. Edited by Solomon Solis-Cohen, A.M., M.D., Professor of Medicine and Therapeutics in the Philadelphia Polyclinic; Lecturer on Clinical Medicine at Jefferson Medical College; Physician to the Philadelphia Hospital, etc. Vol IX. Hydrotherapy, Thermotherapy, Heliotherapy, and Phototherapy. By Dr. Wilhelm Winternitz, Professor of Clinical Medicine in the University of Vienna; assisted by Dr. Alois Strasser and Dr. B. Bunbaum, and Balneology and Crounotherapy, by Dr. E. Heinrich Kisch, Professor in the University of Prague. Vol X. Pneumotherapy, including Aërotherapy and Inhalation Methods. By Dr. Paul Louis Tissier. Philadelphia: P. Blakiston's Son & Company, 1904.

The information derived from the title pages of these important volumes scarcely gives an adequate idea of the scope of the work and the ground covered. There are, besides the various chapters on technique and methods in the use of water externally and internally, supplemental chapters on saline infusions and irrigations by Harvey Cushing; balneotherapeutic indications for the individual forms of chronic disease as well as the physiological basis of hydrotherapeutic measures in general. The part devoted to the uses of light has been supplemented by chapters on heliotherapy, phototherapy, and thermotherapy by Dr. Kellogg, of Battle Creek, so that we have a volume of over 550 pages, carefully prepared and quite abreast of the times. The translation of Winternitz's work has been done by Augustus Eshner in his characteristic style. While complicated measures requiring special apparatus have been fully considered, simple every-day uses of packs, baths, douches, etc., are by no means neglected, and the home treatment, no less than that of institutions, is presented in a clear way. Crounotherapy will be a new name for most readers, meaning the internal use of mineral waters, or drink cures, as distinguished from balneotherapy or bath cures. Dr. Pearle, of the National Museum, has contributed to the classification of mineral springs, which will make this volume one of useful reference. Air as a therapeutic agent has received too little attention, and the editor has done well to present this subject in its various bearings in an attractive form. Compressed-air baths, the pneumatic chamber, differential pressure measures, respiratory gymnastics, pneumatometry, spirometry, inhalation of vapors, atomization, nebulization, insufflation of powders, and many other chapters go to make up a most instructive book. The general features, illustrations of apparatus, and make-up are in keeping with the previous volumes which have received favorable comment.

Static, High Frequency, Radio-, Photo-, and Radium-therapy. By William Harvey King, M.D., LL.D., Head of Clinic of Physical Therapeutics at the Flower Hospital. New York: Boericke & Runyon, 1905.

This is a small, unpretending volume, dealing with elementary medical electricity, with chapters on the newer forms of radient energy. It is in the main carefully prepared matter, but the repeated use of the term "effleuve," which is neither English nor French, but which is so spelled in a recent work on high frequency would indicate a certain amount of borrowing without full investigation. The illustrations of diseases treated are not convincing. On page 77 is a cut taken from Allen's Phototherapy, but without credit, and erroneously labeled. In the same way the picture of a protecting shield on page 183 has a faulty description. Aside from such evidences of carelessness, the work presents the uses of the various curative forces in a fair, unbiased manner.

Allgemeine Fieberlehre. Von Dr. Eduard Aronsohn. Berlin: August Hirschwald, 1905.

This interesting little work opens with an introduction in which the various "fever theories" are discussed, after which the author considers the pathogenesis and etiology of this condition. The basis of his presentation of the subject rests on experimental observations made some years ago in conjunction with Sachs, as the result of which it was determined that a temporary increase of temperature may be produced in animals by puncture of the corpus striatum. This phenomenon is considered by the author to represent the simplest type of fever, which in the presence of an infection is complicated by the effects of the bacteria and their toxins. Clinically, these simple types of fever are to be found in such cases where the cause is a purely thermogenic one, which involves only the heat center and its tracts. Included in this category are traumatisms, brain tumors, epilepsy, tabes, paralyses, hysteria, etc. In the remaining chapters he considers thermometry, the site and the manner in which fever is produced, the clinical course, and the effect on other body functions. In the concluding chapters he presents in a fairly complete fashion the various methods for treating fever. The book is evidently an attempt to popularize what information is at hand on the subject of body temperature. It is written in an entertaining fashion, but contains many references which defy accepted theories to such an extent that its value as an authoritative work of reference will be lessened thereby.

Cleft Palate and Harelip. By W. Arbuthnot Lane, M.S., F.R.C.S., Surgeon to Guy's Hospital, London. London: The Medical Publishing Company, Limited, 1905.

The operation for cleft palate, known by the writer's name, has been employed by him in several hundred cases, and the publication here reviewed contains a résumé of the various papers written by him on this subject from time to time. After tracing the development of these buccal deformities, he discusses the indications for operation, and claims that the latter should be done as early as possible—if practical, on the day after birth. At this time the tissues are much more vascular and the arch of the palate is still unmodified by the effects of the deformity or the growth of the teeth. There are a number of excellent illustrations.

# Society Reports.

## THE PRACTITIONERS' SOCIETY.

*One Hundred and Ninety-eighth Regular Meeting, Held Friday, November 3, 1905.*

The President, Dr. T. Mitchell Prudden, in the Chair.

**On Certain Forms of Ocular Tuberculosis.**—By Dr. Charles Stedman Bull. (See page 925.)

Dr. W. Gilman Thompson said the only cases of this kind that came under the observation of the general practitioner were those in which the eye lesions were secondary to a meningitis, generally the result of a miliary tuberculosis, and in that connection they were of considerable advantage as an aid to diagnosis.

Dr. Bull said that tuberculosis of the palpebral conjunctiva was usually rapid in its development, especially where the margin of the lid was also involved. *Per contra*, he could recall only three cases which involved the ocular conjunctiva, the lids being free, and in those instances the disease was of very slow growth. They were all unilateral. The only cases that were pretty certain to be bilateral were those of choroidal tuberculosis.

Dr. John Winters Brannan inquired whether local treatment in these cases of tuberculosis was regarded as more important than general hygienic treatment, such as was now so universally recommended in the treatment of pulmonary and other forms of tuberculosis. He stated that at the Sea Breeze Hospital for tuberculous children there was one case that had been there since last autumn. Besides a tuberculous rib, the child had on entrance a tuberculous sinus at the outer angle of the orbit, as well as a patch of ulceration on the cheek. All of these lesions had healed satisfactorily under the influence of sea air and good food, in addition to some local applications.

Dr. Bull said it had been his experience that local treatment was not necessary in the treatment of these tuberculous lesions of the eye. It was only comparatively recently that the prognostic value of tubercles in the choroid had been recognized. He recalled a case of tuberculosis of both lungs, with rapid deterioration of the general health, where the patient's eyes were repeatedly examined under the influence of a mydriatic, and it was not until a week before the patient's death that the tubercles of the choroid were visible. In reply to a question as to whether he thought that fifty per cent. of cases of miliary tuberculosis showed choroidal tubercles, Dr. Bull said he had seen quite a number of cases of intraocular tuberculosis where the choroidal tubercles were, at the time, the only symptom. He thought it probable that fifty per cent. of the cases of miliary tuberculosis would show the choroidal tubercles in the later stage of the disease. The history of his cases had shown the complete uselessness of tuberculin as a remedial agent. It produced a general reaction in eighty-five per cent. of the cases in which it was employed, and in some of them a marked local reaction. In cases of tuberculous meningitis, choroidal tubercles were present in only twenty-five per cent. of those examined, so that much value could not be placed upon them in the recognition of that disease. Single observers saw comparatively few instances of ocular tuberculosis: personally, Dr. Bull said, he had seen less than one hundred cases, in both private and hospital practice, in living subjects. In reply to a question as to whether the presence of choked disk would make the examination for choroidal tubercles any more difficult, Dr. Bull said it would not, as the tubercles were scattered all over the fundus. There was very little interference with the vision in choroidal tuberculosis in cases where the optic nerve was not involved.

**Cases of Typhoid Fever with Malaria.**—Dr. W. Gilman Thompson said he had reported the first three cases of typhoid fever with demonstration of the plasmodium malariæ in 1894, and since then many such had been placed on record. In the majority of these cases it seemed that the plasmodium remained latent until the typhoid fever ran its course. An example of this had recently come under his observation. The patient was a man who had lately returned from Panama, and when he entered the Presbyterian Hospital, with the history of an acute illness dating back three weeks, his symptoms pointed more to malaria than to typhoid fever. It was expected that the estivoautumnal type of malarial parasite would be found in the blood, but three successive examinations gave negative results, although the patient had had no quinine. In the meanwhile, symptoms developed which led to the diagnosis of typhoid fever, and an examination of the blood gave the Widal reaction. Subsequently, he had several hemorrhages from the bowels, and on the fifty-third day he developed a small perforation, for which an operation was done. An examination of the blood at this time revealed the malarial parasite of the simple tertiary variety, although one could not tell from the temperature chart that the case was one of mixed infection. The case resulted fatally from general peritonitis. Dr. Thompson said he had seen cases of this mixed infection where the presence of the plasmodium would give rise to decided interruptions in the course of the fever. There would be a sudden rise and fall, indicating a definite malarial paroxysm, which would temporarily entirely supplant the usual typhoidal temperature wave.

Dr. Brannan recalled one case coming from Cuba in which the presence of this mixed infection had been recognized by Dr. Alvah H. Doty at the Quarantine Station. No plasmodium could at first be found in the blood, but after the patient had recovered from a typical attack of typhoid fever, as well as a relapse, he developed an attack of malaria which persisted for a long time. The plasmodia were not found until late in the course of the disease, and the malarial symptoms did not manifest themselves distinctly until after the typhoid fever had run its entire course.

**Spontaneous Fracture of the Humerus.**—Dr. Robert Abbe reported this case, and showed a number of *x*-ray pictures of the affected bone. The patient was a lad of eleven, who, while throwing a stone into a chestnut tree, felt his right arm suddenly give way. The first physician who saw him regarded the condition as a sprain. Subsequently, another physician was consulted, who detected motion and crepitus, and upon having the limb skiagraphed observed that the medullary space above the fracture was cloudy. This led to the suspicion of a central sarcoma of the bone, and the patient was referred to Dr. Abbe. Examination of the affected limb showed that the bone was apparently uniting firmly five weeks after injury. Several *x*-ray pictures had been taken, which revealed a fusiform swelling of the shaft above the fracture, the medullary space being filled with a cloudy substance. While the appearance of the expanded bone and contents was suspicious, still the fact that the bone was uniting militated against the diagnosis of osteosarcoma and it had been decided, after consultation with Dr. Robert F. Weir, to postpone exploratory operation for two weeks. If the lesion proved to be a sarcoma, it would necessitate amputation at the shoulder. In this case there was no history of pain in the limb prior to the injury. The Röntgen pictures were shown because of the beautiful evidence of tumor growth, while good union of the fracture was the only evidence against malignancy—justifying a short delay.

Dr. Joseph D. Bryant said that while he was not inclined to believe that the growth outlined by the *x*-ray was a sarcoma, still it was open to that suspicion, and he thought it would be wiser to decide the question by an immediate incision rather than to wait even two weeks, as no one could estimate exactly when sarcoma or other malignant disease would begin to spread. With sarcomatous growths, the danger of infection through the circulation was well recognized.

## NEW YORK ACADEMY OF MEDICINE.

*Regular Meeting, Held November 16, 1905.*

DR. CHARLES L. DANA IN THE CHAIR.

THE meeting was held under the auspices of the Section on Surgery.

**The Surgical Treatment of Cirrhosis of the Liver Associated with Ascites.**—DR. FORBES HAWKES said that a sufficient number of cases had been reported by various operators to show that in properly selected cases the operation of Talma of Utrecht offered such distinct hopes of a fairly permanent improvement that the medical practitioner should keep it constantly in mind and be ever ready to suggest it as an early alternative to those patients with ascites so great as to require repeated tappings. Its advantages might well reach to those cases also of cirrhosis associated with intestinal, gastric, or esophageal hemorrhages, or even to those where there were gastric symptoms without hemorrhages. The Talma operation comprises the following procedures, after the opening of the general peritoneal cavity and the evacuation of the ascitic fluid: Roughening or scarifying the peritoneal coat of the liver, spleen, and great omentum and the opposed peritoneal surfaces, so that intimate vascular adhesion might be brought about between these organs and the opposed peritoneum. Next the fixation of the great omentum to the tissues in the anterior abdominal wall, so that the vessels might be inosculate, all of these procedures contributing to the establishment of the desired collateral circulation. Certain precautions, both operative and postoperative, which seemed to be essential to the establishment of an ample collateral circulation, he noted as follows: (1) A very thorough denudation of the surface of the vascular planes which were to carry on this collateral circulation. (2) The accurate coaptation of the large denuded surface of omentum to the anterior abdominal wall. (3) The keeping in apposition of all prepared surfaces until intimate adhesions could occur between them. This meant that no ascitic fluid should be allowed to collect between them. This was best obtained by adhesive plaster compression of the upper abdomen after the operation, and by ample pelvic drainage continued for some time, the drain issuing just above the bladder. (4) The prevention of too much compression of the newly formed blood vessels by a subsequent accumulation of ascitic fluid in the abdomen; keep up pelvic drainage for some time, probably three or four weeks or more after the operation, guarding against infection most carefully, and later tap the abdomen as often as may be necessary and before distension became even moderate. Many of the cases of reported cures had required several tappings after the operation and an immediate cessation of the ascites should not be expected. Dr. Hawkes then detailed a recent case of his own, one of atrophic cirrhosis with very rapidly accumulating ascites and which, though not entirely cured as yet, had been very much improved by the operation, although the complete Talma operation could not be carried out in this case. The consideration of this case, and the facts he mentioned warranted him in expressing the hope that even in the very bad, almost moribund, cases of atrophic cirrhosis with ascites, even such a procedure as a simple omentofixation might be followed by marked alleviation of symptoms, if not absolute cure, and that they were justified in holding out such hope to such a patient.

DR. GEORGE E. BREWER said he had been interested in this subject for a number of years, although his experience with it had been an unfortunate one. At the same time he recognized the value of this operation, because he considered it to be founded on correct principles. Dr. Brewer's cases numbered four, and all were seen at the Charity Hospital. In all in addition to the ascites and cirrhosis there was Bright's disease. Three of these patients died as the result of the operation, and it occurred to him at the time that the drain might have been responsible for these deaths, especially in one case. In the fourth case the drain was omitted and the wound sewed up. A good operative recovery followed. The fluid though accumulated and reaccumulated at increasing intervals and it seemed to be a favorable case. He said that a certain number of cases did recover spontaneously after ascites supposed to be due to liver cirrhosis. He reported an instance of a man who was admitted to Roosevelt Hospital with an enormous abdominal distension, one of the greatest he had ever seen. This patient was about 40 years old, and had been a confirmed alcoholic for 10 or 15 years. Ascites slowly developed, and he was tapped a number of times. The distension was so great the man could not stand, and cyanosis was very marked, the pulse weak; he was anemic and emaciated. The first tapping withdrew 48 quarts, and even that did not empty the abdomen. Only temporary relief followed removal of these large amounts, and he decided to leave the hospital. Dr. Brewer supposed he would live no longer than 10 days. One and a half years later he was apparently well, and when asked what cured him he answered "Christian Science." He believed that if these cases were taken at an early period the death rate would be a comparatively small one and the best chances would be offered in cases of ascites from cirrhosis.

DR. FRANZ J. A. TOREC said that the condition of the patient requiring the Talma operation was frequently such that such an extended operation was impossible, and he referred to the publication of an operation in which the transposition of the omentum was performed in a similar manner. The incision was made in the median line between the sternum and umbilicus, and a pocket was formed in the abdominal wall by dissecting away the skin and fascia from the deeper layers, and placing the omentum in this pocket and closing the abdominal parietes so far as the omentum would permit without constriction of the circulation. This procedure seemed to him to be well worth trying. Three weeks ago he performed this operation upon a patient whose condition was very low, and to-day the collateral circulation could be observed as being established by this simple method.

DR. C. A. MCWILLIAMS said that eleven patients had been operated upon at the Presbyterian Hospital, and all but four had died. All of these patients were in bad condition. Of the four, one was operated upon four years ago and was now apparently well and with no ascites. The second was operated on 18 months ago and was also apparently cured. The third received not the slightest degree of benefit, there being prompt recurrences of the ascites, and this patient died six months after the operation. The fourth patient was still in the hospital, and was operated on six weeks ago. From the literature he learned that there had been 267 cases operated on with a mortality of 30 per cent. or 40 per cent. The presence of jaundice seemed to contraindicate operation. Where there was a marked degeneration of the liver cells the ultimate prospects as regards life and even prolongation of life seemed slight. Kidney involvement was another contraindication.

DR. GEORGE M. EDEBOHLS said he had only four more cases to contribute, and one of these was a very unique one and opened up a new field. The first of these patients was operated upon four years ago, and died within four or five weeks after operation. The second was relieved of the ascites while in the hospital, but left at the end of six weeks and he had been unable to trace this patient since. The third case was a successful one done two years ago. This patient had been a hard drinker, and six weeks prior to operation both the abdomen and pleura had been tapped. He was brought in delirious and partially comatose and his physician asked if something could not be done. Both pleural cavities and the abdomen were emptied. The same afternoon the typical Talma operation was performed with a striking result. He recovered from the delirium and coma within two days. The fluid reaccumulated in both abdomen and pleura and was again tapped. That patient to-day was in business in Wall street and considered himself a

well man. Dr. Edebohls said that such a result in one out of ten operations showed that it should be more often adopted. The fourth case was a very unique one. This patient was sent to him seven or eight months ago from the country with a diagnosis of Addison's disease. There was the bronzed skin, cachexia and emaciation, with an intense itching all over the body. There was felt a fairly large tumor in the right hypogastric region. His attending physician diagnosed enlargement of the suprarenal capsule, or Addison's disease, or tuberculosis of capsule, and the patient was sent to him for the purpose of seeing whether the suprarenal capsule could be removed. The tumor turned out to be a hypertrophied liver, both kidneys and suprarenal glands being found to be normal. The liver, though, was in a state of hypertrophic cirrhosis without ascites. Thinking of what had ben done it seemed to him that if the Talma operation relieved the ascites it might relieve the hepatic cirrhosis, and therefore he performed the Talma operation. Within one week after the operation the itching ceased and had never returned since. In the course of five weeks the tumor gradually diminished in size, and this patient was doing very well. The point he raised was that one might occasionally operate in the precirrhotic stage with happy results. Dr. Edebohls was convinced that the Talma operation was a valuable addition to one's therapeutic armamentarium, and that it should be tried in every case of hypertrophy of the liver complicated by ascites.

Dr. George D. Stewart said that he had operated upon three cases. He did not believe it was possible in many cases to do the typical Talma-Morrison operation; when it could not be done one should then fasten the great omentum to the peritoneum. His experience with the three cases was an unfortunate one, all of them dying after two, three, and five weeks, and until he could hear of more successful results, and until he was taught to properly select cases for operation he did not propose to operate upon any more of these cases.

Dr. Arthur L. Fisk referred to two cases that had been operated upon, both dying within two or three months after. He called attention to an article that appeared in the *Boston Medical and Surgical Journal,* which made a thorough review of the subject under discussion. Here it was stated that most of the cases of cirrhosis of the liver were associated with chronic interstitial nephritis and general arterial sclerosis. Therefore, the first operation of Morrison-Talma he did not think to be justifiable. Until they were able to properly select their cases the operation should be undertaken with great care and consideration. In patients between 45 and 50 years of age, with kidneys affected, with a general arteriosclerosis, he believed it was a better plan to leave alone than to operate.

Dr. Samuel Lloyd said he had done this operation seven times, four of the patients dying in a comparatively short time, three to eight weeks after. The first case was operated upon when the method was first suggested; this patient was still living and the ascites had entirely disappeared and she was in as good a condition as she ever was. This was undoubtedly a very successful case. In his second case the technique was varied; here he took out a large portion of the parietal peritoneum and then attached the omentum directly to the abdominal wall over the denuded area. This patient had an atrophic cirrhosis. The caput medusæ rapidly appeared, the veins being tremendous ones. The ascites decreased for a number of months and then began to increase again, and the patient was operated upon the second time. This patient became septic as the result of abdominal drainage, and finally died. The third case he operated upon he thought had disappeared entirely, but showed up at the dispensary ten days ago, reporting well. This patient had been tapped after the operation a few times in the dispensary, with decreasing frequency, and it was at the present time several months since this was necessary. The patient was having now some trouble with considerable irritation of the stomach, and he thought that the probabilities were that there would be a relapse, as did the second case reported. Dr. Lloyd did not think that jaundice contraindicated the operation unless it was a prolonged jaundice with a saturation of the tissues with bile and when the condition was reached in which one might expect hemorrhages from any operative procedure, a sort of pseudo-hemophilia. But in the ordinary cases of jaundice it really was indicated.

Dr. Forbes Hawkes closed the discussion.

**Cholecystectomy, with a Report of Twenty-seven Cases.**—Dr. John F. Erdmann presented this communication and said that it was a well-known fact that one could exist without a functionating gall-bladder, and this had been proven many times by the autopsy and operating table findings. In many gall-bladders the cystic duct was occluded by stone, exudate, kink, etc., so that the storehouse function of this organ had not been carried on for months or years. Therefore, when one had a case of cholecystitis, or disease of the gall-bladder in which time as a curative agent could not be relied upon, or when the condition was a menace to life, judgment should demand the removal of the organ. Cholecystectomy had been, and was yet considered the operation of choice only when marked gangrene, or malignancy of the bladder was present. Personally he was not in accord with these views, and he had not selected his cases for the operation by limiting himself to these two conditions. Primary operations only were considered in his paper, and he reported results in 27 cholecystectomies, complicated or not with other diseases and conditions (two being pregnant), and drawing attention to the fact that no waiting time for subsidence of infection, etc., was given any of these cases by doing a previous cholecystotomy, nor was any local treatment advised. He also called attention to the fact that the worst cases of infection and most active invasions did fully as well, if not better, than those of lesser, or practically no inflammatory activity. The argument that it was not good surgery to do a cholecystectomy during an active invasion was not supported by the results in his cases. He said he was a firm believer that active interference in these cases by complete removal was as good practice as appendectomy was now considered to be. The time of repair and convalescence was shortened very markedly when cholecystectomy had been done, as compared to that of cholecystotomy and the possibility of secondary operation when the latter had been done was great, while following cholecystectomy it was rare. Twenty-two out of the 27 cases occurred in females, the youngest being 27, the eldest 66. Four of the entire number were over 50 years of age. About 20 per cent. gave histories of a previous attack of typhoid fever. It was more than probable that by closer questioning of the families a larger percentage of typhoid would have been in evidence. Two deaths occurred in this series, both in non-suppurative, but not uncomplicated cases. The appendix was removed in 16 of these cases, in several instances being markedly involved. Eight had gangrene of one of more coats of the bladder; one was doubly perforated, contained two stones and a large abscess walled off. In five cases the common and hepatic ducts, or both, were opened for stones. History of jaundice was obtained in 12 cases. Twenty-two of the cases were operated on for acute inflammatory conditions, and all recovered. Marked adhesions were present in 22, slight in three, and in the remaining two there were none present. Stones were present in all except one. The following were the indications for operation: Perforations by trauma, ulceration other than due to abscess or gangrene, obliteration or stricture of the cystic duct, chronic cholecystitis with thickened walls, atrophy, gangrene, acute suppuration, enlargement by dilatation, marked adhesions, hour-glass contractions, chronic or recurring cholecystitis, or cholelithiasis, and malignancy. The following contraindications were given: Apparently healthy bladder in cholelithiasis and pericholecystitis, perforations into other viscera when difficulty of closure of the anastomosis was

great, perforations in the suppurative variety when adhesions were extensive and where life would be jeopardized by such radical interference, malignancy when extensive, and those cases where hurried operation was indicated to save life. After considering the technique of the operation and relating the histories of some of the 27 cases he said in conclusion that the operation was advocated for its simplicity, diminution of post-operative convalescence, elimination of secondary operation, and that it dispensed with a viscus, dangerous to the owner when once infected. He did not advise the operation in all cases, but riper judgment, as now was exhibited in appendiceal surgery, should be exercised in this branch of surgery.

Dr. Forbes Hawkes said that he had been interested in cholecystotomy *versus* cholecystectomy, and he reported the case of a woman upon whom he operated about one and a half years ago who had previously been operated upon for gall-bladder pain, two stones being removed from the common duct, being melted out, with a perfect convalescence. Over a year later she began to have gallstone colic with jaundice; two months later the jaundice was quite marked and there was distinct tumefaction which could be felt under the liver. This turned out to be a distended and dilated gall-bladder. The common duct looked like an old strictured urethra.

Dr. C. L. Gibson said that the operation, cholecystectomy, antidated the operation for appendicitis. Six or eight years ago he presented two specimens, cholecystectomy having been done for the gall-stones, and he then was severely criticised for doing such an operation. Cholecystectomy was now rather the rule than the exception. A marked advantage followed the removal of the offending viscus. This operation he considered a comparatively easy one if uncomplicated. If done properly there would be no sinus left; but if a cholecystotomy be done one was apt to have a persistent mucous sinus left, not a biliary one. Another objection to cholecystotomy was that if a secondary operation was necessary it was performed with difficulty and was attended with more or less danger.

Dr. W. Gill Wylie said that whenever he opened the abdomen below the umbilicus, if large enough to admit the hand, he invariably examined for stone in the gall-bladder, and he was very often surprised to find stones. Those cases after abdominal section that suffered so much from nausea and vomiting he found had, as a rule, distended gall-bladders.

Dr. Charles A. Elsberg said that 80 cholecystectomies had been done at the Mt. Sinai Hospital during the past three years for acute and chronic disease; of these 80 cases, over 50 had been done for acute disease. They had come to the conclusion that in the majority of the cases when the gall-bladder had been found but mildly diseased that its extirpation was indicated.

Dr. Alex V. Moschcowitz said that he had gone through three stages, as follows: A few years ago he did cholecystotomy, with poor results, many cases dying, and those that survived had for a long time fistula, etc. In the second stage he did cholecystotomy, but here he sutured the drainage tube in the gall-bladder by the method that is frequently used in gastrostomy. The results were better. Later he adopted the operation, cholecystectomy, and now did it exclusively. In all the cases of cholecystectomy all but one case recovered. Personally he believed this to be the ideal operation.

## NEW YORK COUNTY MEDICAL ASSOCIATION.

*Stated Meeting, Held November 20, 1905.*

Dr. Francis J. Quinlan in the Chair.

**General Infection Through the Tonsils.**—Dr. Isaac Adler read this paper. He said that it was now generally conceded that the faucial tonsils might serve as portals of entry of infection for a number of diseases, as acute articular rheumatism, pleurisy, acute osteomyelitis, various forms of general sepsis, nephritis, and tuberculosis. It had even been suggested that typhoid fever might possibly originate here. The purpose of his paper was merely to emphasize a few points which might possibly be of some practical value, avoiding all theoretical speculation. That the tonsils offered, under certain conditions, a convenient passage for all sorts of infectious material into the lymph and hence into the blood current might now be considered a certainty. If one considered that an abundant flora of pathogenic and non-pathogenic bacteria was normally found to cover the tonsils, that the crypts and lacunæ usually contained more or less disintegrated and decomposing material, and if one considerd also the intimate connection between the tonsil and the lymph channels it became quite obvious that all the necessary factors of an infection were given. It was evident that there must be some powerful defensive apparatus, but what it was nobody as yet knew, although there was no doubt that powerful factors were the resisting power and disposition of the epithelium and the reactive vigor of the leucocytes. By far the most frequent infection of tonsillar origin was rheumatic, and it had been satisfactorily proven that acute articular rheumatism at least was a bacterial disease depending upon an infection. At present it was a generally accepted fact, based upon a large literature and much accurate experience, that this infection entered the system in probably the majority of the cases through the tonsils, and that acute articular rheumatism, endocarditis, pleurisy, and many other forms of streptococcic disease were thus introduced. He wished particularly to emphasize the fact that the rheumatic infection need not necessarily be introduced by the common form of follicular tonsillitis with more or less high temperature, considerable swelling of the tonsils, great pain on deglutition, etc. On the contrary, it very often appeared as if an intense inflammatory reaction served somewhat as a preventive of general systemic infection. It had been demonstrated that under favorable circumstances even quite virulent microbes could pass through the tonsillar portals without reactionary or inflammatory changes in the tonsillar tissue. The thin layer of epithelium in the interior of the crypts was most easily and most frequently damaged and afforded a ready passage for infection into the lymph channels, and, therefore, one found that very slight tonsillar irritation was the precursor of more or less severe rheumatic or septic systemic infection. Dr. Adler was convinced that muscular rheumatism was also a bacterial infection depending upon some microbe, possibly a highly attenuated streptococcus; also that many of these cases were of tonsillar origin. It was a fact not sufficiently appreciated that the muscles of the neck and, to a large degree, of the shoulder, were the favorite localization of a chronic muscular rheumatism. The acute onset was almost invariably preceded or accompanied by an attack of tonsillitis. It was quite possible that certain forms of pneumonia, streptococcus pneumonia, as well as the pneumococcus pneumonia, might have their origin in infection through the tonsil. General and severe septic infection might take their origin from tonsillar disease, and he cited a case to illustrate the fact that the gravest general septic infection might take its origin from the tonsils without the formation of tonsillar or peritonsillar abscesses and without any great anatomical tonsillar lesion. He called special attention to the relation of tonsillitis to nephritis, the form usually designated as desquamative nephritis, with no edema, no vomiting, no headache, in fact, no subjective or objective symptoms except those contained in the urine. In the overwhelming majority of the cases the nephritis disappeared simultaneously with the tonsillitis or soon thereafter. Sometimes it persisted long after the disappearance of the tonsillitis. He was convinced that chronic nephritis in the train of an ordinary tonsillitis was of much more frequent occurrence than was generally believed. It was the unquestioned duty of the physician to permit no case of nephritis following tonsillitis to reach the chronic, that

was to say, the incurable stage, and more attention should be given the urine during and after every attack of tonsillitis. The real function of the faucial tonsils was unknown, but they might act as valuable defensive mechanisms. However, it was certain that the organism could get along very well without any appreciable loss of function without the tonsil. No matter what its normal functions might be, they were transformed into abnormal ones on very slight provocation, and the slightest abnormality in the tonsils constituted a very serious menace to the entire system. Under such conditions one was almost led to feel about the tonsils as many felt about the appendix, that the body would be better without them. He did not mean to urge the methodical eradication of every tonsil, healthy or otherwise, but to urge unhesitating radical measures wherever the tonsils showed signs of disease. Enlarged and hypertrophied tonsils should always be removed except in few instances where there were positive contraindications. Wherever there was any tendency to even slight attacks of follicular tonsillitis, and particularly of the fosscular form, the slight inflammation of the crypts was a serious menace to the system and should be placed out of harm's way *before* any serious trouble occurred. For many years, he said, he had advised burning over the surface of the tonsil either with a broad Paquelin burner of with a galvanocautery. It was not wise, in his opinion, to pick out the crypts one by one for cauterization, but the best results were obtained when the entire surface of the tonsils down to a considerable depth was destroyed and converted into scar tissue.

Dr. Alexander Lambert thought that every man who was in general practice was struck with the fact that most cases of tonsillitis were distinctly intoxications, and if the paper read did nothing more than call attention to the marked difference between acute articular rheumatism and many of the conditions included under that head it certainly would bear fruit. With regard to the nephritis following attacks of tonsillitis, and the clinical description given by Dr. Adler, this explained many cases of Bright's disease which he had long puzzled over. Usually such a condition was entered as a "cold." Vigorous cutting into these tonsils would, he believed, in a great many instances be attended with very uncomfortable hemorrhages if done by the ordinary general practitioner.

Dr. Emil Mayer said that the enlarged tonsils made the child a "mouth breather," and the picture presented by Dr. Adler clearly emphasized the necessity of removing that obstruction. More than ordinary care should be taken in the examination in order to ascertain the nature of the trouble as well as what the treatment should be. To determine whether the epithelium was abraded or not an applicator covered at the end with cotton should be drawn over the suspected denuded surface; if it showed that it was saturated with blood one could feel confident that there was abraded epithelium. There were dangers in making these incisions into the tonsils, and he believed the galvanocautery to be the prime method for the relief of these conditions. It could be applied in an absolutely painless manner and the crypts could be destroyed readily.

Dr. William K. Simpson said that he was struck forcibly by the fact that Dr. Adler, who was a general practitioner, saw systemic infections occurring through the tonsils, while he, a specialist, rarely saw it except as a mere prodromal or febrile condition which existed with cases of ordinary tonsillitis. Since he saw so many cases of tonsillitis he asked why he did not see more cases of systemic infection. Why could not other portions of the respiratory tract act as portals of entry? Systemic infection did not follow the presence of adenoids. Basing his remarks upon his own personal experience, he said he could not look upon tonsillitis other than as a purely local affair. If bacteria entered the system through the tonsils they then were there, and he did not see how incising the tonsils, or slashing them, or cauterizing them, was going to prevent that infection. All patients that came to him with tonsillitis were asked if they ever had rheumatism, and his experience showed they seldom did have it.

Dr. Morris Manges, replying to Dr. Simpson's remarks, said that the family doctor first got these cases and later on they were sent to the specialist. He referred to a case seen by him 12 years ago of purpura rheumatica which had resisted all methods of treatment. This was one of the most painful forms and hemorrhages occurred into the peritoneal cavity, with intense attacks of colic, with a great deal of distress, etc. The attack lasted over two months. The only positive findings were the streptotoccus in the throat, and this then was treated with nitrate of silver. Then the purpura rheumatica yielded at once and no recurrences followed. Two other cases were reported to corroborate the position taken by Dr. Adler.

Dr. Wolff Freudenthal said he had devoted much time and thought to the matter of infections of the upper air passages, especially tuberculosis and rheumatism. He had seen many cases of acute articular rheumatism following acute attacks of tonsillitis. The tonsils were only one part of the tonsillar ring, and he considered the upper part of the pharynx as a portal of entry as being even more important than the tonsils. It seemed to him that many cases of rheumatism first had their origin in the upper part of this lymphatic ring. When the tonsils were small and soft he did not like to burn them with the cautery, but he preferred to open the crypts and scrape them out, then using a mild caustic. If hypertrophied he did not always remove them; he did not advocate the removal of tonsils that were but slightly hypertrophied.

Dr. S. J. Meltzer continued the discussion, which was closed by Dr. Adler.

**Diarrhea and Its Diagnostic Significance.**—Dr. James P. Tuttle read this paper. H said that diarrhea was a symptom and not a disease, and consisted in abnormal frequency and fluidity of the alvine passages. He said that Foster defined 101 different diarrheas but that all might be classified under one of the following types: 1. *Simple diarrhea.* This consisted of an abnormal frequency and fluidity of the alvine discharges, the stools containing no undigested food or pathological elments, being normal in reaction, and unaccompanied by tenesmus or burning pain, and they rarely disturbed the patient at night and caused no progressive loss in weight or strength and were not associated with any digestive disturbances. This type was more a habit than a disease, and occurred in large eaters and drinkers, especially those who drank much beer or dry wines. The condition was of no diagnostic importance. 2. *Serous diarrhea.* This followed any great mental strain and often occurred in the crisis of acute diseases. It occasionally occurred in chronic nephritis as a vicarious offering on the part of nature to relieve disabled kidneys. It was said to occur in hysteria. It was usually associated with a relaxation of the sphincters, and the patient was often unable to reach the toilet before the discharge occurred. They presented no evidence of gastroenteritis but pointed directly to some derangement of the nervous system which caused an outpouring of serum into the intestinal canal, the mucous membrane of which was rendered more susceptible to stimulation by the same cause. 3. *Lienteric diarrhea.* This was a condition in which undigested particles of food in the stools first pointed to too much or imperfectly masticated food, and secondly to impairment of the digestive processes. Lienteric diarrhea might point to more serious organic lesions. It was difficult to realize what serious involvement of the stomach might exist without any marked gastric symptoms. The import of such diarrhea while generally simple was sometimes very serious. 4. *Toxic diarrhea.* This was due to the ingestion of decayed or poisonous substances whether inorganic or bacterial, and included such specific diarrheas as cholera, cholera morbus, cholera infantum, dysentery, etc., and those of ptomaine, arsenical, strychnine, mercurial, and other

poisons. It began with nausea and vomiting, with loose fecal stools gradually running into the serous type and terminating, if protracted, in bloody mucopurulent discharges. The simpler types were relieved by thorough cleansing of the alimentary tract, but the more serious ones were not so easily controlled and their significance was, therefore, more important. Ptomaine, fermentative diarrheas, and those due to corrosive substances were usually profuse, painful, and associated with nausea and vomiting and could be usually associated with some ingested substances. Dysentery could not be so associated. Briefly sudden, painful, profuse diarrhea associated with nausea and vomiting and great relaxation, indicated some toxic ingestion and not inflammatory affections. These cases might run into chronic purulent diarrheas and when seen for the first time in this stage their origin became obscure unless one carefully examined into the type of the commencing diarrhea. 5. *Mucopurulent diarrhea.* This always indicated some lesion of the mucous membrane, usually of the colon. When it was periodic and accompanied by great griping and tenesmus, the subsequent stools being largely composed of coagulated membranous mucus, this diarrhea indicated a simple or reflex mucous colitis. He made bold to state that it was not a neurosis but a hypertrophic catarrh, probably of infectious nature or due to autointoxication from retained fecal material at some point. This condition was sometimes due to constrictions of adhesive bands, to gallstones, to chronic appendicitis, and possibly to floating kidney. When the diarrhea was persistent and more or less profuse and accompanied by much griping it pointed to ulceration high up in the small intestine. If the stools were scanty, composed chiefly of glairy mucus, pus and fresh blood with aching pain in the sacral region and not much griping they pointed to lesions of the rectum or sigmoid. The character of such lesions could always be determined by proctoscopical examination. Such cases might have a perfectly normal stool in the morning preceded by small mucopurulent stools and this invariably pointed to lesions in the upper part of the rectum. A very nagging diarrhea with increased peristalsis, desire to go to stool without satisfactory results, and the occasional passage of a little mucus was one of the earliest symptoms of carcinoma of the intestine. 6. *Reflex diarrhea.* This might probably come under the head of nervous affections, but they were really rarely so. They occurred in such conditions as enlarged prostates, stone, uterine and abdominal tumors, appendicitis, gallstones and painful affections in almost any part of the body. A diarrhea that followed marked constipation was always to be looked upon with suspicion. It was very often caused by the lodgment of hard fecal particles in sacculi or diverticuli and by fecal impactions around or through which the fluid feces passed. Such cases were always associated with autointoxication which might be mistaken for anemia or chlorosis. He had seen such a case result in acute mania which was promptly relieved together with the diarrhea by cleansing out the mass which was arrested in the sigmoid.

Dr. Samuel G. Gant discussed the significance of diarrhea as regarded disease of the colon, sigmoid, and rectum, and said that this was not sufficiently recognized and was very often overlooked. Among the common diseases which he discussed were ulcerations of the bowel, prolapse, invagination, fecal impaction, enteroliths, adhesions by bands, tumors from without the bowel which produced obstruction and cancer; and he presented specimens of an enterolith and a vesical calculus, the latter pressing upon the bowel and producing symptoms.

Dr. Max Einhorn said that diarrhea from digestive disturbances formed a very important group, and it was quite characteristic that no mucus or blood was to be found in the stools. It was astonishing to see some of these cases take such a severe course and last for years, so that the condition of the patient made one think possibly malignant disease might be present. In such cases the abnormal condition of the stomach was accountable for the diarrhea, especially achylia gastrica. A study of the diet and food conditions would check the diarrhea. Too much acidity in the stomach would cause a very severe form of diarrhea and could readily be cured by the use of alkalies. In those forms of nervous diarrhea the will power had much to do with it. In such diarrheas the patient had frequent movements but the feces were of good consistency. To cure such cases it was necessary to have them exercise a restraining inclination and not respond to the call so often.

Dr. William C. Lusk wished to emphasize an important point, that in chronic diarrheas an examination of the lower bowel should always be made with the protoscope. He related the histories of three cases, one of ulcerative proctitis and two of mucous colitis, all very severe, and all having suffered about one year, and before appearing at the dispensary had never been examined with care. The use of the proctoscope was a very simple matter and could be used with great ease if the anus was not too irritable.

Dr. James P. Tuttle said in closing the discussion that he did not attempt to enumerate all the diseases that caused diarrhea but he merely wished to call attention to the direction of research in the different types of diarrhea. If a patient had a serous diarrhea he saw no use in introducing the protoscope; the cause was further up. In a mucous or a mucopurulent diarrhea it was one's obligation to look into the bowel and see just what the conditions were. He emphasized the importance of testing the reaction of the stools; he believed this to be as important as testing the reaction of the urine when one suspected bladder trouble. An alkaline stool irritated the rectum as did an acid one, and was usually associated with disturbances about the liver, pancreas, or small intestines; whereas an acid stool was associated with fermentation occurring in the large intestines.

## Philadelphia Pediatric Society.

At a stated meeting held November 14 Dr. Eleanor C. Jones exhibited "A Case of Atypical Hemiplegia." The patient was a child eight years old who, following a febrile attack at the age of 18 months, attended with vomiting and convulsions, presented left hemiplegia with flaccidity of the affected upper extremity. Convulsions recurred for a time, the paralyzed members failed to develop equally with the healthy, and mental backwardness was evident. The affected hand was the seat of athetoid movements, and the reflexes were increased on the paralyzed side. The conditions were believed to be dependent upon an encephalitis and it was suggested in the discussion that there might have been also a coincident poliomyelitis. Drs. W. G. B. Harland and T. H. Weisenburg exhibited "A Case of Latent Hemiplegia Made Evident by Etherization in a Child of Eight Years." The patient had been born at term, the delivery being instrumental. Nothing abnormal was noted until after the administration of ether for narcosis in the performance of an operation upon a suppurating mastoid process of the left temporal bone. Following the operation symptoms of left hemiplegia were observed. Further operation being required at a later date, symptoms of right hemiplegia additionally supervened, and at the time of demonstration the child presented the features of a spastic diplegia. Dr. J. H. W. Rhein exhibited "An Infant of Eight Months with Bell's Palsy." A previously healthy child developed paralysis of the right side of the face following an incision for the evacuation of an abscess below the chin on the right side. The occurrence is rare so early in life, and it was suggested that facial paralysis complicating middle-ear disease during early life is as uncommon as it appears to be because of the spongy character of the petrous portion of the temporal bone at this time and the greater freedom of the nerve in its bony canal. Dr. Robert S. McCombs reported "A Case of Multiple Exostoses," and he exhibited skiagrams illustrative of the condition. The swellings to the number of 49, were distributed with a cer-

tain symmetry and they seemed to make their appearance in the sequence of traumatism of some sort or other. There was no history of similar disorder or of syphilis or alcoholism in the family. Dr. Hubley R. Owen exhibited "A Case of Rickets with Marked Deformity of the Clavicles." The patient was a child 21 months old presenting characteristic bone-changes of rachitis, the chest being depressed laterally and chicken-breasted, with enlargements of epiphyses of long bones and square head with prominent parietal eminences. The most striking feature, however, was the deformity of the clavicles, which were symmetrically bent upon themselves at the junction of the inner third with the outer two-thirds. The overlapping was so marked as to be suggestive of a fracture with faulty coaptation and union, but the symmetry of the lesions and the absence of a cause of fracture seemed to exclude this condition. Dr. Courtland Y. White exhibited "Card Specimens of Miliary Tuberculosis." The organs were derived from the bodies of three children and they exhibited characteristic lesions, in one associated with tubercles in the spleen and in another with solitary tubercles in the kidney. Dr. C. H. Lefkowitch reported "A Case of Diabetic Purpura in a Boy of Three Years." The case appeared at first to be one of alimentary glycosuria complicated by purpura, but the sugar did not disappear from the urine although improvement took place on restriction of the diet. Dr. J. P. Crozer Griffith exhibited specimens of various forms of leguminous foods, the proportions of whose proteid and carbohydrate constituents was designated. These may be used as adjuncts in infant feeding when animal proteid in the form of the casein of milk is not well borne. Dr. C. F. Judson and C. D. Camp presented a communication entitled "Final Report with Post-mortem Findings in a Case of Cerbebellar Tumor." The patient was a child presenting characteristic gait, with a tendency to deviate to one side, with choked discs, and other symptoms of cerebellar tumor. Post-mortem examination disclosed the presence of a large glioma within the body of the cerebellum.

### Philadelphia County Medical Society.

At a special meeting held November 15 Dr. A. C. Abbott, President of the Board of Health, delivered an address entitled "The Essentials of Successful Public Health Administration." He pointed out that the problem of public preventive medicine is not to be solved by means of specific laws and the appointment of Boards of Health empowered to enforce their observance. Such a combination is merely the nucleus around which are assembled the various accessories that collectively constitute the machinery that in accordance with the perfection of its organization and the smoothness of its running determines the failure or success of the undertaking. For the purpose of collecting the data essential to a full understanding of prevailing conditions the cooperation of the medical profession is required to the extent of the prompt notification of all matters bearing upon the public health that comes under its notice. Experience has shown that where there exists a close and intelligent cooperation between the medical profession and the body in authority the interests of the community are best subserved by giving to those in authority absolute power and by holding them rigidly accountable for the judicious exercise of such power. The regulations formulated by the body in authority should have the force of laws and it should be possible promptly to amend, modify, or repeal them as conditions dictate. The primary object of a modern public health organization is to safeguard the public health by direct attention to preventable diseases. Any disease transmissible from person to person should be preventable, particularly if the exciting factor and the manner in which it is disseminated be known. In order that appropriate preventive measures may be employed it is necessary that all cases of transmissible disease should be regularly recorded at some Central Bureau, and the notification should be made by practitioners of medicine in the community. The public must be made to understand the importance of the end to which public health officials and physicians are striving and to appreciate the relation of all measures directed toward that end. The campaign for the health of the people is a campaign of education.

### College of Physicians of Philadelphia.

At a stated meeting held November 1, Drs. Wm. G. Spiller and Chas. H. Frazier presented "A Case of Athetosis Treated by Nerve-transplantation Nine Months After the Operation." Dr. Wm. J. Taylor reported "A Case of Hypernephroma; Recovery from Operation, but Death from Recurrence of the Disease." Dr. Alfred Gordon presented a communication entitled "On Auto-suggestion in Hysteria, apropos of a Case, with Remarks on the So-called 'Hysterical Insanities.'" He reported the case of a young woman who presented convulsive seizures whose nature was at first obscure, but subsequently appeared to be in part hysterical, in part epileptic. In addition there were evidences of mental aberration of varied character. The patient was extremely suggestible, relating as events in her own life occurrences that she had read of in novels and the like. Dr. W. W. Keen presented a communication entitled "A New Method of Operating on Dupuytren's Contraction of the Palmar Fascia, Together with the Successful Use of Neural Infiltration in Such Operations." In the case in question a rectangular flap was made in the palm, with its attached margin nearest the wrist. The flap was reflected back and the palmar fascia beneath the skin dissected out. As the patient had a serious heart-lesion cutaneous anesthesia was induced by infiltration of the skin and thus beta-eucain was injected into the sheath of the radial and ulnar nerves. This proving unsuccessful a four per cent. solution of cocain was injected into the sheath of the nerves and the operation could be proceeded with without pain.

## Books Received.

*While the* Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Memoranda on Poisons. By Dr. Thomas Hawkes Tanner. Tenth Revised Edition. 32mo, 171 pages, muslin. P. Blakiston's Son & Co., Philadelphia.

Disorders of Metabolism and Nutrition. By Professor Dr. Carl von Norden. 8vo, 211 pages, muslin. E. B. Treat & Co., New York.

Neurotic Disorders of Childhood. By Dr. B. K. Rachford. 8vo, 432 pages, muslin. E. B. Treat & Company, New York.

Faulty Diction, or Errors in the Use of the English Language and how to Correct Them. By Thomas H. Russell, LL.B. George W. Ogilvie, Chicago. Price, leather, 50c., cloth, 25c.

Operative Surgery. By Dr. John J. McGrath. Second Edition. 8vo, 617 pages, muslin, illustrated. F. A. Davis Company, Philadelphia.

Experimental Psychology. By Dr. Edward Bradford Titchener. Second Volume. 8vo, 416 pages, illustrated, muslin. The Macmillan Company. Price, $2.50.

Treatise on Diseases of the Skin. By Henry W. Stelwagon, M.D. Fourth Editon. 4to, 1,109 pages, illustrated, muslin. W. B. Saunders & Company, Philadelphia and London.

A Text-Book of Physiology for Medical Students and Physicians. By Dr. William H. Howell. 8vo, 886 pages, illustrated, muslin. W. B. Saunders & Company, Philadelphia and London.

Anatomy and Physiology for Nurses. By Dr. Leroy Lewis. 8vo, 302 pages, illustrated, muslin. W. B. Saunders & Company, Philadelphia and London. Price, $1.75.

A Manual of Diseases of Children. By John Ruhräh, M.D. 12mo, 392 pages, illustrated, leather. W. B. Saunders & Company, Philadelphia and London. Price, $2.00.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending December 2, 1905.

| | Cases | Deaths |
|---|---|---|
| Measles | 438 | 11 |
| Diphtheria and Croup | 285 | 34 |
| Scarlet Fever | 157 | 6 |
| Smallpox | 1 | ..... |
| Chickenpox | 154 | ..... |
| Tuberculosis | 421 | 174 |
| Typhoid Fever | 71 | 10 |
| Cerebrospinal Meningitis | 15 | 15 |
| Typhus Fever | ..... | ..... |
| Yellow Fever | ..... | ..... |
| Cholera | ..... | ..... |
| Totals | 1,542 | 250 |

**The Treatment of Ringworm of the Scalp by the X-Rays.**—Walter Charles Oram declares that it seems probable that in the *x*-rays we have an agent which, when carefully and judiciously used, will reduce the treatment of ringworm of the scalp from years to months with the smallest possible trouble and inconvenience both to patient and physician. His patients have four treatments a week. He has two masks made of fine-meshed wire gauze and covered with lead foil, so that they may be opaque to the rays. In one of these the openings are back and front, while in the other they are at the sides. These masks are used on the alternate days, Monday and Thursday, Tuesday and Friday. In this way each area receives two exposures weekly of ten minutes' duration. By the end of the third week the scalp begins to show some erythema. The hair has as a rule entirely fallen off by the end of the fourth week, leaving the scalp bare and free from fungus. As to the position of the tube, the anticathode must be placed directly opposite the area to be treated, so that the rays fall perpendicularly on the skin. The tube must be placed not less than six inches from the skin. The writer uses the current that is given by three or four ampères running in the primary of a 12-inch coil, interrupted by a Mackenzie-Davidson mercury motor break. A storage battery of twelve elements giving twenty-four volts is used. He thinks that a soft tube gives the best results. Now and then slight folliculitis develops. This is superficial, and disappears on appropriate treatment. The writer has never treated a child less than four years old. The hair takes about three months to grow again. There is little reason to think that any untoward results will follow this method. The writer believes that a milliampèremeter should always be used when the *x*-rays are employed for therapeutic purposes.—*The Dublin Journal of Medical Science.*

**Acute Rheumatic Fever as Treated by the O'Connor Surgical Treatment for Acute Articular Rheumatism.**—J. Benjamin Dennis reports this interesting case. The patient was a white man, twenty years old, by occupation a coal passer. He became ill in April, 1903. The first symptoms were a slight cough, husky throat, and malaise, followed by pains in the right hip and shoulder. The temperature was 100° F. Salicylate of sodium was administered. The pain became worse, and the temperature became higher. The tongue was coated, sweats occurred, and the patient suffered from anorexia. The knees and ankles became involved. The heart action was labored. Six days after his admission to the hospital, a double arthrotomy was done on both knee joints, which were irrigated with normal saline solution under aseptic conditions, and drained by the insertion of rubber drainage tubes. Several ounces of serous fluid were removed from each joint. Both ankles were incised in three places, the joints opened and drained by three gauze drains. The right shoulder joint was opened, irrigated with normal saline, and drained by a gauze drain. All medical treatment was discontinued. The patient began to improve at once, and in two days had no pain, and was able to move his joints. For over a year he has had no rheumatic trouble whatsoever, and has been able to work laboriously. This case was the twenty-first upon which O'Connor has operated. In none of these has there been any secondary involvement of the heart, in which it was not present prior to the operation. The writer thinks that this treatment, to be most efficacious, should be done immediately on diagnosis in the acute stage.—*Journal of the Association of Military Surgeons of the United States.*

**Treatment of Enuresis and Polyuria by Epidural Injections.**—W. T. Freeman has obtained beneficial results in a number of cases, of which he gives the histories, by the use of epidural injections of physiological salt solution, into the sacral canal. The fluid passes into the space between the periosteum of the vertebræ and the membranes of the cord. There is plenty of room in the canal, but the passage for the needle is quite small in young children. From the age of nine years upward the operation is easy, and can be done without any anesthetic. The fluid seems to act upon the nerve roots of the cauda equina, rather than on the spinal cord. The effect is a stimulation of the nerve roots, which spreads up to the lumbar controlling center, and reflexly excites its corpuscular elements so as to produce inhibition. The fluid injected does not seem to matter, and a good effect is obtained after one injection, but it should be repeated two or three times to get permanent effect. A large needle is required, from 1½ to 3 inches long. The landmarks are the sacral cornua and the tip of the coccyx, keeping in the middle line, and the needle should be pushed home upward and forward, and when it has entered it will be felt that there is plenty of room in the canal.—*The British Journal of Children's Diseases.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended December 2, 1905:

### INHIBITORY AND ANESTHETIC PROPERTIES OF MAGNESIUM SALTS.*

By S. J. MELTZER, M.D.,

NEW YORK.

I INTEND to report to you to-night, in very brief outline, the results of several series of experiments which Dr. John Auer and I have carried out with magnesium salts. The facts which came to light are new and indeed somewhat surprising, and some of them have the advantage of already having been, to a degree at least, subjected to a practical test. These investigations, however, were undertaken on a purely theoretical basis with a view of testing a far-reaching biological hypothesis. Before proceeding to report the various experimental results I shall, therefore, state briefly the theory which gave the impulse to these investigations.

This theory deals with the question of inhibition, a subject which I have already twice had the honor to discuss from the platform of the Academy. The meaning of inhibition is easily understood when it is illustrated by the well-known action of the vagus nerve upon the heart. The contractions of that ever-beating organ are stopped, inhibited, when the peripheral end of the vagus nerve is stimulated by induction currents or otherwise. It is generally assumed that stimulation of a living organ, a nerve, for instance, will produce an active state: for instance, stimulation of a sensory nerve will produce a sensation, and stimulation of a motor nerve will produce a contraction. But here in the experiment upon the vagus we see that the stimulation of a nerve, instead of increasing the automatic contractions of the heart, stops them. This clean example of inhibition is, however, not an exceptional phenomenon in the functions of the animal body. In my former papers I collected a great number of well-established facts showing the ubiquity of inhibition in the various manifestations of animal life. I entertain and defend the view that the phenomena of life are not simply the outcome of the single factor of excitation, but they are the results of a compromise between two antagonistic factors, the fundamental forces of life—excitation and inhibition. I cannot think for a moment, in the short time at my disposal, to enter now into the particulars of this theory, of which, by the way, I am profoundly convinced that it contains a great truth which will be recognized in a future not far off. However, for the better understanding of what is going to come, I wish to say this: In the domain of motor phenomena the normal movements of the body present the physiological, and tetanus presents the pathological predominance of the factor of excitation, while the various forms of bodily rest present the normal, and paralysis the pathological predominance of inhibition. In the sensory sphere pleasant sensations present the physiological and unpleasant and painful sensations the pathological predominance of the factor of excitation, while the absence of sensation in the visceral sphere presents an instance of the physiological, and anesthesia in any part of the body exemplifies the pathological predominance of the factor of inhibition. Finally, in the sphere of consciousness the normal consciousness presents the physiological, and excitation mania exemplifies the pathological predominance of the factor of excitation, while sleep shows the physiological and narcosis and coma the pathological predominance of inhibition. I beg you not to quarrel with me over the particulars in this statement.

Now the conditions and substances which might influence the phenomena of excitation have been studied extensively. What constituents of the animal body might be specially concerned in the processes of inhibition? To this question another query was joined in my mind. Four substances are the main inorganic constituents of the animal body; they are sodium, potassium, calcium, and magnesium. The effects of sodium, potassium, and calcium upon muscle and nerve have been studied very extensively. But not so with the effects of magnesium; they have hardly been touched upon. May this inorganic constituent of the body be indeed of no importance to the vital processes? Or may not magnesium be just the substance which favors the process of inhibition? For years the last-mentioned possibility was more than a guess to me. In studying the effects of intracerebral injections of various substances which produced the immediate onset of characteristic convulsions, I made the observation that the injection of magnesium sulphate produced no convulsions at all, but, on the contrary, a state followed which was similar to that of paralysis—a state of general inhibition.

That is the hypothesis upon which Dr. Auer and myself have conducted for the last eight months in the Rockefeller Institute various studies of the effects of magnesium salts upon the animal body. Several series we have completed, others are in progress. But so far all our results had one general feature in common: we have not yet come across one single fact which could be interpreted that magnesium salts favor excitation; but, on the contrary, all the found facts point unmistakably to the conclusion that these salts produce inhibitions, depressions; and beyond all expectations these depressions proved to be of a very profound character.

So far, then, our experiments have indeed sustained our theory. But we did not come forward to ask you to accept our hypothesis. We wish to communicate to you our facts, and we have told you of the hypothesis which was the means of bringing these facts to light. As to the hypothesis, wise men look sometimes upon theories simply as tools to dig out hidden treasures, and, if you wish, you might with reference to my pet theory be as generous as

*Read at a meeting of the Academy of Medicine, December 7, 1905. From the Rockefeller Institute for Medical Research, New York.

Fiesco, and say, "The Moor has done his duty, the Moor can go."

Now to our results, which we shall state in the briefest possible way:

In one series of experiments we have injected intravenously solutions of magnesium sulphate or magnesium chloride. The main result of that series is that a very small dose of these salts is sufficient within a few seconds after injection completely to abolish respiration and inhibit all movements of the body. Without artificial respiration the animal would die without the struggles of asphyxia and without any sign of sensation. The animal lies there perfectly limp without any outward sign of life except for the nearly normal heart-beat and blood pressure which are affected only by larger doses. Artificial respiration restores the animal, but sometimes only after an hour's continuous work. If injected very rapidly, 0.1 of the salt will produce a profound toxic effect, but in a very slow injection nearly 1.5 of the salt can be administered within one hour without any visible poisonous symptoms. This last fact possibly explains the daily experience that thousands of people are frequently enough taking large doses of sulphate of magnesium without any other than a purgative effect. Some absorption surely takes place, but it may be so slow as to render it harmless.

In another series we have applied solutions of magnesium salts directly to the nerve trunks. When a 6 per cent. solution of sodium chloride is applied to a motor nerve the muscles belonging to it will soon begin to contract; the concentrated salt stimulates the nerve. The application of a 25 per cent. solution of magnesium sulphate, however, produces no such effect when applied to a motor nerve, and apparently causes no pain when applied to a sensory nerve. But it causes a complete block in the nerve, it abolishes conductivity and excitability. When the sciatic nerve of an animal is stimulated it causes effects in the central direction and contractions of the muscles of the leg. But when a solution of magnesium salts is applied to some part of the nerve it causes there a complete block; stimulations central to this block will cause central effects but no contractions of the muscles of the leg, and stimulations peripheral to the block cause contraction but no pain or other sensations. The same was observed in other nerves of various functional characters. Magnesium salts act here like the local application of cocaine. But by washing out with physiological salt solution, or still better, with Ringer's solution, conductivity and excitability can be completely restored.

In a third series we studied, in seven different species of animals, the effects of subcutaneous injections of solutions of magnesium salts. By this method in all animals a state of complete narcosis can be produced from which they can completely recover. There is complete anesthesia with perfect relaxation of the muscles, without impairment of the vital reflexes. The narcosis can last two or three hours. Larger doses of the salt are fatal also by subcutaneous injection.

In a fourth series of experiments we have injected solutions of magnesium salts in the subarachnoidal space of the spinal cord, mostly by lumbar puncture. The anesthetic effect of this procedure was clearly seen in the experiments on dogs, cats, and rabbits, but it is difficult to carry out lumbar puncture in these animals, and the results are not always beyond some doubt. It is different with monkeys; in them lumbar puncture can be carried out with the same ease and reliability as in human beings. The results were uniform. The injection of magnesium sulphate in a dose of about 0.06 per kilo animal in the third lumbar space will cause, within a minute or two, complete anesthesia and paralysis of the tail and posterior extremities. Within an hour the anesthesia will spread upward, reaching neck and head, and soon a sort of paresis of the entire animal appears. The monkey, who an hour before was fighting and biting every one coming near him, now lies perfectly limp, offering no resistance. The lid reflexes are never abolished, there seem to be some hyperesthetic areas around the ears and head, the heart-beats are hardly changed, but the respiration is slowed. It is not easy to decide how much perception and consciousness are impaired. The animal would remain in this state for many hours, but the following morning would be found completely recovered. Three animals stood such injections a few times, at comparatively short intervals, apparently without any after effects. A dose four times as large as the above proved to be fatal to the animal within a few minutes, apparently due to paralysis of the respiratory center. The horizontal position of the animal apparently hastens the spread of the anesthesia and paralysis towards the head.

To recapitulate: intravenous injections of very small doses of magnesium salts inhibit the respiration and cause paralysis of the entire body; local applications to nerve trunks block the conductivity and abolish the excitability of the nerves; subcutaneous injection produces deep narcosis with complete muscular relaxation, and subarachnoidal injunction produces nearly immediate anesthesia and paralysis of the posterior extremities. All these inhibitory and anesthestic phenomena may completely disappear again. To these statements we may add, from some of the series of investigations which are now in progress, that intravenous injections of magnesium salts stop almost instantaneously all intestinal peristalsis, and that a severe tetanus and opisthotonus produced in monkeys by tetanus toxin can be completely relieved for many hours by subarachnoidal injection of magnesium sulphate.

These facts are surely new and surprising, and they concern a substance in such common use as Epsom salt.

Now a few remarks regarding the practical test I have mentioned at the beginning of this paper. The effects of intraspinal injections were so prompt, so striking, and so harmless, that I felt encouraged and prompted to induce some of my surgical friends to test it in proper cases of human surgery. Twelve patients have so far been operated upon under the sole or essential influence of the intraspinal injection of magnesium sulphate. Seven operations were performed by Dr. Haubold at the Harlem Hospital, two by Dr. Blake at the Roosevelt Hospital, and three by Dr. Willy Meyer at the German Hospital. I wish to express here my deep obligation to these gentlemen for their readiness to give a trial to this method, and to-night I hope to hear them tell of their experience. I shall permit myself, however, to give a brief survey of the experience gathered so far from that small number of cases.

As I have stated above, the dose employed in monkeys was about 0.06 of the magnesium sulphate per kilo animal. The highest dose employed so far in human beings was about one-third of that amount, 0.02 of the salt per kilo, or rather one c.c. of a 25 per cent. solution for each 20 pounds of body weight of the patient. At first I did not expect to obtain a complete effect from the salts alone on account of the smallness of the dose, and I have, therefore, advised that it be aided slightly by general anesthesia. But we have learned from our cases. Only in the first eight some chloroform was administered;

in the last four cases no general anesthetic was given. We have learned that the best time for operation is about three to four hours after the spinal injection.

Of the four patients who received no general anesthetic, three were operated upon after such an interval, and although the amount injected in these cases was less than in any of the others (perhaps not more than one c.c. to 26 pounds body weight), and although two of the operations were very painful ones, the patients, nevertheless, felt practically no pain at all. One other patient who, through some miscalculation, received one c.c. of the 25 per cent. solution to about 16 pounds of body weight, was operated upon in the leg one hour after the injection without the aid of a general anesthetic; but two and a half hours later this patient passed into a deep, general anesthesia, in which he remained for about five hours. The pulse varied between 70 and 80 during the entire time, and was of good quality; but the respirations fell to 10 per minute. A spinal puncture in which some of the spinal fluid was let out and the spinal cavity treated by repeated irrigations with sterile physiological saline solution soon restored the respirations to normal.

In one case of rectal fistula the spinal injection seemed to have very little effect, and about two hours after the injection the patient had to be operated upon with the aid of one ounce of chloroform, which he took very badly. Nevertheless, soon after the operation paralysis of the legs sets in which lasted a few hours. It is probable that even in this case the patient could have been operated upon three to four hours after the injection without a general anesthetic. In the other cases which were operated upon early with the aid of a general anesthetic, the amount of the anesthetic used varied between 1.5 c.c. and 15 c.c. of chloroform. In a complicated case of appendicitis, the operation on which lasted 47 minutes, the patient received 7.5 c.c. of chloroform. Pulse, respiration, and blood pressure remained perfectly normal, and the lid reflex was present throughout the operation, which was carried out without the slightest resistance on the part of the patient.

To sum up the experience as far as I could gather from these twelve cases: One c.c. of a 25 per cent. solution of sterile magnesium sulphate to 25 pounds body weight causes, in three to four hours after intraspinal injection, paralysis of the legs and the region of the pelvis, and analgesia, which is sufficient to permit the performance of any operation upon these regions. Sensation and motion return within 8 to 14 hours; retention of urine and the necessity for catheterization may be present for one or two days. There is, however, one case in which only a moderate dose of magnesium sulphate was used, but the after-effects were very prolonged. Retention of urine lasted for about twelve days, and the paresis improved only very slowly; for days there were also irradiating pains into the legs. It is too premature to discuss the causes for the protracted after-effects in this particular case. I am inclined to believe that it was due to some of the incidents of lumbar puncture, and was not specifically an effect of the magnesium sulphate. I feel quite confident, however, that an irrigation of the intraspinal cavity soon after operation will shorten or do away with all after-effects.

A dose of one c.c. to 20 or 18 pounds body weight would permit, a few hours after the injection, the performance of extensive operations on the abdominal cavity, and probably even higher up without the aid of any general anesthetic. However, from what I have seen I am of the opinion that it is preferable not to wait so long, but rather to operate about two hours after the injection with the aid of a very small quantity of chloroform. But in this case I would urge that a lumbar puncture be made again immediately after the operation, and a quantity of spinal fluid be let out at least as large as that of the injected solution of magnesium sulphate, and then that the canal be irrigated several times with sterile salt solution, finally leaving some of this fluid in the canal.

Of two patients who had the same dose of magnesium (1 c.c. to 20 pounds), and who throughout the prolonged operation were under complete anesthesia with the aid of chloroform, the one who had only 7.5 c.c. of it, but on whom no lumbar puncture was made after the operation, remained in a state of general anesthesia for some 20 hours, and had some other after-effects for about 4 days after the operation, while the other patient who had about 15 c.c. of chloroform, but in whom lumbar puncture and irrigation were carried out immediately after the operation, had practically no unpleasant after-effects at all.

I shall not dwell on this occasion on many of the interesting particulars incidental to the spinal injections of magnesium sulphate in human beings. I shall only point out especially the scientifically important observation, already mentioned, that with a dose of 1 c.c. of a 25 per cent. solution to about 16 pounds body weight a state of deep general anesthesia followed which lasted many hours. In this case the circulation remained normal, but the respiration sank to 10 per minute. In other cases, with somewhat smaller doses of the solution, but with the addition of small quantities of choloroform, the general anesthesia lasted even longer. In these cases circulation and respiration remained perfectly normal, but there was some slight vomiting, or rather a little regurgitation, after the awakening of the patient.

Before closing the subject of anesthesia I wish to add the following remark: The immediate dangers of anesthesia concern the function of the heart, blood pressure, and respiration. The dangers of heart failure and shock are almost beyond our control. Not so with respiration. As long as heart and vasomotor system are not profoundly affected we can overcome nearly every case of failure or respiration, at least in animals, by properly conducted artificial respiration. The dangers of anesthesia by magnesium sulphate come practically only from respiration; heart and pulse remain normal. But the usual methods of artificial respiration employed in human surgery are absolutely insufficient in emergency cases. I wish to urge most emphatically that hospitals should be provided with a Fell-O'Dwyer apparatus* for artificial respiration, and I would especially urge this as a prerequisite for the employment of magnesium sulphate as an anesthetic.

Finally, I feel a special delight in being able to report that at the Roosevelt Hospital a desperate case of tetanus was cured. After the employment of 115 c.c. of antitoxin without any avail the first injection of a solution of magnesium sulphate afforded great relief for 36 hours, and after a few more injections the patient seemed to be cured. Dr. Blake, in whose service this happy incident occurred, will tell you the particulars.

Obviously, there are many other conditions in which the inhibitory and anesthetic properties of magnesium sulphate could be tested, but I do not wish to enter here into a vague discussion of untried possibilities.

# REMARKS ON THE TREATMENT OF CERTAIN AFFECTIONS INTERESTING BOTH THE PHYSICIAN AND THE SURGEON:

## TUMORS OF THE BREAST, MOVABLE KIDNEY, FRACTURES OF THE PATELLA, FLAT FEET, ECTOPIC PREGNANCY, CIRRHOSIS OF THE LIVER WITH ASCITES, AND ENLARGED PROSTATE.*

By CLARENCE A. McWILLIAMS, M.D.,

NEW YORK,

INSTRUCTOR IN SURGERY, COLUMBIA UNIVERSITY, N. Y.; SURGEON TO TRINITY HOSPITAL, ASSISTANT SURGEON TO PRESBYTERIAN HOSPITAL.

In casting about in my mind for a suitable subject with which to address this Society, it occurred to me that it might prove interesting and instructive to discuss the treatment of certain common affections with which the general practitioner is brought frequently in contact, and for an opinion upon which he is consulted. While the physician rarely has the desire or perhaps the technical skill to perform the operation, at the same time he is expected by the patient to advise correctly as to whether anything had better be done or not, and if so, what? From this standpoint then let us take up a few subjects, and, in passing, let me remark that the principles of practice here described are those commonly held at the Presbyterian Hospital, New York. There is no intention to be dogmatic about the many controversial points touched upon. Each person must make up his mind for himself about these questions, but in doing so the experience of others is very helpful.

**Tumors of the Breast.**—While we shall speak specifically of tumors affecting the female breast, at the same time it must not be forgotten that the male breast likewise may be the seat of tumors both benign and malignant. Any tumor in the female breast should be looked upon with the greatest suspicion and distrust, for it is a well-known fact that 85 per cent. of all such tumors are malignant. A small tumor in a young girl may be closely watched for any increase in size or other physical change. Sooner or later, however, it should be removed, as it may undergo malignant change. In older women no one by physical examination can say whether a given tumor, when small, is malignant or not—only the microscope can then differentiate. There should be no waiting in order to make the diagnosis by physical examination. For the purpose of microscopical examination, the small nodule should be excised under cocaine or a section removed. Should the growth prove to be malignant, then the radical operation ought to be at once performed. Patients with larger tumors, the diagnosis of which is uncertain, are prepared as for the radical operation. Ether is then given and a section of the growth is removed, which is handed at once to the waiting pathologist, who makes a frozen section on the spot, and thus determines the nature of the tumor. The patient is maintained under light etherization during the ten minutes required to make this examination. Should the report be that it is a benign growth, then the tumor alone or the whole breast is removed, depending upon the amount of disorganization of the breast. Should the growth be malignant, then the radical operation is at once proceeded with. This consists in the removal of the entire breast, the excision of the skin going wide of the growth, both pectoral muscles, and the lymphatics and fatty tissues of the axilla. In one hundred operations for cancer of the breast at the Presbyterian Hospital there were four deaths as the immediate consequence of the operation. At the end of three years there was no recurrence in 34 per cent. of the cases (*Medical News*, April 28, 1900). It is the duty of the medical profession to impress upon the laity the fact that malignant tumors of the breast when small are rarely painful, that the smallest nodule in the breast may become the source of the greatest danger to life, and that the only hope of a cure lies in an early and radical operation. Disability after such an extensive operation is surprisingly small, there being under my observation at the present time a woman who had both breasts and all four pectoral muscles removed, who, notwithstanding, is now earning her living at the washtub. *X*-ray treatment should never be applied to a patient in whom the tumor is still operable. Recurrences that are inoperable should be treated by the *x*-rays, or radium. In operable recurrences in menstruating women life has been prolonged by the performance of double oophorectomy (*Lancet*, July 11, 1896, *Münchener medizinische Wochenschrift*, 1898, No. 24, also Sept. 5, 1905).

**Movable Kidney.**—This condition has proved a stumbling block in the path of all of us, I am sure, for nothing is more difficult to successfully handle than patients with this complaint. The first requisite is to determine just how many of the symptoms are to be referred to the loose kidney, as a cause, with its attendant prolapse. It is a very familiar fact to all of us that many women have very movable kidneys with no symptoms from them whatsoever. Many have in addition prolapse of the other abdominal organs, liver, stomach, intestines, etc. To take cognizance of the kidney alone, leaving out of consideration the remaining viscera, would be to make a very fatal error.

The symptoms referable to prolapsed kidneys, either with or without general enteroptosis, may be divided into three classes: 1. Those with pain alone. This is apt to be a dull, aching backache, situated at the upper lumbar vertebra, and radiating transversely around the waist. There is nothing characteristic about it which would differentiate it from the innumerable causes of backache in women, hence the frequent lack of appreciation of its importance as a symptom. In the recumbent position this pain disappears. It may be absent. There may also be attacks of actual renal colic, due to twisting of the renal pedicle. 2. Those patients with gastrointestinal disturbances, with or without the pain as just described. 3. Those with nervous, neurasthenic, and circulatory symptoms with or without gastrointestinal symptoms, with or without pain. It is exceptional to have symptoms referable to the urinary apparatus, and for this reason the underlying cause of the trouble is often overlooked. These disorders when present are manifested by irritability of the bladder, which is pronounced in the day, and disappears at night in the recumbent position. In this respect it differs from irritation of the bladder due to uterine disease, which is more often complained of at night, causing the patient to get up a number of times during the period of rest.

In considering the treatment, I may say, at the outset, that there are two extremists who hold very divergent views: the one believes and teaches that an operation should never be performed in these cases, and the other holds that an operation should always be done. Needless to say, each view is extreme and unreasonable. It seems to me that the proper attitude lies between these radical opinions. The result of considerable study of these patients

*Read at a meeting of the Orange Medical Society, N. J., October 20, 1905.

at the Presbyterian Hospital has led us to adopt the following line of treatment, the indications being, first, to elevate and maintain the prolapsed viscera in their proper positions, and, second, to correct functional derangements and improve general nutrition. Let us consider first movable kidney, which is not complicated by prolapse of other viscera. We may hold this in place in one of two ways, first, by mechanical support, *i. e.* by a belt or by a corset, or, second, by open operation. Mechanical support should always be tried before operation is resorted to, and I feel confident that it will suffice in about 75 per cent. of the patients. The belt is the less expensive, the cheapest properly constructed one, made to order, costing about $6.00. The ordinary laparotomy belt is not to be used for these cases, for it is not successful. The movable kindey belt should be made tight over the hips, exerts maximum pressure over the suprapubic area, fits snugly at the waist, and extends to just above the umbilicus, the region above the waist being free. On the inside of the belt a pad is placed which should exert pressure just below the lower pole of the kidney, thus supporting it by obliterating the space immediately below the kidney, into which it might otherwise sink. The pad should not press upon the kidney itself. The belt is put on in the recumbent position, the knees being flexed and the hips elevated, and it is tightened and fastened after the viscera have been crowded toward the diaphragm by the hand. The wearing of a belt in addition to their ordinary garments, including a corset, is distasteful to fastidious women. This fact led Gallant to endeavor to so adapt the ordinary corset, made in a particular way and according to definite principles, as to serve the same purpose as the belt. It has proved most satisfactory in our hands and is highly to be recommended. It is made to reach down to the pubic bone, it exerts the greatest pressure over the pubis, curves in gracefully at the waist line to support the kidney. It fits tightly over the hips and suprapubic area, snugly at the waist, and loosely above that point. The ordinary corset fits most tightly over the lower ribs, which are pressed in, while the movable kidney corset is loosest at this point. The usual corset by its area of pressure forces the viscera downward into the pelvis, while the kidney corset forces them upward, by pressure from below, into a space beneath the diaphragm, which is left free. The corset must be laced and put on according to definite rules, about which the patient must be carefully instructed. The corset laces are put in as follows: Beginning at the sixth eyelet from the bottom, lace downward, carry lace through bottom holes twice, insert top lace from upper eyelets down to waist line, leaving the back open five or six inches. Wrap the corset around the waist, lie down upon the bed, pull the corset well down over the hips, draw up the knees, raise the hips well up from the bed, crowd the viscera toward the diaphragm, and fasten the corset in front, beginning with the lowest hook, and proceed upward. While the hips are still raised draw in the lower laces, closing the corset as snugly as possible before rising. The top lace must be left loose, for if tightened it will cause distress after eating and pain in the pit of the stomach.

The corset thus made has the great advantage of not adding another garment to the ordinary woman's apparel. Its costliness, however, the cheapest being made at $12, debars our poorer patients from its use.

Constitutional treatment combined with such a support is all that is required to cure the great majority of these patients. Are these measures unavailing, then operation should be seriously considered. Should the movable kidney be only one element in a general enteroptosis, then one should only operate when persuaded that the kidney itself is responsible for most of the trouble, *i. e.* when there is the characteristic dragging pain relieved by holding the kidney in place. Should pain be the only symptom, then the operation is almost certain to cure, but a very guarded prognosis should be given in patients who have complicating gastro-intestinal and nervous symptoms.

There should be practically no mortality as a result of the operation. In following 45 unselected patients for some time after operation at the Presbyterian Hospital, it was found that 52 per cent. were cured of subjective symptoms, 35 per cent. were benefited, and 10 per cent. were unimproved. Recurrence of the movability occurred in 16 per cent. (*Medical News,* Oct. 4, 1902.) Sir Frederick Treves in *The Practitioner* of January, 1905, describes a particular kind of truss which he has devised to hold the kidney in place. He speaks as follows: "Of its efficiency (the truss) I can speak very definitely, for since 1895 I have abandoned the operation of nephrorrhaphy except in the following examples: Cases in which there were torsion symptoms, some cases in which the patient would be residing in the tropics, many hospital cases in which the patient had to work for her living and could neither indulge in a long-sustained rest nor properly manage a truss requiring some delicacy in its adjustment. In 95 per cent. of the cases the truss has proved absolutely efficient; the kidney has been kept in place, and the distress that has existed has entirely vanished." From personal experience, I may say that the same results are obtained with the corset.

**Fractures of the Patella.**—Our practice is to operate openly in almost all cases where age or some constitutional dyscrasia do not contraindicate, provided there be considerable separation of the fragments, *i. e.* one-half inch or more. Our reasons, briefly, are a much speedier recovery with a better anatomical and functional as well as a stronger result as a rule. Bony union is almost always obtained with the open operation, and almost never with conservative treatment. The reason why conservative treatment does not produce bony union is not because of the blood effused into the joint, nor because of the spasm and pull of the quadriceps extensor muscle, for each of these can easily be overcome without operation, but because of the fibrous aponeurosis stretched across the front of the patella, which, as the fragments separate, is drawn out into a ragged fringe which falls down between the fragments, thus preventing any close bony approximation, regardless of whether adhesive straps are used or whether a subcutaneously passed suture without an open wound is employed. The sole objection to the open operation is the danger of infection of the joint, but this has never happened in any of our cases. Powers in the *Annals of Surgery,* 1898, reckoned the mortality in 711 cases as about ¼ per cent., surely a very low death rate. Compound fractures of the patella, if they be seen at once after the accident, are thoroughly cleaned and the joint drained. The fragments are then sutured, if there has not been too great soiling of the joint, in which case the wound is allowed to heal before the fragments are sutured. Old compound fractures with infected wounds are cleaned up and allowed to heal before any attempt is made to suture the bone. Refracture of the patella may occur after either conservative or operative treatment. It has been reckoned at 27 per cent. of all the conservatively handled fractures. After open operation with suture refracture is much less frequent. We do not

operate in simple fracture of the patella until at least five days have elapsed after the injury, because infection has been shown to be eight times more liable to occur if the operation be done immediately after the injury when one must deal with acutely inflamed tissues, than if one operates at an interval when processes of repair are well established.

The operation is conducted under the most strict asepsis. The hands are always gloved, and, if it be possible, are not allowed to come in contact with any part of the joint, only instruments touching the joint surfaces. The transverse incision of the skin is used so as to expose the fibrous expansions of the capsule on the sides of the patella, which are usually torn, often to a considerable extent. The joint is first thoroughly irrigated with salt solution to remove the effusion of blood and then the frayed-out tags of aponeurosis, hanging down over the fractured surfaces, are cut away. The fragments are approximated and sewn together by interrupted sutures of chromicized catgut which pass through the firm, fibrous aponeurosis covering the anterior surface of each fragment. The torn fibrous expansions of the capsule on the sides of the patella are likewise sutured. The skin alone, and not the joint, is usually drained. A plaster-of-Paris splint is applied, extending from the ankle to the groin, a window being cut in the splint over the joint for the purpose of dressing the wound. At the end of sixteen days the plaster splint is removed daily for the purpose of massage, not only of the muscles, but also of the patella itself, which is grasped as a whole and very gently moved from side to side, the idea being by this maneuver to prevent the adherence of the patella to the femur. At the end of three weeks the plaster splint is removed permanently, and is replaced by a posterior wooden one, and the patient is then allowed to walk about with this splint in position. At this time also the joint is begun to be gradually and carefully passively flexed when the daily massage is given. At the fourth week all splints are removed and the patient is encouraged to walk about and to bend the joint. In six weeks the patient is ready to leave the hospital with a very serviceable knee. Conservative treatment requires from four to six weeks longer time. This operation should never be performed except by those who have had experience in operating, who have formed the habit of taking the utmost precautions, and who have the aid of careful and skilled assistants. Flint, in the *Annals of Surgery*, October, 1905, page 575, reports 150 operations for simple fractures of the patella. Seven of these became infected and required subsequent operations, *i. e.* one out of every 21 or 22, or about 4.66 per cent.

**"Rheumatism of the Feet."**—Very many patients come to us complaining that they suffer from pain in the feet, for which they have been treated medically for a long time without the slightest benefit. They have all been treated for rheumatism, and they usually say that the pain is becoming steadily worse. Many declare that the trouble came on without ascertainable cause, or that it resulted from much standing on the feet, to which they were unaccustomed; others attribute it to a contusion, or to a sprain, or to an increase in bodily weight. It affects persons who have to stand a great deal rather than those who walk a great deal. In making a diagnosis in these patients the last thing to be thought of is rheumatism, for it is a very rare affection. The following conditions should be kept in mind while making an exact and careful examination: flat feet, including the weak foot, anterior metatarsalgia or Morton's toe, gonorrheal arthritis or periarthritis, tuberculosis of the ankle or tarsus, the result either of an old fracture or sprain of the tarsus, tabes, etc. Morton's metatarsalgia is a neuritis or neuralgia of one of the metatarsal nerves, usually that between the third and fourth toes, caused by compression of the nerve between the two metatarsal bones, which come together by reason of the breaking down of the anterior transverse arch under the ball of the foot. This condition is usually easily remedied by placing a small pad in the center of the ball of the foot, held in place by a transverse piece of adhesive plaster, which prevents the metatarsal bones from spreading apart. Time prevents my speaking of any of the remaining difficulties save that of flat feet. This very frequent trouble is of easy diagnosis when the pathological changes are well marked, *i. e.* flattening of the arch with abduction of the foot, but the time of greatest pain is really when there are no evidences of flatness or abduction, for which reason rheumatism is most frequently and erroneously diagnosed. It is when the ligaments, holding up the arch, first begin to weaken and to stretch that we are apt to find the greatest suffering. It produces the so-called weak foot, which is the first stage in the production of the flat foot.

There is no constant relation between the amount of flattening and abduction and the symptoms of pain and discomfort, for we see feet at times so flat that the whole arch rests on the ground, yet without pain. The sole criterion is the presence of pain. The weak foot causes pain and weakness in the instep, under the malleoli, under the soles, or in the calf, without any physical signs except possibly some tenderness, and without deformity. For pains in the feet without physical signs, treat as for flat feet, instead of giving the salicylates and alkalies, and the patient will get well speedily. When untreated the weak foot develops into the flat foot with the physical signs of prominent head of the astragalus, flattening of the arch, and abduction at the midtarsal joint, together with pain as in the weak foot.

Treatment of the weak foot consists in supporting the weakening plantar fascia, and in developing the tibialis posticus muscle, whose tendon passes immediately beneath the fascia, thus strengthening the latter. To accomplish the first object, the foot being held forcibly in adduction and dorsal flexion, a strip of two-inch adhesive plaster is started at the external malleolus and carried under the sole and up the inside of the leg almost to the knee. A second strip is passed similar to the first and just in front of it, the object of these strips being to hold the foot in adduction and to take off the tension from the weakened fascia. To develop the tibialis posticus muscle, the patient is instructed to go through the exercise, morning and night, of raising himself on his toes, and then, throwing out his ankles, to come down on the outer border of his feet to his heels again. The patient should be told to walk with the feet held parallel to each other, and to remain in this attitude when standing. If the above adhesive inversion strips do not support the ankle sufficiently, as evidenced by the continued presence of pain, then in addition to the inversion straps, the ankle may be strapped with a one-inch figure of eight, each turn overlapping the preceding by about half an inch. This strapping goes down the outer side of the foot, under the sole, up the inner side, around the leg and down again. The sole of the shoe may also be built up one-third of an inch on the inner side of its exterior. When the foot has become actually flat, in addition to support we shall have to lift up the arch, which must be done gradually, and we shall also have to overcome the adduction. In many patients to lift the arch up to its full height suddenly and at once by a flat-foot

plate causes torture and is entirely unnecessary. Felt pads are used, such as I show here, cut to fit each individual foot, the highest part of the pad being placed under the prominent head of the astragalus. This pad is elevated in height gradually in each successive one. Inversion and adduction straps are used as already described over this pad. We continue to elevate the arch until there is a cessation of pain, and no further than that point, for this indicates the normal height of that particular arch, and to still further elevate it would only continue the pain. We may now fit a flat-foot plate into the shoe, but the plate should be no higher than the already elevated arch. The same exercises are employed as before. At the time of applying each pad the foot should be massaged and gradually twisted into its proper position, *i. e.* into adduction.

When the flat foot is so fixed in its deformity as to be immobile then there is no way but to give ether, forcibly correct the deformity, and after the foot has being forced into inversion and adduction, it is put up in a plaster splint for a month, after which it may be treated as an ordinary flat foot.

The result of treating all these varieties of flat feet is most satisfactory both to the surgeon and to the patient, but it requires patient study and attention to details. The almost certain cure, however, amply repays all efforts.

**Ectopic Pregnancy.**—The possibility of this condition must always be kept in mind in attempting to diagnose the etiology of obscure pelvic discomfort and pain. Pelvic masses should be carefully watched, and if there be a suspicion that extrauterine pregnancy may be present, then operation should be urged and insisted upon, for the danger of sudden rupture of the tube with death from internal hemorrhage is very great. Nothing is more trying than to be called to a case of acute rupture of an ectopic sac, evidenced by collapse, shock, intense pelvic pains, with signs of intraabdominal bleeding. The life of the patient will often depend on the rapid diagnostic acumen of the physician and the promptest operative measures. There should be no waiting for shock to become less before operating, for if the bleeding continues, as it is prone to do, the shock will only deepen. In these patients a laparotomy is almost always performed by us, except in a few cases of low bulging masses into the cul-de-sac, where a vaginal section may be made. Pelvic hematoceles are always the result of extrauterine pregnancies.

A short time ago it interested me to ascertain the after-history of our patients upon whom operations for ectopic pregnancies had been performed. I succeeded in tracing twenty-four patients. Four of these had had vaginal operations, most of them probably being instances of tubal abortion. Three had normal pregnancies following the operation. None had a recurrence of the ectopic pregnancy. Twenty of the patients had had laparotomies for extauterine pregnancies, the affected tube and ovary being usually removed. Five of these afterward had full term children, while two required subsequent operations for second sudden acute extrauterine pregnancies, with recovery in each case. Thirty-three per cent., therefore, in this series had subsequent normal pregnancies, and 8 per cent. had secondary acute extrauterine pregnancies requiring immediate operation.

**Cirrhosis of the Liver, with Ascites.**—The deplorable condition of these patients when ascites has once made its appearance appeals to us all constantly. The ascites yields to no medical treatment for any length of time, and we are forced to resort to tappings which relieve but for a short time, and which must be repeated at constantly shortening periods. There has been considerable discussion in medical circles as to the advisability of submitting these patients to the operation of suturing the omentum to the abdominal wall, combined with freshening the surfaces of the liver and spleen by rubbing, these two latter procedures being done with the hope of forming adhesions between these viscera and the diaphragm. In this way an attempt is made to form a collateral circulation between the portal system and the systemic one, thus affording a channel in the adhesions by which the blood may get around the obstruction in the portal circulation in the liver. It may be interesting to consider briefly the results of ten of these operations performed in the Presbyterian Hospital, this being the total number thus treated. The mortality has been exceedingly high as a direct result of the operation, seven of the patients having succumbed thereto. This is an appalling death rate, and one well calculated to make one hesitate to advise the operation, notwithstanding the forlorn and hopeless condition of these patients. In explanation, however, it is only fair to state that all of them were in a most unfavorable condition for any operation, which was only resorted to as a last desperate hope, most of them being worn out after innumerable tappings. To reduce this excessive mortality, it will simply be necessary for the medical attendant to send his patients to the surgeon at a much earlier date, *i. e.* on the first appearance of the ascites. The ultimate results of the operation are not as yet quite definitely determined. Of the three patients who recovered from the immediate effects of the operation at the Presbyterian Hospital all have been traced since the operation. One man, sixteen months after the operation, was wonderfully benefited, being practically cured. His digestion was perfect, he had gained much weight, and there had been no reformation of the ascites since the operation, previous to which he required tapping every five days. The second patient, four years after the operation, is earning his living as a day laborer. There has been no recurrence of the ascites and his general nutrition is excellent. The third patient, a woman, received no benefit whatsoever. She returned to the hospital in two months much distended, requiring frequent tappings thereafter. She steadily depreciated in health.

In a recent article the mortality of the operation is placed at 15 per cent. in hypertrophic cirrhosis, and at 40 per cent. in atrophic cirrhosis. In another article, containing a list of 224 hitherto reported operations, 70, or 35 per cent., are said to have resulted in a complete cure.

The fairest conclusions on the subject of operation and its contraindications seem to be expressed by Lord and Sears (*Boston Medical and Surgical Journal*, Vol. 147, No. 11, p. 235), in saying that the "conclusion seems reasonable that operative measures are never justified in the presence of jaundice, and rarely with a history of hemorrhages from the digestive tract, since the fibrotic changes in the liver are probably so far advanced as to cut off expectation of greatly prolonging life. But, when practically sound heart and kidneys exist, and the general nutrition is so well maintained as to show that sufficient glandular structure still remains in the liver to maintain its function, and when competent medical treatment has failed, operation may be considered." I could only add to this the admonition to operate early.

**Enlarged Prostate.**—In the brief time left to my disposal I must of necessity treat this important topic somewhat superficially. The views regarding the proper treatment of hypertrophied prostate are

undergoing rapid development, so much so that the opinions here expressed represent merely the current ideas on the subject which perhaps may have to be shortly changed. As to the diagnosis, I can do no better than to quote C. H. Mayo (*Medical News*, April 26, 1902) as follows: "Every male over fifty years of age who complains of frequent micturition of small amounts, sudden stoppages of flow, the symptoms extending over some time, or who reports that total retention has occurred, requiring catheterization or aspiration, leads the surgeon to think at once of prostatic hypertrophy, or of stone. The diagnosis is completed by rectal examination, sounding of the bladder, and the examination of urine passed, which latter determines the question of cystitis and its character. By passing a catheter while one finger is inserted in the rectum, the depth of the prostatic urethra can be estimated by the distance traversed in the prostatic portion before the urine flows. The quantity of residual urine is now ascertained, the condition of the bladder muscle is determined, also the size of the bladder by irrigation. The next important step is the general examination of the patient with regard to the condition of the nutrition, heart, arteries, kidneys, general appearance, and age." It must be borne in mind that urethral strictures are extremely rare in men of the prostatic age, and almost all cases of so-called stricture in old men are cases of prostatic impediment in the posterior urethra. Dribbling of urine is a symptom of overdistension and not one of incontinence.

The symptoms are obstructive and inflammatory, the latter usually being dependent on the decomposition of residual urine. I shall not go into them further, but shall take up the question of treatment, which is a difficult one to formulate in the present state of the subject. The views expressed are my own individual opinions on the matter. It seems to me that it will be necessary at the outset to divide these patients into two distinct classes, first, the well-to-do patient who has time enough and sufficient intelligence to properly take care of himself; second, the average working man who, even should he have the intelligence, will rarely have the necessary time to give to his treatment. Treatment in the working man should consist at once in the operative removal of the prostate, provided there be no constitutional contraindication to the same, because the placing of a catheter in his hands will likely be but the preliminary to signing his death certificate. In the well-to-do man we may apply at once either palliative or operative measures. Each patient may be studied by himself, and no plan of treatment is applicable to all. Palliative measures consist in treating any posterior urethral inflammations by massage, sounds, instillations, etc., and insistence upon having the bladder emptied, as soon as the desire is felt, to prevent overdistension of that viscus, the occasional passage of urethral sounds to straighten out the posterior urethra, the building up of the general nutrition, the avoidance of excesses in eating and drinking, hot rectal enemata to relieve the prostatic congestion, hyoscyamus may be given for urinary discomfort as well as the use of hot sitz baths at night, santal oil, salol, or urotropine to keep the urine sweet, and lastly, and most important, the careful use of the catheter. It seems to me that it is important to have a surgeon supervise these cases of prostatic hypertrophy in conference with the attending physician as soon as it is necessary to resort to catheterism, for then cases that will ultimately require an operation will be early recognized and permanently relieved with comparatively little risk, and thereby much unnecessary suffering will be prevented. The mortality of the operation would then drop to a very low percentage. The surgical world is of the opinion that the danger to the patient commences as soon as it is necessary to resort to the daily use of the catheter, because of the cystitis which, sooner or later, is apt to be the result. All our energies should be bent to prevent infection of the bladder. The patient must be thoroughly instructed as to its use and the precautions to be taken to render it sterile before its introduction. The catheter should be used only when there is residual urine, the amount of which will determine the number of catheterizations. If the residuum is less than two ounces, no catheterization is necessary. When the residual urine runs between two and four ounces, the bladder must be emptied every evening by the catheter, for without this the nocturnal distress cannot be relieved. A residuum running from four to six ounces provokes symptoms in the daytime and requires the catheter twice a day, morning and night. If there are more than six ounces of residual urine, add one more catheterization a day for every additional two ounces present until the catheter is used six times in the twenty-four hours, and never oftener. It should always be used at stated and regular intervals. The catheter should be made of soft rubber and elbowed, or doubly elbowed. At times a stiffer catheter may be necessary, when it can be made of woven silk, but a metal catheter should never be placed in the hands of a patient to use himself, for fear of trauma to the urethra and prostate. Cystitis is benefited by bladder irrigations, etc., also by leaving a catheter continuously in the bladder for a few days.

Such is the palliative treatment of this trying disease. When shall we operate? We may answer this in general by saying that operation is called for only when palliative treatment is a failure. If the symptoms grow constantly worse, if the suffering becomes severe, if the patient cannot urinate without the use of an instrument, if catheterization is painful or impossible, if the patient is too ignorant or careless to trust with a catheter, if only a catheter of very small size can be introduced, if attacks of obstinate retention occur, if there is persistent or recurring cystitis or hematuria, if there are signs of beginning infection of the kindey, if the residual urine gradually increases in amount, and if stone be present, the bladder should be opened. Operation should not be postponed until the patient becomes really sick. Give palliative measures a reasonable trial, and when they show signs of becoming ineffectual, then urge operation while the patient is yet in good condition, for it is neither fair to the surgeon nor to the patient himself to delay until the operation is only held out as a last despairing resort.

The development in the treatment of prostatic hypertrophy in the future will be along the line of earlier operation. The question to be decided is whether the dangers attendant upon the catheter are not greater than those of a radical operation performed at the onset of the symptoms caused by the obstruction? If this can be proved to be true, is not the proper time to perform a radical operation reached as soon as it becomes necessary for the patient to resort to daily catheterization?

In early operation the results are most satisfactory, recovery rapid, the mortality varying between five and seven per cent. In complete prostatectomy in elderly patients with long-standing obstruction and secondary complications, the prognosis is grave, the mortality ranging between fifteen and eighteen per cent. Even though the operation be survived, if the bladder in these advanced cases happens to be

hopefully disabled, dilated, atonied, infected, the results obtained by the operation are negative.

The perineal operation of Young is the one almost always performed at the Presbyterian Hospital. In ninety per cent. of all cases the gland can be readily removed by means of a median perineal incision. Young's prostatic tractor is found to be of inestimable help. Castration, vasectomy and allied operations have been given up, as they afford no permanent relief and fail to justify their statistical mortality.

50 East Fifty-third Street.

## ROUTINE PROCEDURE OF THE CLINIC FOR THE TREATMENT OF COMMUNICABLE PULMONARY DISEASES OF THE DEPARTMENT OF HEALTH.

By JOHN S. BILLINGS, Jr., M.D.,

NEW YORK.

The treatment of tuberculosis in sanatoria and dispensaries is attracting a great deal of attention at the present time. For that reason a description of the routine procedure followed at the Tuberculosis Clinic of the Department of Health may be of timely interest and value.

The clinic is located at 967 Sixth avenue, New York City, adjoining the Department of Health, in a building especially designed and erected for the purpose. It was opened March 1, 1904, and has been a success from the start.

The clinic is open daily, except Sundays and holidays, from 9 A.M. to 4 P.M. and from 8 to 9 P.M., classes being conducted morning, afternoon, and evening. The class on Tuesday, Thursday, and Saturday evenings is limited to colored patients, colored physicians being in attendance.

All the floors and metal furniture are cleaned every morning and the building is disinfected with formaldehyde gas weekly. The gowns supplied to physicians and employees are disinfected at the same time.

The officers of the clinic are: the Director, Executive Associate Director, Medical Associate Director, and Chief of Clinic; twelve attending physcians; two being on duty for each class; six assisting attending physicians available in case of absence of attending physicians; three attending laryngologists; a physician in charge of the *x*-ray room; five nurses (a nurse in charge and one each in the men's clinic, the women's clinic, the registration room, and in the throat room); one drug clerk; one watchman and three scrubwomen.

The name, address, age, sex, nationality, employment, history number, and clinic class of each new patient is entered in a daily journal, also the history number, sex, class, and diagnoses of all patients returning for treatment. An admission card numbered to correspond with history, with its envelope, a sputum jar, and handkerchief, are supplied to each new patient, together with instructions as to the care of expectoration. The information required on the front of the primary history card is then obtained by the registration room nurse. All histories, with their attached later histories, throat histories, and district nurses, reports of home conditions are filed by number, in the registration room. The following system of filing is used: (1) "Active" cases under observation; (2) Cases in hospital; (3) Cases "not found at address given"; (4) Discharged non-tuberculous cases; (5) Inactive, tuberculous cases; (6) Dead cases (obtained from daily tuberculosis death list). All histories are submitted to the Chief of Clinic before filing. A name index card and an address index card are filed alphabetically for each case. In all cases referred to the Clinic, a report is mailed to the physician or institution referring the case, giving the result of examination.

All recommendations by the attending physician for the admission of cases to Metropolitan, St. Joseph's, Lincoln, Seton, and St. Vincent's (S. I. Branch) Hospitals are referred directly to the Department of Charities. In each case a report of such action is made to the Division of Communicable Diseases and the patient is given a card, giving his name, date, age, address, the diagnosis, and the name of the hospital preferred by the patient, which he presents at the Department of Charities. Arrangements for the admission of patients to Riverside, Raybrook, and other sanatoria are made by the Chief of Clinic through the Division of Communicable Diseases.

Each Monday a report is made by the Chief of Clinic to the Division of Communicable Diseases, giving the number of patients seen during the previous week, classifying them as old, new, male and female, the number of prescriptions issued, and the number of cases referred to hospitals and charitable organizations.

All deaths from tuberculosis, as reported daily by the Bureau of Records, are looked up in the Clinic records; such histories are filed separately.

Sputum and urine specimens are sent to the Diagnosis Laboratory of the Department at the close of the day's classes, the slip accompanying each being numbered to correspond with the patients' history number. All results of examination are noted in the sputum record book and on the patients' history card. (If an applicant for examination is apparently not tuberculous, a skeleton history is made out and sent to the physician who decides as to the final disposition of the case.)

All new cases of tuberculosis are reported by card one week after their visit, to the office of the Division of Communicable Diseases of the Borough in which they reside. Doubtful cases, later proving tuberculous, are similarly reported. All the records of the Clinic are filed in the registration room, and from there all reports and recommendations are forwarded. In the examining rooms the patients at their first visit are weighed, the body temperature, pulse, and general condition noted on the history; a complete physical examination made, the results noted, and a record is made of treatment ordered or of recommendations for *x*-ray examinations, extra diet (milk and eggs), admission to hospitals, or discharge.

The patient receives thorough instruction from the attending physician as to diet, mode of living, and exercise; special effort being made, where hospital care is indicated, to induce the patient to enter an institution; in addition, a circular of instruction printed in the language that the patient speaks is supplied—German, Hebrew, Italian, Russian.

Medicines, when ordered on prescription from the Clinic formulary, are supplied from the drug room; special prescriptions, for medicines not in the formulary are obtained from the drug laboratory. Every new case is referred to the throat room for examination and treatment. Cases in which the diagnosis is doubtful are referred to the *x*-ray room for a report from the attending physician in charge of that room, a radiograph being made and kept on file. Every patient continuing under treatment is visited by a nurse. Her report of the home conditions when returned, is attached to the patient's history card for the information of the physician, who indicates how frequently her

visits should be repeated (except in urgent cases, this is not oftener than once in ten days). If visits are to be repeated, suggestions as to diet and general treatment are noted by the physician for the nurse's information.

In connection with the examination and treatment of cases the following points are observed: Each new patient is carefully studied, and at the first and subsequent visits an earnest effort is made by the physician to gain that confidence, and to exercise that moral control of his patient, which are so necessary to good results. To this end, whenever it seems advisable, the patient is frankly told the nature of the disease, the result of the sputum examination, the weight, and the general prognosis. This information is, however, given only to the patients themselves or to those accompanying them.

The great importance of proper and sufficient food, fresh air, and hygienic daily living is emphasized.

The result of the physical examination is dictated to the Clinic nurse by the physician, the following abbreviations being used (Dr. S. A. Knopf). Only the extent of the lesion is shown on the diagram of the chest.

A temporary, tentative diagnosis is made for each patient and written in black ink in the proper space on the history card. The final diagnosis is added as soon as possible thereafter.

At each subsequent visit of the patient, the body temperature, weight, pulse, medication, and general condition are noted on the history. A complete reexamination of the chest with diagram is made at least once in every two months. Patients are advised to return as frequently as the physician considers necessary, the interval between visits being not longer than one week. No patient is refused examination and such medication as is necessary; those having no tuberculous lesion are referred to general hospitals and dispensaries. If for any reason the physician considers that a tuberculous patient should not receive further treatment, the matter is referred to the Chief of Clinic, with a brief statement of the facts in the case.

No patient is discharged as free from tuberculosis if there is cough and expectoration, unless three negative sputum reports have been received, and the physical signs and general history fully warrant such action.

Deserving patients who are in need, are recommended for financial assistance to the Division of Communicable Diseases, by the attending physician, and such recommendations are forwarded to the Charity Organization Society, Association for Improving the Condition of the Poor, United Hebrew Charities, Brooklyn Bureau of Charities, etc. When special diet (milk or eggs) is required, a monthly order on the New York Diet Kitchen Association is forwarded to the Division of Communicable Diseases for investigation and distribution by the district nurse.

Patients not returning for treatment within two weeks, and those of whom notice of reference to the Clinic has been received, but who have not applied for treatment, are visited by district nurses.

The attending physicians are expected to arrive punctually at ten A.M., two P.M., and eight P.M., and should enter their names and the time of their arrival and departure in the time book in the registration room. If for any reason a physician is prevented from attending his class, he should notify the Clinic promptly by telephone.

No tuberculous patient may be discharged except by request, and previous to discharge, patients considered to be cured must be examined and their discharge approved by the Chief of Clinic.

Prescriptions are written in duplicate over carbon paper and show the date, patient's clinic number, and the physician's signature. Each prescription is recorded on the history card in every instance. If the physician desires that the patient should be revisited by the nurse, enter a hospital, receive charitable aid, be discharged from treatment or transferred to other classes, he states this fact on the history card.

Each new patient is referred to a throat class for examination, report, and treatment, if needed.

All patients must attend the classes to which they have been assigned on their first visit. Patients applying for emergency treatment, however, are examined and treated by the physician to whom they may be temporarily assigned. Prescriptions are supplied only to bona fide patients of the Clinic and they must not be renewed except for patients personally attending the Clinic or on presentation of their admission card. Exceptions may be made for good reasons and at the discretion of the attending physician. When the Clinic formulary is not used, both original prescription and copy must be approved by the Chief of Clinic.

Nurses report promptly at 9 A.M. and remain until 4 P.M. or later if necessary. At the night classes, nurses on duty report at 7.30 P.M. One hour is allowed for lunch, but at least one nurse must always be in the Clinic between 12 M. and 2 P.M. Each Clinic nurse must see that the supplies and instruments of the room under her charge are in good order.

Thermometers must be kept in a solution of 1 to 100 carbolic acid. All diagnostic instruments are wiped each day with a cloth wet with a solution of 1 to 100 carbolic acid.

During the noon hour all the windows and inside doors are opened for the airing and ventilation of the rooms.

At the close of each class all histories are returned to the registration room, the physician's name and the date being entered on each. All sputum specimens are placed in the collection box, and rooms left in good order.

# THE TREATMENT OF BRONCHO-PNEUMONIA.

By SAMUEL A. VISANSKA, Ph.G., M.D.,

ATLANTA, GA.

PHYSICIAN TO THE CHILDREN'S DISPENSARY OF THE WOMAN'S BOARD OF CITY MISSIONS AND KING'S DAUGHTERS HOSPITAL.

As the season is upon us when the physicians will be called to treat numbers of such cases, would it not be well to discuss the very best methods of reducing the death rate of this dreadful disease, carrying off thousands of children each year, and which, next to the summer diarrheas, is most fatal? It might be termed the winter disease of infants. There are scarcely any two physicians who treat the disease alike; and this being the case, would it not be more beneficial to both patient and physician, if we could get together, and bring down the treatment to a practical, and not a theoretical, basis? The theory of medicine is one thing: the practice another; blessed is the doctor who is practical!

Taking nature as the best physician, there is no disease which requires more intelligent assistance than that of bronchopneumonia. The two vital organs are affected from the beginning, the lungs and heart, and often a severe enteritis occurs. The age of the child and its surroundings will have to be considered also. The first requisite to treat a case successfully, is, as little as you think of it, to get the confidence of the family. Unless you do, there will be all kinds of suggestions from them as to the internal and external treatment. A good neighbor comes over with the very thing that cured her child, and the parents, intelligent ones, too, are willing to try it. If you use one form of external application and the baby is not doing well, the mother is told of something a doctor used across the street; that patient happened to get well and you will often be influenced to use it. The text-books do not take up these points I mention, but experience, especially my first experience, has brought this to my mind. This meddlesome interference on the part of grandmother, parent, and neighbor has caused the death of many a little patient. My advice to every physician is to be master of the situation, or step down and out. We all should realize that bronchopneumonia is, in a great majority of cases, a secondary disease, and as a rule, bronchitis is the primary cause. This may be either a simple bronchitis, or that which occurs as a part of infectious diseases, among which are measles, whooping-cough, diphtheria and membranous croup, influenza, and possibly typhoid fever. Of course the specific cause of the inflammation is probably the pneumococcus of Fränkel, but the *staphylococcus* and *streptococcus pyogenes*, the bacillus of Friedlander, or, as has been demonstrated, the tubercle bacillus may be the exciting cause. Of the predisposing causes of catarrhal pneumonia, age is the most important, and in children under three years of age it is the lobular form of pneumonia which is found in a great majority of cases. It is especially most fatal in cases occurring under two years of age. With a knowledge of the morbid anatomy and symptoms in our minds, the question might be asked, By what method can we lower the death rate? First, we should be able to make a diagnosis and tell the dividing line between the preexisting bronchial trouble and the extension into the terminal tubes and peribronchial tissue, as a number of errors of diagnosis have been made. Second, the predisposing cause should be borne in mind. My experience has taught me that pneumonia complicating whooping-cough requires the most active treatment, and for convenience we will divide the treatment into hygienic, external, and internal.

Hygienic Treatment.—The room should be large and have at least two windows, and one with a fireplace is preferable. The temperature of the room should be kept at from 68° to 70°. The windows should be opened from above and below, so as to admit plenty of fresh air into the room, as in mild cases that is our method of administering oxygen. It is almost criminal to have your patient in a stuffy room, with a big fire and every window and door closed. You need not allow a current of air to strike the child, as screens can be used. See that the bed of your little patient is made comfortable, and keep your patient on it most of the time, but the position of the child should be changed occasionally.

External Treatment.—By the external treatment I mean the various applications which have been applied to the chest to bring about resolution. This external treatment has been, and is yet, as great a puzzle to me as when I treated my first case. I wish I knew positively if such applications do good and which is most beneficial, and I would be extremely grateful if my fellow physicians could enlighten me on this subject. Many things, from the sweet-scented onion poultice to mother earth, have been used, and the man who gets the cure with one preparation or the other naturally advises its use, but is it in any way due to the external application? One will use a mustard plaster, the flax-seed poultice, a combination of turpentine, lard, and camphor, or fifty other combinations, and all claim good results, yet the death rate remains extremely high. We often forget what the disease really is, and the changes which have taken place. It is in consultation that you will find in most cases the absurdity of the external application, for if you are using one application, the consultant will often advise another, and yet there is no more reason for it than for the first. The theory of the external treatment is to attract the blood from the lungs to the surface of the body. To do that you must use a method to attract the blood equally and not just over the area of the chest wall. Nothing has served me so well as the hot mustard bath, and the child should remain in the bath until there is a pink glow over the body. It should then be wrapped in a blanket and placed in bed, where, as a rule, it falls into a peaceful sleep. At the same time the high nervous tension is relieved, the child breathes more easily, the pulse is not so rapid, the capillaries dilate, and the little patient often breaks out in a copious perspiration, which carries off the toxins, thereby throwing less work on the heart, kidneys, and intestinal canal. These baths should be repeated as often as necessary. Returning to the applications used (manufactured or home-made), I believe they do little good unless there is a pleuritic condition, and the child is made more comfortable by them. I prefer, then, the hot camphorated oil with mustard, applied anteriorly and posteriorly over the lung area by gentle massage; children enjoy being rubbed and will often go to sleep while it is going on. If you wish a quick counter-irritant the mustard plaster will suffice, then if you like, a close-fitting flannel undershirt, lined with cotton material, can be worn next to the skin. Nothing heavy should be allowed over the chest, as nature often brings into play all the auxiliary muscles of respiration, so as to convey

oxygen to the system. Then again, if these thick and heavy applications are used you cannot make repeated examinations of the chest without disturbing your little patient. Even the bedclothes should be light.

Internal Treatment.—As we usually find a torpid liver and furred tongue in these cases, it is well to begin with small doses of calomel, followed by oil, or a simple saline mixture. In not a few cases the gastrointestinal symptoms are a grave complication. Most children swallow the mucus, unless vomited up, therefore, keep the tract cleansed. Tympanites is often very troublesome, pushing the heart and lungs out of position, adding greatly to the discomfort of our little patient. The treatment then is the same as for gastroenteritis. For the cough, which is usually dry at first, the simplest and most palatable mixture is the best. I might write a number of different prescriptions, yet the one I give will usually answer:

℞

Spt. ammon. aromat.,
Vini. ipecac.....āā 5ii
Syr. pruni virg.....5vi
Syr. tolutan.....5iv
Aq. anisi.....q.s. ad 5iii

M. Sig.: A teaspoonful every two hours to a child one or two years of age.

Another is as follows:

℞

Pot. citrat.....gr. xxiv
Vin. ipecac.....5ii
Spt. minderer.....5vi
Syr. tolutan.....5iv
Aquæ.....q.s. ad 5iii

M. Sig.: A teaspoonful every two hours. If the cough is quite troublesome, add a few drops of paregoric or deodorized tincture of opium, according to the age of the child. Never order anodyne in the mixture, as you might wish to increase or decrease the dose or leave it out entirely.

Stimulants.—In the mild cases very little stimulation will be necessary; if so, whiskey alone will suffice. It is the severe cases, in which the pulse is so rapid you can scarcely count it, that will tax you to know what to do. Here whiskey, strychnine, and my sheet anchor, tincture of digitalis, should be used. For a child one year old I order thirty drops of best rye whiskey every three hours, and strychnine gr. 1-250–gr. 1-200. Should the child show the effect of too much strychnine, decrease the dose or leave it off for a while. Where the pulse is over 130 I use tincture of digitalis, and so far have never had any ill effects. Tincture of digitalis is a cardiac regulator. By its effect upon the cardiac ganglia and the muscle itself, it induces contraction, and strengthens the systole; by its effect on the vagi it prolongs the diastole. The result of this double action is that the diastole of the heart is lengthened so that more blood is allowed to enter the ventricles, while the systole is made stronger, so as to impart more vigor to the flow of blood into the arterial system, and at the same time a rapid and irregular action of the heart is slowed and steadied. As digitoxin, the most active ingredient, is insoluble in water, and is, therefore, precipitated by it, never order the tincture in combination, and give it in a few drops of syrup, so that it will be absorbed at once. No water should be allowed the patient for several minutes after swallowing. The dose is one to two drops every three hours for a child one year old. You must watch carefully the effect on the pulse and know when to leave off the digitalis. I have used adrenalin with good results, especially where there were signs of cerebral trouble.

Fever.—An ice cap to the head and sponging with either tepid or cool water is all I use to lower the temperature, and I have never had to resort to other methods.

Nourishment.—Happy are the little ones who are breast-fed; they not only have a greater power of resistance, but there is less tendency to abdominal complications. Broth, milk, and egg albumen will constitute the principal diet list.

Oxygen.—Oxygen should be used at the beginning, if the disease complicates whooping-cough. Here you have the double cough to deal with, and as a rule, get cyanosis from the first. Even when the lung is greatly involved in other cases, it is a good idea to give oxygen early, and not wait for cyanosis.

405-406 Peters Building.

## CIRCULATORY FAILURE, ITS NATURE AND TREATMENT.

By LOUIS FAUGERES BISHOP, A.M., M.D.,
NEW YORK.
PHYSICIAN TO LINCOLN HOSPITAL.

There is no fact more sadly evident in most serious diseases than that circulatory failure is the element most deserving of attention and most needing relief. It is our experience in general hospital work, and in the graver cases in private practice in which there is danger of death, to have constantly presented this problem in the double aspect of a process to be explained, and a condition to be relieved.

There are two great classes of cases. In the first the circulation has failed as part of the general failure of the whole system in wasting diseases. In exhausting and acute disease this is the case. The other class of cases, and the one which will occupy most attention is composed of those in which the failure is primarily of the circulatory apparatus. The mechanism of the failing circulation requires for its appreciation a study of the physiology of the circulation particularly in its relation to disease.

In former times this problem was approached purely from the point of view of the heart, and all such conditions were spoken and thought of as heart disease.

In the broader view of modern medicine we prefer to speak of circulatory disease because we know that the heart is only one element in the condition. The study of the philosophy and treatment of circulatory failure has been much elucidated when approached from the point of view of the study of variations of blood pressure, always keeping in mind the profound influence of the nervous system.

The supply of blood to the tissues is really an elaborated system of irrigation depending upon a proper pressure in the place from which the blood is to be drawn. The conception of the circulation of the blood is often erroneous. We can even conceive of the blood circulating without being of any particular use to the tissues. This might be the case where an artificial communication formed between the arteries and veins. The office of the heart is to maintain a suitable pressure in the arterial system, which is a reservoir from which the tissues receive their nourishment. The veins

reconvey the blood to the heart. The heart does not concern itself with the circulation of the blood, but with the maintenance of a suitable pressure in the arteries. Thus, when the body is quiescent, the amount of blood circulated is very small, and the pulsations of the heart are very slight.

Disturbance of circulation, though among the commonest manifestations of disease, are yet the most difficult to explain. The variations of local circulation manifested by every possible symptom from redness of the nose to coldness of the feet, make a study which we must lay aside for the present for a consideration of more important forms of circulatory disease.

There is this about the study of the graver forms of circulatory failure, including, as they do, the worst complications during the course of chronic conditions, that we are too apt to pass them over as hopeless, and not to give them the attentive consideration that they deserve. I must confess myself that until by the accident of having the care of cases of this class, which were of relatively great importance on account of the value of the lives at stake, that I had always treated them in the same routine manner, as I had seen done in my hospital experience. This seems still to be the attitude of the profession; it implies that there is little to be learned and less to be done for the more advanced stages of circulatory disease. Any one who feels thus, when in contact with a case showing extensive dropsy, numerous heart murmurs, paralysis present or impending, with every organ in the body from the brain to the kidneys clogged and functionally out of order, should know that even such a case has the possibility in it of restoration to comparative health. Particularly is this true of first and second attacks of circulatory failure, when they are cases in which the circulatory failure is the result of primary disorder of the circulatory apparatus, and not secondary to wasting disease. It is just the difference between a worn-out machine which an expert would despair of ever restoring to any useful purpose, and a machine in which only one part is out of order. So the paradox appears that the more striking manifestation of circulatory disorder, the more chance there is for the application of therapeutic measures.

Bearing in mind always the true function of the heart, namely, to maintain a suitable pressure in the arteries, we come immediately upon a great error in therapeutics, namely, the employment of vasodilators in the later stages of circulatory disease. They absolutely do no good, and were it not for the fact the nervous control of the peripheral circulation is too much paralyzed to respond to them they might do harm. In the presence of secondary low arterial tension, when the arteries are contracting in an attempt to create a back pressure, to enable the heart to bring about adequate tension in the arterial system, the use of vasodilators is foolish. In these cases we are misled by the fact that the road traveled toward the condition was through the condition of harmful high arterial tension.

Another error is in overestimating the importance of the usual kidney complications. Our attention is too much directed to kidney disease, while in many instances the patient does not improve until the idea of directly influencing the function of the kidneys is abandoned and the attention entirely given to the circulation. There is no greater stimulus to the action of any organ than the demand on the part of the system for the functions of that organ. The kidney is more than willing to eliminate the dropsical effusion; just as soon as its circulation is restored it frequently does so. Why induce a dropsical person to take large quantities of fluid, in order to stimulate a kidney which is acting particularly badly on account of secondary low arterial tension, and why give so-called diuretics to further irritate the kidney if inflammation is already present.

Another error in treatment of cases of advanced circulatory disease, is in underestimating the sluggishness of the whole organism, and the resulting necessity of increasing the dosage of remedies. Drugs, while meant to cure disease, nevertheless can never do so directly. They act through the exaggeration or restraint of some physiological function which needs more stimulation than it receives from the demands of the system, or needs to be controlled. Strychnine is a great standby in circulatory disease, because it arouses the nervous system, and thus stimulates all physiological processes. But in the graver case of this character strychnine in small doses has no effect whatever. It should therefore be given in divided doses until some physiological evidence of the drug is present. The same is eminently true of digitalis. Digitalis is proverbially one of the hardest drugs to handle. Its effects vary much in different individuals; the preparations vary much in strength or active principle. It should be given until there is evidence of its physiological effect. Third in importance I place the iodide of sodium, which a long trial has satisfied me to be of an eminently beneficial effect in circulatory disease accompanied by degeneration of fiber. In advanced cases morphine should be used to bring about satisfactory rest, provided of course, that the simpler hypnotics have ceased to act. The patient should not always be confined to bed. It is often very hard to make a patient comfortable in bed; while reclining in a ship-chair, or even a rocking chair, he is often much more comfortable. Nor must the comfort of supported elbows be forgotten where dyspnea is intense. In our absorption in the science of medicine we are too apt to overlook the cultivation of the art which is the fruit of all the rest. There is no class of work where art is in greater evidence than in giving comfort and restoring to comparative health the subjects of circulatory failure.

While concentrating our attention upon the symptomatic relief of circulatory failure, we must not forget that the promotion of vitality is the most important element in the restoration and maintenance of health. Vitality is the great element sought in the cure of tuberculosis, and many plans of treatment that are applicable to this disease are equally applicable to circulatory failure. The vitalizing effect of a change of climate, a change of food, and of massage and exercise should always be remembered. It is this element of vitality that makes it important to cut short the bed treatment of circulatory cases as soon as possible, and to promote in every way a more generous oxygenation of the system. Under wise management a patient, the subject of progressing circulatory failure, can many times be rescued from a situation which often appears hopeless. And under wise management the recurrence of these conditions can be postponed. Of course, each succeeding attack is more difficult to handle, and it is always a pertinent question, however bad the case may seem, as to how often the patient has been rescued from a similar condition.

There are, at the present moment, two patients in my hospital wards. One was admitted some weeks ago with a dilated heart, presenting murmurs at both valvular orifices, a chest full of fluid, and many other evidences of circulatory failure. This patient now has a heart free from murmurs, and every appearance of fair health. Another patient admitted only a few days ago, presenting a similar cardiac condition, and was suffering from general anasarca, so that to prolong life, it was necessary to withdraw the fluid from both chests and from the abdomen. This patient has also recovered from her cardiac murmurs, which were unquestionably due to dilatation, and is rapidly getting rid of the anasarca. Both patients recovered under what might well be called heroic treatment. I know that these things are often considered too commonplace for repetition in medical literature, but it seems to me that their great importance justifies a review of our ideas upon them from time to time.

54 West Fifty-fifth Street.

## THE THERAPEUTIC VALUE OF STATIC ELECTRICITY.

By MAY CUSHMAN RICE, M.D.,

CHICAGO.

PROFESSOR OF GYNECOLOGY AND CLINICAL ELECTROTHERAPY AT THE ILLINOIS SCHOOL OF ELECTROTHERAPEUTICS.

In consequence of its high intensity, static electricity is able to overcome a great deal of resistance and to permeate the cells and tissues of the body to a greater extent than any other electric current. Because of its low amperage, its polar effects are not so marked as those of galvanism, amperage being an important factor in producing electrolytic changes. For functional and nervous disorders static currents have no equal, as patients often are benefited who have resisted drug medication and climatic treatment, as well as various other forms of electricity. The fact that these currents so nearly resemble the normal physiological currents of the body largely accounts for the beneficial results obtained from their use.

The term static refers to bodies in a state of equilibrium. If equilibrium already exists, static electricity has no effect. If, however, there is a loss of equilibrium, that loss is supplied. Whenever the body is under a static charge, each nerve is taking up its own normal vibratory impulse. For example, I have often noted in treating patients with valvular heart disease a decided improvement in the rate and character of the pulse, the latter becoming quite normal, while the charge is maintained. Although the abnormal condition again appears after the cessation of treatment, by often repeated applications compensation is assisted and the general health of the patient improved. As with the pulse, so with the respiration and functions of the body in general, all of which are stimulated to normal physiological action.

There are so many modes of application of these currents, varying from the most mild, as in the breeze, to the exceedingly severe, the heavy spark, for example, with corresponding sedative or stimulating effects, that it is possible to adapt them to a great variety of cases. The positive breeze is especially valuable for relieving congestion. In sprains and contusions its early application is a most valuable adjunct to other treatment. Congestive headaches, which have resisted all other remedies, yield to a positive breeze; even the headaches of the menopause, which are generally most difficult to cure, respond to a course of treatment with the positive pole. If, on the other hand, the negative pole be used, the headache is increased in severity. Contrary to theory in general and the opinion of some electrotherapists, experience has fully convinced me that results depend largely upon the selection of the proper pole.

It is a common thing for physicians with limited experience in the use of static electricity to attribute its beneficial effects to suggestion. I have known physicians to treat at least twelve patients in an hour, allowing about five minutes to each treatment. No doubt any result obtained from such treatment is due to suggestion. The physician who is more anxious to make money than to cure the patient had better choose some other line of work. No static treatment can be given satisfactorily in less than twenty minutes, and in most cases one-half hour would be much better.

What class of cases is more puzzling to the general practitioner than the functional neuroses, neurasthenia, hysteria, and epilepsy? Whatever the causative factor, there is always present nerve irritation with faulty metabolism and resulting autointoxication. How often, after all else has failed, is the patient advised to try electricity more as a means of getting rid of a hopeless task than with any real expectation that electricity will be of any benefit?

The electrotherapist, on the other hand, administers with confidence the positive static breeze, knowing its power to allay nerve irritability, to bring about nutritive changes through its action upon cell protoplasm, to increase secretion and excretion, and improve elimination, and thus to prevent that autointoxication which is responsible for the most distressing symptoms of neurasthenia, namely, fatigue, headache, and insomnia. All this is accomplished without resulting depression or the patients becoming addicted to the use of drugs. So far as epilepsy is concerned, nothing can be said to cure it. However, I believe that electricity compares favorably with other forms of treatment. One of my patients, who had been having two epileptic seizures a week, was free from attacks for seven months, while during the six months following the cessation of treatment she had but two light attacks. This was an unusual result, yet I have always been fairly successful in these cases. While the results are only palliative, even these are a great boon to the afflicted individual, and are to be preferred to the stupefying effects of such medicines as bromides.

The static spark is the opposite of the static breeze. In the latter we have a marked sedative, in the former a pronounced stimulant. Sparks produce counterirritation and muscular contractions, and are powerful stimulants to the tissues. They are useful in breaking up adhesions, and in hastening the absorption of deposits. While they are particularly adapted to chronic rheumatism, they will abort acute rheumatism, provided patients are anxious enough to be cured to endure heroic treatment. I have been able to ward off acute rheumatism by three or four applications of static sparks. A young man suffering with acute rheumatism came to my clinic at the Illinois School of Electrotherapeutics. Three years before he had had an attack which had kept him away from his work for weeks. He said it was simply out of the question for him to leave his work again, and he was willing to endure anything that would make such a contingency impossible. He had two swollen, painful joints, to which I applied static sparks vigorously and followed it by a soothing breeze. On his return, two days later, the pain and swelling had subsided, but a third joint was

inflamed (quite characteristic of that disease); another treatment was given, and when he returned the third time, there was a slight stiffness, but no pain or swelling.

I never give sparks to timid patients, however, and never without the patient's consent, after having explained that the treatment is severe.

Contrary to the prevailing belief that inflamed nerves should be put at rest, W. J. Morton of New York considers sparks as much of a specific for acute neuritis as is quinine for malaria. My success with the Morton wave current in neuritis has been such that I have not been inclined to change from a mild modality to the severe, though no doubt successful spark method. Short, thick sparks, applied in rapid succession to ganglions so often appearing upon the back of the hand, will cause the wall of the sac, unless very thick, to rupture. Instantaneous evacuation of the cyst takes place and there is a rapid absorption. The walls of the sac adhere and a cure results.

While it is not possible to localize static electricity, the entire body always receiving somewhat of a general charge, the above mentioned, the breeze and the spark, are generally applied for the relief of some particular part of the body. A sprained ankle receives a breeze from the point electrode. A head-breeze is given for the relief of a headache. Sparks are given to stimulate the circulation of a part. Although at the same time there is a general charge, the treatment is given chiefly for its local effect. This is not the case with static insulation or electrification, as it is sometimes called. The latter is given not for its local but for its general effect. This form of current in particular is well termed an equalizer, because with this application there is a stronger tendency to restore lost equilibrium than is the case with any other form of administration of static electricity.

While the patient is receiving static insulation, every part of the body is heavily charged with a high potential current, which acts as a powerful tonic and restorative. Convalescence from exhausting diseases, such as typhoid fever, is greatly hastened by static electrification given twenty minutes daily. After operations upon the pelvic viscera, patients suffer from nervous disturbances due to a loss of equilibrium, especially after those which result in an early menopause. A few weeks of static insulation at this time greatly assists in enabling the nervous system to adjust itself to new conditions. Under static electrification tuberculous patients gain in strength, increase in weight, lose their night sweats, improve as to cough, and are rendered in better condition to resist the tubercle bacillus.

Of the many ways of applying static electricity, none has a wider range of usefulness than the Morton wave-current. By means of it, powerful muscular contractions are produced without causing pain. It is especially useful for the relief of pain in ulnar, brachial, sciatic, and other forms of neuritis. Even tic douloureux, that bête noir of physicians, yields surprisingly to the Morton wave current. About two years ago I treated an old gentleman with tic douloureux who, in spite of two operations, was suffering so intensely that he was unable to get more than five minutes of sleep at a time. After a month's treatment the patient awakened only once or twice during the night. Another patient who had a brachial neuritis with a paralysis of the arm following an operation on the axillary glands yielded to three months' treatment. At the end of that time she was able to use the affected arm to comb her own hair. The pain is frequently relieved after the first application. The Morton wave current is used for torpidity of the liver, and is my favorite method for the treatment of chronic constipation, many cases of long standing having been cured after from ten to twenty treatments. There are many other uses for all of these currents.

I have attempted in this brief paper to enumerate only some of the principal indications for this form of electricity. My object has been to emphasize the fact that while static electricity is by no means a cureall, it is so valuable an adjunct to other therapeutic measures that it should be better understood by the general practitioner. While all cannot be specialists, all should be sufficiently acquainted with every line of treatment to understand what will be the most likely to benefit the patient for whom he is held responsible.

## THE TREATMENT OF CHRONIC CONSTIPATION.

By J. A. MACMILLAN, B.A., M.B.,

DETROIT.

CONSULTING PROCTOLOGIST, HARPER HOSPITAL, CLINICAL PROFESSOR OF PROCTOLOGY, DETROIT COLLEGE OF MEDICINE.

In a number of cases of chronic constipation the associated pathological conditions are so urgent and important that they are not included in this category. Such for example are intestinal cancer and stricture. The same may be said of chronic constipation in patients suffering from grave nervous diseases. When all such cases are excluded we shall find that a very large proportion of these cases depends upon intestinal muscular atony.

In the early months and years of the disease many of these patients declare that, with the exception of the sluggishness of the bowels, they are in perfect health. Their capacity for work and their power of endurance does not seem to be much affected. From statistics covering nearly two hundred cases coming under my care during the past two and one-half years, I am led to believe that about eighty per cent. are due to atony of the intestinal muscle.

The rationale of the treatment about to be described would not be materially affected if the intestinal nervous system were included in the conception and the term "neuromuscular" substituted. The fundamental fact is that normally the stretching of the intestinal muscularis by the contained feces causes peristalsis. It is quite possible that the nerves may control and coordinate the muscular movements and convey the impulse from fiber to fiber. My confidence in the physiological and etiological importance of stretching the intestinal muscle arose primarily from the use of rectal tampons. Their therapeutic action in chronic constipation due to intestinal muscular atony is nothing short of specific. In a large proportion of cases enemata and cathartics may be discontinued from the first, and regularity in the passage of normal stools begins to be reinstated. The insertion of a rectal tampon is not attended with any difficulty for the physician and with little or no inconvenience for the patient. For the tampons I have used either absorbent cotton, cheese-cloth, or lamb's wool. It should be of sufficient size to cause some distention of the bowel. I have generally made it long and narrow, so that it may be rolled upon itself and the desired amount of stretching obtained. It can be inserted through an ordinary proctoscope and packed into place by means of a long forceps. I have found that when it is placed above the rectal valves and made to distend the gut at the rectosigmoidal junction the best results are obtained. Each tampon is provided with a piece of cord to facilitate its with-

drawal. The size of the tampon and the length of time it should be retained depend upon the degree of atony in the particular case. From two to six hours is generally sufficient. If a tampon is used between two and three in the afternoon and withdrawn at seven or eight in the evening a constipated movement will generally occur the following morning. Occasionally there is a movement when the tampon is withdrawn. The efficacy of the treatment is early made manifest by the fact that in nearly every instance there is a bowel movement also on the second morning. These movements are at first usually deficient in amount. In the great majority of cases I begin by using a tampon on alternate days, and as progress is noted increase the time between treatments. I am encouraged to present this therapeutic agent to the medical profession on account of the following considerations:

1. Prompt and uniformly good results following the use of tampons in more than one hundred cases of chronic constipation. Some of these have been under observation for over two years. The treatment was absolutely ineffectual in a patient suffering from a nervous disease resembling locomotor ataxia. In another patient with considerable tenderness in the region of the uterus and ovaries rectal tampons failed to relieve the constipation. In a patient suffering from what seemed to be chronic inflammation of the valvular region of the rectum, the tampons would produce regular evacuations for several weeks, but the chronic constipation showed a great tendency to recur. Another case which must be considered at least as a partial failure was in a woman thirty-eight years of age. She had suffered with a very stubborn constipation for a number of years. When she consulted me she said she had had no natural bowel movement during the past four or five years. She would often go for more than a week without an evacuation. Large quantities of very severe cathartics, followed by copious injections of water, were generally necessary; quantities of fecal material would then be expelled. Of late the evacuations had been attended with considerable suffering and some exhaustion, from which, however, she quickly recovered. Her general health was good, tongue clean, no headache, and appetite always good. This seemed to be a case of almost complete atony. The treatment by tampons improved her condition. By regulating her diet and devoting considerable time and attention to herself, she is able to get along without cathartics or enemata. This patient came from Michigan, and remained only three weeks for treatment. In two or three other cases the patients did not take the treatments regularly or for a sufficient length of time, and I do not know the results. But with these exceptions, all cases of uncomplicated atony of the intestinal muscle yielded promptly to this treatment, and many other cases as well, in which displaced uteri and ovaries, enlarged prostate, indigestion, or neurasthenia seemed to complicate the condition.

2. Muscle stretching by rectal tampon is a measure directed toward the removal of the immediate cause of the chronic constipation when it is due to muscular atony.

3. That distention is the physiological stimulus of peristalsis has been already referred to, and that the intestinal muscularis owes its very origin and development to this same agent.

4. Muscle stretching is a well-known therapeutic measure; its power of stimulating contraction has been long known in connection with the uterus and vagina. The distention of the stomach during gastric lavage is a powerful therapeutic agent for the relief of atony of the gastric musculature. The distention of blood-vessels when saline transfusion or enemata are used may very probably operate in the same way, increasing blood pressure by stimulating vascular and cardiac tone.

5. When distention is to be used as a therapeutic measure in a hollow viscus there are three important requisites:

(*a*) That the agent should produce no other effects that might militate against the desired result. Liquids suit very well for distention of the stomach, urinary bladder, and blood-vessels, and solids for the vagina, uterus, and lower bowel. In other words, the agent used must resemble in consistency the physiological stimulus. The lower bowel does not tolerate liquids any better than the urinary bladder tolerates solids. In this respect the rectal tampon is justified by its resemblance in consistency to the normal stimulus of peristalsis in the lower bowel. (The tampon is usually lubricated with vaselin.)

(*b*) The reaction or other chemical characteristics of the agent must not produce abnormal irritation. The fecal material in the rectum and sigmoid is sometimes acid, more frequently alkaline or nearly neutral; the rectal tampon therefore does not violate the rule, nor does it contain any chemical irritant.

(*c*) The amount and duration of the distention should be regulated by the amount and duration of the normal agent of distention. In the case of rectal tampons these two features are directly under the physician's control. Bearing in mind that feces collect gradually in the sigmoid and upper rectum, we know that physiological distention in this region may continue for several hours before strong peristalsis is induced. Accordingly, the tampon should be sufficient in size to cause some distention, and should be retained from one to six hours.

6. The rectal tampon compensates in these cases for the shrinkage of the fecal mass due to absorption.

7. The rectal tampon may be placed in that portion of the bowel in which distention is known to provoke normally the powerful peristaltic contractions which result in bowel evacuation, viz., the rectosigmoidal junction.

8. The rectal tampon is a therapeutic agent attended with no danger and little or no discomfort to a patient. It seldom interferes with his occupation.

It is obvious that the treatment by rectal tampons is not applicable to cases of obstipation due to hypertrophy of the rectal valves or other form of obstruction.

## REPORT OF A CASE OF A FRACTURED TIBIA AND FIBULA; DELAYED UNION AND ITS TREATMENT.

By L. M. KOMMEL, M.D.,

NEW YORK.

Mr. J. C. A., 30 years of age, while attempting to board a moving car, missed his footing and fell, sustaining a fracture of the right leg. This accident happened in the latter part of May, 1905. The fracture was reduced and a plaster-of-Paris cast was applied, but removed at the end of two weeks. There being no attempt at union, another plaster of Paris dressing was applied and allowed to remain for two weeks longer, and on removal only a slight attempt at healing was noticed. The cast was replaced. The patient was able to walk about with the aid of a pair of crutches.

At the end of three weeks—seven weeks after the accident—the cast was removed. All local symptoms having long since disappeared, the patient found that he still could not walk without the aid of his crutches, and the moment he tried to put the weight of his body on the broken member, excruciating pain would set in.

In the latter part of July, or about eight weeks after the accident occurred, I was called in to see the man. On examination I found a slight swelling of the right leg, slight discoloration at the point of fracture, slight lateral deformity, and marked anteroposterior movements of fragments, *i. e.*, pseudarthrosis. There was no localized pain or crepitus present.

From the above related history and findings I concluded that it was possibly a case of delayed union, due perhaps to improper or partial opposition of the fragments.

Before commencing treatment I had an *x*-ray picture taken of the limb. The plate showed the following: Complete fracture of both tibia and fibula; the point of fracture was at the junction of the upper two-thirds and lower third of the bones. The fibula was fractured transversely, the fragments overriding. The tibia was fractured somewhat obliquely, the fragments being apposed only at the outer angles. The lower fragments showed more than normal separation. There was very slight formation of new bone.

The treatment that I instituted was the artificial production of a venous hyperemia at the point of fracture by means of the tight application of roller bandages above and below the seat of injury. This produced a local reaction and promoted the formation of new bone and callus, and the consequent union of the broken bones.

The congestion of the part was allowed to remain for two hours daily. Phosphorus, gr. 1-100, in pill form, was given three times a day. This treatment was kept up for thirty days. At the end of the first two weeks the patient was encouraged to walk about with the aid of his crutches after the bandages were removed and the local congestion had disappeared. At the end of the third week canes were substituted, and finally, at the end of thirty days, the patient was able to discard entirely the artificial accessories and to bear the whole weight of his body on his broken leg.

Five weeks after commencing this treatment the patient walked twenty blocks (about one mile) to have another *x*-ray picture taken, and did not suffer any inconvenience from this long walk. The second plate showed an abundance of callus and complete union of fragments.

The facts of the case here described leave no doubt in my mind that the rapid and abundant formation of new bone was due entirely to the local reaction excited by the promotion of this venous hyperemia, and that nature would never have done her work in this case, as was shown by the little that was accomplished in eight weeks.

209 Alexander Avenue.

---

**Intussusception in Infancy and Childhood.**—J. H. Hess gives the following summary of treatment: Intussusception demands an early diagnosis and immediate treatment. There must be abstinence from all food, and purgation must be absolutely prohibited. The question of sedatives in the form of opium must rest with the physician. Irrigation may be tried once or twice under the proper conditions and in properly selected cases. There must be preparation for immediate laparotomy in case of failure, and complete anesthesia. Hot salt solution or plain water may be used under a pressure of not more than three feet, the fluid being allowed to remain in the bowel not more than ten minutes. The contraindications to irrigation are recurrence after a previous complete or partial reduction; the very acute and severe types of this disease which result in early destruction of the bowel wall, but which cases are fortunately not the most frequent type; signs of beginning gangrene or ulceration, evidenced by subnormal temperature, profound toxemia, and other septic symptoms; enteric intussusceptions. Laparotomy should follow failure of irrigation without delay; attempted simple reduction from below upward; in irreducible cases. Resection within the bowel in selected cases, or, where this is not feasible, resection with end-to-end anastomosis should be attempted where the patient's condition makes it practicable, as an artificial anus or simple packing about the bowel requires a secondary, and only too frequently fatal, operation.—*Archives of Pediatrics.*

**On the Urine Separator of Luys.**—F. M. Caird emphasizes the value of this instrument in various cases of obscure renal trouble. Luys has also shown its value in solving obscure diagnoses in the case of lumbar and other swellings of doubtful origin. This instrument is more easy to manipulate than the cystoscope. The method is within the power of the skilled physician, and may entirely replace the difficult catheterization of the ureters. The instrument should be sterilized immediately before use by plunging it into boiling water for five minutes. Soda will damage the rubber. The patient should assume the horizontal position and the urine is drawn off with a soft rubber catheter. The bladder is then washed out with warm sterile boric solution till it returns clear. No air must be allowed to enter. Thirty to forty grammes of the boric lotion are left in the bladder. There is little pain or difficulty in the passage of the instrument in the case of women. There may be some pain in the insertion of the instrument into the male urethra. If there is the slightest resistance the separator should be withdrawn and the urethra gently dilated with Hegar's bougies. In the process of the introduction of the instrument it may be helpful to place a finger in the rectum or vagina. When the fluid has escaped by the catheters, the patient is raised into a sitting posture on the edge of the table, the thighs being separated and the feet and back supported. The diaphragm is then raised and the contracting bladder grasps the instrument. The urine can then be collected. The diaphragm is lowered by reversing the screw and the instrument is withdrawn. After the patient's bladder is washed out with boric lotion he is sent to bed.—*The Scottish Medical and Surgical Journal.*

**Malaria in the Vicinity of New Haven.**—Charles D. Phelps speaks of his experience in relation to malaria, and summarizes his observations for the past ten years. They lead him to conclude that an attack of malaria is likely to be assumed by the patient, first where a disease is ushered in by a chill or chilly sensations; second, in the acute indigestion in children in Summer; the prompt cure caused by vomiting and purging being credited to the quinine which is at once given; third, almost any condition of weakness, sleepiness, or languor—pregnancy, the effect of bromide in epilepsy, the confinement in bed owing to a broken limb, the after-effects of a night's debauch. All of these are included among the writer's cases in addition to the numerically more numerous class of those who had simply "that tired feeling." The writer believes that results will speedily be apparent if the medical profession will only cooperate. In this climate mosquitos are practically absent during at least five months in the year. No new infections will take place during that period. The writer urges the necessity of giving other medicines a fair trial before using quinine in cases presenting indefinite symptoms. The patient who has malaria should be impressed that his duty is to continue treatment until his blood is entirely free from plasmodia, and he is no longer a menace to the health of those about him. If suitable precautions were taken the writer believes that the malarial problem in this climate would soon disappear.—*Yale Medical Journal.*

# MEDICAL RECORD.

*A Weekly Journal of Medicine and Surgery.*

THOMAS L. STEDMAN, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, December 16, 1905.

## THE ACADEMY OF MEDICINE AND THE PUBLIC.

ANNOUNCEMENT is made that on Friday evening, December 29, Dr. Thomas Darlington, Health Commissioner of New York, will deliver a public lecture at the Academy of Medicine on the results of the work of the two commissions appointed last spring to study pneumonia and cerebrospinal meningitis. The early findings of the pneumonia commission were published some time ago, and were interesting, though incomplete, but it is believed that those of the meningitis commission, while no less interesting, contain greater promise of fruitful results.

Apart from the importance of the subject of Dr. Darlington's lecture, the occasion will mark a noteworthy advance in the history of the Academy. The day of secrecy and mystery in the practice of medicine has passed. Public interest in medical progress is acute, and the newspapers give prominence to every new theory and discovery regarding the nature or treatment of disease, such matter being regarded as "news" of the first importance. This fact has been recognized by the Council of the Academy, and it has inaugurated these public lectures through which the public may be taken into the confidence, as it were, of the medical profession. It is the purpose of the Council to furnish a forum upon which medical men of authoritative position can voice the opinions of the profession upon the many topics that possess a common interest to both the layman and the medical practitioner. The lectures are intended to be popular, and, whenever possible, to be illustrated. They will be to the laity what the lectures of the Harvey Society are to the profession—a means of translating to the general body the technical work done by specialists.

Hitherto the newspapers have been forced to rely for their information regarding medical topics of public interest upon interviews with individual physicians, a system liable to great abuses, and one exposing the complacent "interviewees" to the often unjust accusation of "advertising." These public lectures under the auspices of the Academy of Medicine will do away in a measure with the newspaper need of individual interviews, but the principle might, we think, be extended with advantage. The lectures must of necessity be formal and be on prearranged topics, but it often happens that subjects arise overnight upon which the press wishes to be enlightened and cannot wait for a lecturer to prepare his theme and discourse upon it after a proper announcement. To meet such an emergency (the Koch disassociation of bovine and human tuberculosis, the various cancer cures, Behring's consumption prophylaxis, even Burke's radiobe nonsense, are examples) it might be expedient for the Academy to appoint a "publicity committee," composed, say, of a clinician, a laboratory worker, and one other, to which the reporters could be referred for a medical opinion. This committee, which might be anonymous so far as its individual composition is concerned, could be called at an hour's notice and formulate a provisional opinion which would be given to the newspapers as the professional judgment regarding the matter in question. The opinion given might not be final, of course, but it would be provisionally authoritative and would carry more weight than any which might happen to be given by the casual physician. It would satisfy the public, and would spare the "popular doctor" the pain of submitting to an interview on some subject of which he knows nothing, and which the report of his interview shows that he knows nothing.

This is merely a suggestion, but in the meanwhile it is a matter of congratulation that the Council of the Academy has inaugurated these public lectures, which cannot fail to be productive of great good. The tuberculosis exposition, which has just closed, has been of incalculable educational service, but the field of the Academy in public medicine is far greater, and it is hoped that much good will be accomplished by the lecture course which it is about to inaugurate, and by the further extension of this principle of the education of the laity in matters relating to public health.

## PHYSIOLOGICAL STIGMATA OF DEGENERATION.

SINCE the followers of the school of Lombroso first began to direct attention to the prevalence among all classes of individuals bearing on their bodies palpable evidence of certain mental or psychical defects, the study of this subject has developed to lengths that border on the extreme. Measured by the standards of some of the strictest of these censors of the human body, but few mortals would escape being docketed with telltale stigmata of one sort or another, and the happy distinction of inconspicuous mediocrity would be hard to attain. In the fields of criminology and morbid psychology, however, the study of the physical stigmata of degeneracy has proved of signal value, but although the alienist at least has not failed to derive practical benefit from it, the subject has not been brought very prominently before the attention of clinicians. It is true that some similar idea is suggested by the two old antithetical categories of the *habitus phthisicus* and the *habitus apoplecticus*, but these were regarded rather as mutually hostile manifestations of individual conditions, than as expressions of an inherited vice of somatic conformation. Stiller has for many years stoutly held out for a recognition of the etiological significance of such physical types, and in a recent publication (*Berliner klinische Wochenschrift*, No. 38, 1905), he associates the *habitus phthisicus* with the *habitus enteroptoticus*, and considers them as practically identical expressions of inherited weak-

ness founded on the *habitus asthenicus* or *atonia congenita universalis*.

In view of the modern tendency to accentuate the functional aspects of disease, the thought suggests itself that perhaps it may be possible to discover abnormalities of certain functions which can be regarded as physiological analogues of such physical signs as aural asymmetry, reduced facial angle, or high arched palate. Individuals exhibiting such disturbances would not necessarily be sick, and might for years live in apparent health until, at some moment of special mental or bodily stress, more or less slight and temporary aberrations of function would manifest themselves. Albu discusses this subject in the "Ewald Festschrift" of the *Berliner klinische Wochenschrift*, and suggests as possible affections of this decsription achylia gastrica and orthostatis albuminuria. He says that if the history of such patients is investigated with sufficient care it will usually be discovered that the sufferer is the victim of an inherited tendency to some disorder of metabolism, blood dyscrasia, or nervous disease. The abnormality of the patient's immediate or distant ancestors may be pronounced, or may manifest itself only in "irritable weakness of the nervous system," as often indicated by the syndrome associated with the neurasthenic type, of trembling hands, tongue, and eyelids, pulsating abdominal aorta, increased reflexes, floating tenth rib, etc.

In the heirs to such a tendency to disordered metabolism, the weakness may show itself in the special form of a localized disturbance of innervation of separate organs, resulting in damage to the particular function concerned. In illustration of this view, Albu describes cases of simple gastric achylia and orthostatic albuminuria which occurred in one or more children of very neurotic parents. The gastric achylia meant is, of course, the purely nervous form described by Einhorn and not the glandular atrophy depending on organic disease of the mucosa. The author agrees with Martins in regarding this as a form of congenital functional weakness of the stomach, depending on depression of the secretory nerves, and he holds that the custom of considering it simply as a neurasthenic symptom does not concede to it the dignity as a far-reaching entity that it deserves. The condition of orthostatic albuminuria again is certainly not physiological, but on the other hand it cannot be called a disease, since it may persist for years unchanged, and it is therefore to be termed a congenital renal weakness depending on a disorder of innervation of constitutional nature. This view is strengthened by the observations of Langstein, who discovered that in orthostatic albuminuria englobulin was always present, while it was never found in the urine of nephritis. This urinary englobulin is probably identical with that of the blood, and originates in an excessive production of the latter.

In conclusion, the author suggests that hemophilia may be considered in a similar light as exhibiting one of the forms of constitutional anomalies dependent on inherited weakness, and it is not unlikely that by applying a similar plan of reasoning various other affections might be included in the list of the physiological stigmata of degeneracy.

---

**The Cascara Harvest.**—The yield of cascara bark from the vicinity of Tacoma, Wash., is fully a thousand tons for the season.

## THE COMMISSIONER OF STREET CLEANING.

Among the appointments which Mayor McClellan will be called upon to make at the beginning of his new term, the one which, next to that of Health Commissioner, concerns especially the medical profession, is that of Commissioner of Street Cleaning. Dr. Woodbury has held this important place for four years, having been appointed by Mayor Low, and serving as a holdover during the present administration. From the standpoint of public health this office is one of the highest importance. The street is a natural receptacle for all sorts of filth; not only does it receive the droppings of horses and dogs, but it is a vast spittoon and a culture medium for all the pathogenic bacteria that infest the air-passages of the sick and the well; it is also often made use of as a urinal, and in certain quarters at night a place of deposit for human excrement as well. If the cleaning of the streets is neglected opportunity is afforded for the pullulation of all the disease-producing bacteria contained in this mass of filth, and the winds and the eddies started by the trolley-cars and automobiles throw the dust containing them into the mouths and nostrils of every inhabitant of the city. The responsibility of the Commissioner of Street Cleaning is, therefore, a heavy one, and an incompetent man may have to answer for the lives of thousands of his fellow citizens, especially of the children in the crowded quarter of the town.

Commissioner Woodbury has effected many reforms in his department during the four years of his incumbency. The wasteful plan, followed from time immemorial, of carrying all the refuse of the city streets out to sea and dumping it there, to be carried by the waves to the beaches of the Long Island coast, has been abolished. The ashes and other non-putrescible refuse are used for filling in parts of the water front, and so creating land of great value, while the combustible portion is used in part as fuel for an electric light plant. Other economies are also practised which entail a saving of large sums to the city.

In the important matter of actual street cleaning, however, candor compels us to say that Dr. Woodbury's record is not one to be proud of. The streets are, and for long have been, undeniably dirty, coated with slime in wet weather or when sprinkled, and giving rise to clouds of offensive dust at other times. This may be due, in part, as alleged, to a lack of funds for the purchase of improved machinery, but the chief cause lies in a failure to employ the material at hand to the best advantage. The street sweepers are not kept up to their work as they should be, and they go about their task in a slipshod and inefficient way that shows an absence of proper supervision. For this the Commissioner is, of course, directly responsible. His energies have been directed too largely to economical reforms to the neglect of the actual work of sweeping the streets. This is beginning at the wrong end. The essential thing, and the one which the Mayor should demand of his Commissioner, if he reappoints him, is to safeguard the health of the city by keeping its highways clean at whatever cost.

### The Tuberculosis Exhibition.

The tuberculosis exhibition, held at the Museum of Natural History, under the auspices of the National Association for the Study and Prevention of Tuberculosis, and the Committee on the Prevention of Tuberculosis of the Charity Organization Society, came to a close last Sunday, after having fully realized the expectations of its promoters. Several noteworthy objects were attained by this wisely planned and carefully executed project. In the first place a very large number of the laboring classes received a highly instructive object lesson in what tuberculosis means, and what can be done to avoid and to cure it even by those in comparative poverty. Most of the visitors were, perhaps, of a class which, while not above the necessity for instruction in matters of hygiene and prophylaxis, yet would be most advantageously impressed by so forceful a demonstration of the crying needs for betterment in the manner of life of the poor of great cities, and were, no doubt, by this direct ocular appeal imbued with a sense of personal responsibility in the matter which would make them willing apostles of the prophylactic doctrines. The great value for public instruction of graphic demonstrations, by models or otherwise, was strikingly illustrated, and it needed but a glance into the full-size reproduction of the tenement house bedroom to prove how much more convincing an argument in favor of reform in the poorer quarters of large cities this was than pages on pages of printed descriptions or statistical tables. The row of jars containing tuberculous lungs, revealing all their impressive phenomena of consolidation and cavity formation, if seen by sufficient numbers, would do more to keep expectoration off the floors of public places than warning notices or threats of arrest. But the most important result accomplished by the exhibition was one which, no doubt, its designers had in mind from the first, but which they wisely allowed to follow as a self-evident conclusion. No one who attended the exhibit and observed the interested crowds of visitors from all stations of society could well escape having the conviction borne in upon him that this should not be a merely ephemeral affair, but should be placed on a more stable basis. If an exhibition of this sort can do so much good with the comparatively small number of people it can reach in two weeks, why should it not be made a permanent affair? The similar collection recently assembled at Charlottenburg has been found by the Berlin authorities so valuable a medium for popular instruction that it is to be continued indefinitely, and we see no reason why the best exhibits of the New York exhibition should not be culled out from the large amount of available material and be accorded a permanent home in the museum building. The idea could, no doubt, with profit be amplified somewhat, and while the tubercle bacillus and its ravages would always form the *pièce de resistance* of the department, additional phases of sanitation and the combat against disease could be made instructive and interesting adjuncts, according to their seasonal distribution. Typhoid fever, the intestinal diseases of children, especially in relation to milk supplies, pneumonia, etc., might all be presented. The expense to the museum in money and space would not be great, and the theoretical and practical advantages to visitors would be fully comparable, to say the least, to those achieved by the beautiful and, no doubt, costly models showing the exact manner in which the Esquimau cuts the blocks of snow for his igloo, or the aboriginal African hammers arrowheads out of barrel hoops.

### Brain Tumor Complicating Pregnancy.

Tumors of the brain are uncommon, and instances of this condition complicating pregnancy are, indeed, very rare. A case of this character has lately been noted by Lobenstine and Welch ("Bulletin of the Lying-in Hospital of the City of New York," September, 1905), which is worthy of mention from the clinical standpoint, because the patient went to term despite the presence of this large growth in the right cerebral hemisphere, and but few symptoms were caused up to the very end of life. For six weeks previously the patient had had indefinite frontal headache and occasional nausea, which gradually became worse and was accompanied by vomiting a few days before admission to the hospital. A history of convulsions and the presence of albumin in the urine presupposed eclampsia—labor was therefore induced and terminated spontaneously. The patient's general condition seemed quite good, and only on the second day a slight irregularity of the pupils was noted. Alternate periods of unconsciousness and tonic convulsions and consciousness were followed by dissolution on the same day. The autopsy disclosed a very large neuroglioma ganglionare, a type of cerebral tumor of unusual occurrence. It is believed that these tumors are the result of disturbances of embryonal development in the brain and, continuing during extrauterine existence, are of extremely slow growth. The only way to account for the lack of symptoms during life is to assume that there developed a compensatory action of other portions of the brain, a process which has been observed to occur with other cerebral lesions of long standing.

## News of the Week.

**The Chicago Medical Society** has inaugurated the plan of having its members deliver popular lectures to the laity on subjects pertaining to medicine. These lectures are well attended, and the people take great interest in them. Recently Dr. George W. Webster spoke on tuberculosis before a large audience. He advocated legislation that would compel the notification of the City Health authorities in all tuberculous cases. By prompt reports, he declared the deaths could be reduced 40 per cent., which would mean 32,000 lives saved annually in Illinois. Every new lease for a flat or a house should have pinned to it a clean bill of health, and the public schools should be made an important center in the campaign against the disease. Rented homes, if there is suspicion of infection, should be disinfected. The school buildings should be constructed with a view to proper sanitation, and the curriculum should not be so crowded that pupils are overworked. The pupils should be given proper information regarding the spread of disease and the means of its prevention. Consumptive teachers ought to be barred, and consumptive pupils should not be allowed to enroll. Better provision should be made for the inspection of meat and milk. Special wards should be made compulsory adjuncts to the hospitals. Isolation houses should be provided, where consumptives too poor to go to private sanatoria might be treated at the public expense.

**Philadelphia Hospital Alumni Association.**—The nineteenth annual banquet of the Association of Ex-Resident and Resident Physicians of the Philadelphia Hospital was held at the Bellevue-Stratford Hotel on the evening of December 5. Toasts were responded to as follows: Blockley

Men in New York, Dr. James P. Tuttle; The Refining Influences of Blockley, Dr. Thomas F. Duhigg; Blockley Men in Military Life, Dr. George H. Halberstadt; Reminiscences, Dr. Roland G. Curtin; Blockley of To-day, Dr. Thea; Blockley as a Center of Medical Teaching, Dr. De Forest Willard. Dr. Alfred Stengel was toastmaster and the following officers were elected for the ensuing year: *President*, Dr. E. L. Duer; *First Vice-President*, Dr. H. C. Wood; *Second Vice-President*, Dr. R. G. Curtin; *Secretary*, Dr. E. R. Stone; *Chairman of the Executive Committee*, Dr. E. E. Montgomery.

**The War on Nostrums.**—At the annual meeting of the New Jersey State Sanitary Association, held at Lakewood, on December 8, Samuel Hopkins Adams, the journalist, delivered an address on the subject of patent medicines, in which he stated that bills will be introduced in the legislatures of New Jersey and other Eastern States this winter, which, if passed, will put the secret preparations out of business. Embodied in these bills are provisions compelling the makers of proprietary medicines to print upon their labels the composition and ingredients of the article, and also fixing the retail price of the preparation according to the actual worth of the ingredients. These bills, Mr. Adams declared, will be introduced by prominent legislators in each State.

**Trouble at the Rutland, Mass., Sanatorium.**—Dr. V. Y. Bowditch, until recently visiting physician to the Massachusetts Sanatorium for Tuberculosis at Rutland, has severed his connection with the institution, owing to a difference of opinion with the trustees regarding the duties of the medical superintendent. Dr. E. O. Otis has been appointed to fill the vacancy.

**Tuberculosis in the Government Departments.**—In response to a suggestion from the National Association for the Study and Prevention of Tuberculosis, President Roosevelt has appointed a committee to investigate the sanitary conditions existing in the government offices and workshops, with a view to recommending measures for the prevention of tuberculosis. The members of the committee are: Surgeon-General Robert M. O'Reilly, of the U. S. Army; Surgeon-General P. M. Rixey, of the U. S. Navy, and Surgeon-General Walter Wyman of the Public Health and Marine Hospital Service.

**The Interurban Clinical Society,** consisting of some of the younger medical men in New York, Boston, Philadelphia, and Baltimore, met on November 10 in the Cornell University Medical College and was entertained by the presentation of some unusual cases illustrating the serum treatment of various disorders. The laboratories connected with this College have lately produced some very valuable sera, and the results of this work were of great interest.

**Dental Surgeons for the Navy.**—A bill has been introduced in Congress by Representative Brownlow to establish a corps of dental surgeons attached to the Bureau of Medicine and Surgery of the navy. The bill divides the dental corps into three grades—"assistant dental surgeon," "passed assistant dental surgeon," and "dental surgeon," who shall have the same rank, pay, and allowance as officers in corresponding grades of the medical corps.

**The West Side Clinical Society of New York.**—A new medical society, with this title, was recently established. Meetings will be held the first Friday of each month, except July, August, and September, at the residences of members. The following officers have been elected for the current year: *President*, Dr. Charles Ross Jackson; *Secretary*, Dr. Charles A. Haffner, *Treasurer*, Dr. A. C. McGuire.

**The Wayne County, Indiana, Medical Society,** at its monthly meeting held at Richmond, Indiana, December 7, elected the following officers to serve for the ensuing year: *President*, Dr. J. N. Study of Cambridge City; *Vice-President*, Dr. T. Henry Davis of Richmond; *Secretary and Treasurer*, Dr. D. W. Stevenson of Richmond; *Board of Censors*, Drs. Charles Marvel and Minnie Hervey of Richmond, and Dr. H. B. Boyd of Cambridge City.

**Water Supply of Illinois To Be Investigated.**—Plans were adopted at a recent conference, which was attended by Edward Bardow, Director of the State Water Supply, J. A. Harmon, Sanitary Engineer, and Dr. James A. Egan, for the investigation of the water supply of Illinois. This investigation will include the sewage purification system and operation in twenty cities of the State.

**The Marine Hospital Service.**—In his recently-published annual report, Secretary of the Treasury Shaw, recommends more or less radical changes in the Marine Hospital Service. The principal retrenchment proposed is the abolition of a number of the hospitals forming a part of the service on the ground that they are conducted at a greater cost per patient than would be required in private institutions. It is alleged that the number of physicians and attendants is out of proportion to the number of patients, the latter being sometimes actually in the minority.

**Nobel Prize Awards.**—The Nobel prizes, each amounting to about $40,000, were distributed by King Oscar, at Stockholm, on December 10. The list includes the following: Physics: Philip Lenard, Professor at Kiel University, for researches into cathode rays. Chemistry: Adolph von Boeyer, Professor at the University of Munich, for researches leading to the evolution of organic chemistry and the development of chemical industry. Medicine: Professor Robert Koch of Berlin, for researches on the prophylaxis of tuberculosis. Literature: Henryk Sienkiewicz.

**Insanity in New York State.**—According to the statistics of the New York State Charities Aid Association, the proportion of insane persons in this city and State is decreasing, for the increase in the number of insane persons committed in the past year had been less than in any year since 1890. The total number was 547, as compared with 927 last year, and an average of 758 a year for the preceding ten years. The number of recoveries was 1,429, as compared with 1,303 for the preceding year. The total number of committed insane in State hospitals and private asylums on October 1 was 27,408.

**Bellevue no Longer a Drunkard's Refuge.**—Inebriates who have been in the habit of going to Bellevue Hospital to recuperate will no longer find a hospitable welcome waiting them. Dr. S. T. Armstrong, Superintendent of the institution, considers it an injustice to give up the clean beds of the wards to patients of this class, and will no longer receive them, unless there is some good reason to entitle them to hospital care. There are cases, however, in which experience is fallacious and judgment difficult, and police sergeants and ambulance surgeons have been in trouble before this over deaths in police stations of persons supposed to be suffering only from alcoholism.

**Charges against a Hospital.**—Charges have been filed with the Mayor of Jersey City by members of the Jersey City Board of Hospital Trustees against the management of the City Hospital. The statement alleges that there is a general lack of discipline in the institution, and that jealousy and discord prevail among nearly all the employees and officers. Reflections are also cast upon the nursing department, and on the care received by the patients.

**Medical Department of the University of Vermont.**—The new building of the medical department of the University of Vermont, erected to replace the old structure, which was burned a year ago last fall, was opened on December 2. The building cost $100,000. The principal address was made by Dr. John B. Grout, Superintendent of the State Hospital for the Insane, at Waterbury; President M. H. Buckham of the university, and Dr. H. C. Pinkham, dean of the medical faculty, spoke briefly. There are about fifty students in the entering class, while the total enrollment in the college amounts to 175.

**Yellow Fever in Havana.**—The outbreak of yellow fever in Havana shows no signs of coming to an end. The number of cases reported exceeds fifty, and at least fourteen deaths are known to have resulted. The quarantine which has been in force for some time against certain United States ports, because of the prevalence of yellow fever at New Orleans and other places, has been raised.

**Railway Surgeons' Association Formed.**—About forty of the railroad surgeons of Kentucky met recently at Lexington and organized a Railway Surgeons' Association. By-laws were adopted and the following officers elected: *President*, D. R. C. Falconer of Lexington; *Vice-President*, Dr. C. H. Vaught of Richmond; *Secretary and Treasurer*, Dr. J. B. Kinnaird of Lancaster. The first annual meeting will be held at Richmond, June 15.

**"The Alkaloidal Clinic"** makes announcement that, with the beginning of a new volume in January, the name of the journal will be changed to the *American Journal of Clinical Medicine*. The journal will remain under the able editorial management of Drs. Abbott and Waugh.

**Appeal for the Foundling Hospital.**—The officials of the New York Foundling Hospital, at 175 East Sixty-eighth street, have issued an appeal for funds. More than 3,000 individuals were cared for last year, and 1,800 are now in its care. Nearly 600 needy mothers have been provided for, and 272 are being taken care of at present.

**A Nitrous Oxide Death.**—A death from this anesthetic is said to have occurred in the office of a Bronx dentist. The patient was stated by his family physician to be a safe subject for anesthesia, but after an alveolar abscess had been opened under the influence of laughing gas, he could not be resuscitated, and died in half an hour.

**The Rockefeller Institute,** it is announced, will soon be housed in its new building, at the foot of East Sixty-sixth street, which will be ready for occupancy early in January.

**Professor von Leuthold,** Surgeon-General of the German Army and the Emperor's body physician, is dead.

**Professor Neisser** has returned to Germany after a nine months' sojourn in the island of Java. The journey was undertaken in order to prosecute studies on the transmission of syphilis to monkeys, which could no longer be continued in Europe on account of the difficulty of getting sufficient numbers of the higher apes required in this work. The results of the observations made are said to be of great interest.

**National Fraternal Sanatorium for Consumptives.**—At the first meeting of the committee appointed by the National Fraternal Congress and the Associated Fraternities of America, officers were elected and it was decided to view the property offered by the Santa Fe railroad for the establishment of a national fraternal sanatorium. This is situated six miles from Las Vegas, N. M., and contains about 900 acres of land on which are located buildings said to be worth $500,000. This property was formerly used by the road as a summer resort, and is now offered free to the National Fraternal Sanatorium. It is expected that the offer will be accepted and that the institution will be in operation not later than February 1, 1906.

**Buchanan County (Mo.) Medical Society.**—At the annual meeting of this society, held in St. Joseph, on December 3, the following were elected as officers: *President*, Dr. O. B. Campbell; *Vice-Presidents*, Drs. C. G. Geiger and O. G. Gleaves; *Secretary*, Dr. C. W. Fassett; *Treasurer*, Dr. J. B. Reynolds.

**Dr. Ménière,** director of the National Deaf and Dumb Asylum in Paris, is dead.

**Dr. Samuel A. Graham,** who has been Chief of the staff of physicians at the Illinois Eastern Hospital for the Insane, Kankakee, for some time, was recently reappointed.

**Obituary Notes.**—Dr. John Matheson of New York City was killed by a revolver shot, fired by the watchman of a building in the course of erection in the Bronx. Dr. Matheson was thirty-five years old and was a native of Prince Edward Island, Can. He was graduated from the medical department of the University of the City of New York, in the class of 1896.

Dr. Evelyn D. Bissell of New Haven, Conn., died on December 9, after a short illness. Dr. Bissell served in the Civil War and was sixty-eight years of age.

Dr. Edward Osborne of East Hampton, L. I., died of heart disease on December 4, at the age of seventy years. Since 1735 his family had occupied the same homestead in East Hampton, and he was universally loved for his charity and kindness to the poor.

Dr. Joseph Berens of Philadelphia, died on December 6 as the result of a cold. He was ninety-two years old and had practised for sixty-four years. He was born in Germany, came to America with his parents in 1839, and received his medical education at the old Medical College of Pennsylvania.

Dr. J. Ernst Meiere of Cripple Creek, Col., is dead, at the age of seventy-five years. He had practised in Colorado for over a quarter of a century. He served in the United States Navy until the Civil War, when he enlisted in the Confederate Army.

Dr. T. B. Hunt of St. Louis, Mo., died at Warsaw, Ill., on November 17. He was seventy-four years of age and was for many years a member of the State board of health of Illinois.

Dr. John S. Arwine of Columbus, Ind., is dead, of heart failure, at the age of seventy-one years. He had practised in Columbus since 1868, and served both as county and city health officer.

Dr. Warren C. McManus of Edgerton, Wis., is dead, at the age of thirty-four years. He was

born in Brunswick, Me., and received his medical degree in 1889. He then settled in Edgerton and had built up a large practice.

Dr. S. A. Owens of Center City, Tex., died on November 19. Dr. Owens was born in 1824, and came from Missouri to Waco, Texas, in 1859, where he practised his profession for about thirty years. He was a veteran of three wars.

Dr. Daniel T. Plumer of Newbury, Mass., died on December 4, of pneumonia, after a long illness. He was born in Newbury on May 4, 1819, was graduated from Dartmouth College in 1840, and received his medical degree from the Harvard Medical School two years later. He retired from active practice in 1860.

Dr. J. D. Searles of Huntington, Ind., died of apoplexy on December 2. He was secretary of the Huntington Board of Health, and had practised in the county for nearly fifty years.

Dr. Morton Grinnell of Milford, Conn., died on December 10, in his fifty-first year. Dr. Grinnell was graduated from Yale in 1875 and four years later from the Bellevue Hospital Medical School. He studied medicine in Europe for a year or more and then settled down in this city to practise. Fifteen years ago he retired and went to Milford to live. After his retirement he wrote several books on nature subjects.

## Correspondence.

### AMERICAN HOSPITAL ECONOMICS.

To the Editor of the Medical Record:

Sir:—Will you kindly allow me space for discussion of Dr. Arpad G. Gerster's interesting article on Hospital Economics in your issue of December 2, 1905? I am in most hearty accord with all he says regarding the need of avoiding waste by careful supervision. But as to the further centralization of hospital service, I want to record a protest—not on personal grounds, as I have my share of attending and consulting appointments and more material for serial study, through the courtesy of other attending physicians, than I have time to utilize, but because European conditions cannot, from our present viewpoint, be duplicated in America. In a certain economic sense it would be better if our hospitals could be concentrated and the services condensed and systematized. In the same sense it would be better for fifty to seventy-five per cent. of the medical profession to be set at productive manual labor, placing all medical practice under Government control and systematizing the work of the profession so that there should be a considerably higher average professional income, no loss of time or worry, and still at a vastly lower aggregate tax upon the community for medical service. I shall not take the time to present the arguments for our present system in the latter regard, but would like to say a few words as to hospital centralization.

First of all, the large, systematized services of European hospitals, though more imposing and more satisfactory from the statistic standpoint, do not impress an American favorably after the first thought. Very few men are capable of personally attending to 400 or 250 (the ordinary European limits of hospital services), or even 100 sick or injured persons. Taking hospital patients as they run and allowing that the physicians in charge of services had no private practice, a service of 100 patients would be about the maximum which could receive careful attention, with assistance from nurses and internes. This number with an ordinary private practice or any greater number without it implies one of two alternatives: Either the man in charge is simply a superior executive officer relegating details to assistants, or the attendance degenerates into a routine, good enough if one is simply looking for statistics as to alimentary glycosuria, movable kidney, duration of sickness, mortality, etc., but not good enough if we consider the matter from the standpoint of the patient demanding individual care and the best chances of recovery with the minimum loss of time and the maximum of comfort. The military system does not appeal to the average American physician. If a man is competent to look after patients at all, except as an interne seeking practical experience, he wants to be independent, to have the care of interesting as well as uninteresting cases, and to be subject only to ordinary necessary supervision. If he is in private practice, as is and long must be the case in this country, barring exceptional conditions, it would be impossible for him to arrange his work so as to act, properly, as an assistant. To a certain degree, however, I would acquiesce in the plea of Dr. Gerster and others for a centralized control of hospital service. Without interfering with the responsibility and independence of the regular attendant, or reducing him to an assistant, I would favor making the consulting staff an active body, instead of using such positions as emeritus consolations or for the purpose of sidetracking possible rivals. In short, I would make the consulting staff exactly what Dr. Gerster wishes to make the regular attending staff for all practical purposes, without detracting from the independence of the latter or imposing upon the former executive responsibilities which they cannot personally assume.

It must be clearly understood that the relatively enormous development of small private and semi-private hospitals and the comparatively large number of divided services in large hospitals in this country do not represent a primary phase of evolution. The early services in this country were large, at least in comparison with the population. The present division of work is directly attributable to the general demand for the retention of cases by physicians and the retention of physicians by patients. So far as any distrust of the application of European hospital methods to America is concerned, and so far as the development of the present system of small hospitals and divided services rests upon other than individual ambition and desire, it is because of the general belief among the profession and the laity that, in some instances, the very men who controlled large hospital services, turned loose upon those of the community who pay for medical care, practitioners to whom they denied the care of ward patients on the ground of incompetence. There is no question but that this view has been based on exaggeration and on what is commonly called soreheadedness; and certainly it would be most unjust to allude to it with any intention of reflecting upon Dr. Gerster, or, indeed, the majority of the men who are pleading for a restoration of large, systematized hospital services. At the same time we must admit that it is, in a considerable, though small, minority of cases, correct.

But the crucial test must depend upon results. With very imperfect State control and, until recently, totally inadequate standards of medical education, America has taken a leading place in medical and surgical art, and recently even in strictly scientific fields of medicine. In my own city, with a total medical population of not much over 600, I can count at least twenty expert abdominal surgeons, including those that radiate toward general surgery and gynecology. Under the system of centralized hospital services it would not be possible to breed six. I do not mention medicine or the various localized specialties, because the conditions are somewhat different, and because my opinions might be considered prejudiced. But the general experience throughout the country is that the number of competent practitioners has been greatly increased by dividing the sources of serial study of cases. My visits to European hospitals have been brief and few, but they seem fairly to justify the conclusion that we are, on the whole, doing better work here. The indexes of medical magazines show that at least 5,000—nearly 2 per cent.—of the total American profession are doing original work of high order, and the conclusion is almost irresistible that not only the practical issues of saving life and recovering health depend upon a large number of excellent physicians and surgeons, but that the aggregate attainment of the profession is elevated by the number of workers in various branches and by the stimulus to research and endeavor that comes from such large competition. It is difficult to believe that either in numbers or standard of excellence could any such results be attained under the European system of hospital service, especially in view of the imperfect methods of undergraduate medical instruction that prevailed when the present leaders of medical thought were studying medicine. We must remember that, except for certain statistical purposes, one gets about the same experience, not only in a crude practical sense, but in the development of a truly scientific attitude, from an experience of 100 as from one of 1,000 cases. One might much better examine and treat twenty patients thoroughly than run through a ward of 200 and try to pick the interesting cases and give only routine attention to the rest. And this statement is true not only from the patient's standpoint, but even more so, though not so obviously, from that of the attendant.

The restoration of the old method of large, undivided hospital services is clearly impossible under present or foreseeable circumstances in America. To many it seems undesirable, for various reasons, except in the sense that what is a large hospital service in a small city may be reasonable in a large one. The aim should be to secure the benefits of both systems by freer use of an adequate consulting staff and by reciprocity and courteous welcome in the case of any one seeking large statistics on any one point of investigation.

Finally, I question whether, in the narrow sense of financial economy, the large, centralized hospital service has any advantages over the moderately small service. Of course some degree of aggregation of patients is necessary, but, after a certain point is reached, will not the per capita cost remain stationary, or even increase, as has the cost of ordinary living in very large aggregations of the healthy population?

A. L. Benedict, M.D.
Buffalo, N. Y.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

WORKERS' SANATORIA—NORMAL CARDIAC CHANGES—INFLUENZAL ENDOCARDITIS—ABDOMINAL TUBERCULOSIS—OSTEOARTHRITIS OF SPINE—A MYSTERIOUS EPIDEMIC—DAMAGES FOR LIBELING A DOCTOR—QUACK DOG DOCTORS—THE LATE MR. CROFT.

London, November 24, 1905.

On Saturday afternoon the Princess Christian of Schleswig-Holstein attended a meeting of the Society for the Establishment and Maintenance of Sanatoria for Workers Suffering from Tuberculosis. She is president of this association and was well supported by "society," while the "aristocracy of labor," as represented by friendly societies and trade unions, appeared in great force. The representatives of these organizations profess to be willing to maintain sanatoria if only the public will build them. At the same time they do not ask for elaborate architecture, and several speakers urged that expenditure on bricks and mortar ought to be rigidly limited. The committee desires to erect one sanatorium and hand it over to working men to run for themselves. The meeting unanimously approved a site of 250 acres, already secured by the committee, for the first sanatorium, and as representing the organizations of workers resolved to maintain the institution when started. I hope the committee will obtain a binding agreement from these organizations, for we know pretty well the difficulty of dealing with trades unions from their recent action. When cast in damages, after a lengthy trial, they at once commenced an agitation to force legislation to protect their funds from attack. This same spirit of injustice and selfishness was again displayed on Monday by a section of those who got up a procession on behalf of the unemployed. Happily that section was small, or it might tend to dry up the stream of charity which has been flowing so freely for these desirable ends—the abolition both of poverty and of consumption. Banners and speeches insulting the donors seem scarcely calculated to impress them with the idea that the deserving sufferers are those who cry "Down with charity!" and "We will take all we can get and demand more."

With regard to these sanatoria it is most gratifying that the workers should themselves condemn excessive expense in buildings. Perhaps the chief blot on this mode of treatment will prove to be the cost. It seems inconsistent to proclaim in all directions the danger of infection and at the same time erect elaborate buildings in which to assemble numerous patients who are declared to be, without exception, foci of fresh infection. A colleague remarked to me the other day that he thought consumption hospitals must swarm with innumerable bacilli against which disinfection could do next to nothing. If so, the sanatorium would differ little and permanent buildings may come to be centers of infection. I suppose their advocates will hardly admit this, but we have had other occasions when time has disappointed what seemed well-founded hopes.

Would it not be more consistent to try at first temporary buildings? Wooden huts have been found sufficient shelter for troops and would, perhaps, commend themselves to the advocates of out-of-doors treatment. They could be burned if they could not be disinfected, and there are methods of saturating them with disinfectants to begin with. Iron buildings again can be taken down and perhaps subjected to heat. Of course it is a question of costliness, and most people hold that bricks and mortar are very expensive. The internal fittings of these buildings ought also to be of a more simple and economical character.

At the Medico-Chirurgical Dr. William Gordon read a paper on the normal cardiac sounds and dullness. He said careful observation showed that change of position produced a change in the character of both sounds, sometimes slight and sometimes more marked. The two sounds were more alike in the upright position, so that the "lup-dup" of the text-books (mostly taken in the recumbent posture) became "lup-lup" in the erect position. He attributed the change to the relation of the valves to the weight of blood in contact with them in the two positions. Further posture affected the deep cardiac dullness. In the erect position this dropped a rib's breadth further from the clavicle and became an inch wider at the level of the fifth cartilage, the increase being greater to the right than to the left.

Mr. Stephen Paget confirmed the observations as change of dullness in the two postures. Dr. Newton Pitt agreed as to the difference, but thought the position of the valve did not affect the dullness which was due to the head of blood above. Dr. T. J. Horder thought gravity could scarcely have any effect compared with that of the pressure within the ventricle.

A paper on influenzal endocarditis was read by Dr. Horder. He had cultivated the bacillus in two cases which appeared to be instances of influenzal septicemia. The blood was taken during life; in one case on four different occasions, in the other on two. In each the bacillus influenza was obtained and no other organism. Both patients died. In one the diagnosis was reached by the cultures six weeks before death, in the other, five weeks. Post mortem verified the diagnosis in both. In both cases the organism obtained before and after death had all the characters of Pfeiffer's bacillus. Clinically, both cases would be regarded as chronic, malignant endocarditis; there was leucocytosis in both and both had had rheumatism. Dr. French thought leucocytosis uncommon in hospital cases and that influenza cases had better not be taken into a ward containing heart cases. Dr. Pitt said such causes were overlooked in an ordinary blood film. At least a syringeful of blood should be cultivated in broth by Dr. Horder's method.

Two cases were exhibited at the Medical Society fifteen and twenty-seven months after operation for tuberculous glands in the upper mesentery. 1. A boy of 12, who for some months had had occasional streaks of blood in the stools and for the last three months attacks of sharp abdominal pain, usually lasting less than one-half hour, but without sweating or vomiting. A movable swelling was found in left loin as large as an adult kidney—no resonance. 2. A boy of 6, with slight swelling in appendicular region, well defined, size of cricket ball. Cases were mentioned which were discovered on operating for hernia and the latency of abdominal tubercle referred to. In one of supposed tubercle of peritoneum adrenalin injected had been followed by recovery.

A case was shown of osteoarthritis of the spine ("Poker Back") in a woman of 36, with a previous history of colitis. She could not bend her back without pain and had to stoop in walking. There was also limitation of movement of costovertebral joints restricting thoracic expansion; no other joints affected. Skiagrams showed nothing. Dr. Buckley did not regard this case as osteoarthritis. He had met several such. Dr. Kauffmann was much interested in the previous history of colitis. He thought the arthritis being limited to the spine noteworthy, and it was probably incurable. Dr. Poynton asked how osteoarthritis was to be defined. He had seen a similar case improve under iodide.

Yesterday a conference of medical officers of health was held respecting a "recent mysterious epidemic in East Herts," which seems to have simulated in various ways and degrees, scarlatina, tuberculous meningitis, influenza and cerebrospinal meningitis. One hundred and sixty-two cases were traced, of which sixteen were fatal. Drs. Dunn and Gordon have sent in reports to the Local Government Board. Dr. F. Freemantle, M.O.H. for the county, presided and said it was pretty certain the epidemic would recur in this and future winters, and therefore important that steps should be taken to study it and notify cases. In the discussion there was some diversity of opinion as to the nature of the disease, but a general unanimity as to the necessity for co-operative investigation into the cases that might be met with this winter.

The reckless manner in which some journalists assail medical men received a sharp lesson at Manchester assizes this week. A local paper charged a doctor with incapacity in having failed to diagnose a case of smallpox, and further with having deliberately hushed up such a case. A plea of justification set up was withdrawn and counsel addressed the jury in mitigation of damages. The jury awarded the doctor £1,000 for the libel.

A member of the British Royal College of Veterinary Surgeons, in a recent interview, said that "the growth of quack dog doctors and bogus medicines during the last few years has been simply appalling. These 'dog specialists,' as they call themselves, are usually dog dealers with good knowledge of canine habits but absolute ignorance of medicine."

Mr. John Croft, consulting surgeon to St. Thomas's Hospital and an ex-vice-president of the Royal College of Surgeons, died on Tuesday, aged 72. He had filled, in due course, the various surgical offices in the hospital and the chairs of clinical surgery and practical surgery in the school. He was, of course, on the council of the College of Surgeons, and also served as an examiner. He had also examined in surgery for the College of Physicians and the University of Durham. He had been retired from active practice for several years.

## OUR PARIS LETTER.

(From Our Special Correspondent.)

CARDIAC WOUNDS TREATED BY SUTURE—PENETRATING GASTRIC WOUNDS CAUSED BY FIREARMS—THERAPEUTIC VALUE OF LUMBAR PUNCTURE IN FRACTURES OF THE SKULL—PROPAGATION OF CHOLERA BY FLIES—A STUDY OF THE FUNCTIONS IN A MYXEDEMATOUS PATIENT—TREATMENT OF SMALLPOX BY XYLOL—NOMINATION OF THE DIRECTOR OF PUBLIC ASSISTANCE.

PARIS, October 31, 1905.

At the Surgical Society Picqué described two interesting cases of cardiac wounds treated by suture and followed by recovery. One patient, a man twenty-four years old, being cut by a knife in the region of his left breast, was taken to the hospital half an hour after the accident and was at once operated upon. As the patient showed all of the signs of internal hemorrhage, with increase of cardiac dullness, a flap consisting of the third, fourth, and fifth ribs was turned back. A section of wounded lung was first discovered, and behind that the pericardium was found to be distended by liquid. When this serous sac was opened more than three hundred grammes of blood flowed out, revealing an oblique wound of the left ventricle. This wound was sutured by means of two strands of silk and the hemorrhage was at once arrested. The pericardium was closed with catgut and the rib flap was returned to its place without drainage. Two days later a hemothorax was evacuated. At the end of three weeks the patient left the hospital, completely cured. The second patient was a woman twenty-four years old, in whom, in the course of an intervention for left hemothorax consecutive to a perforating wound made by the ball from a revolver, was discovered a wound of the left ventricle. As this wound did not bleed it was not sutured, but was simply drained.

Reynier next reported several cases of penetrating gastric wounds due to firearms. These cases recovered without operative intervention. The speaker concluded that in a number of cases of wounds of this nature it was better to refrain from all operative intervention. In those cases following an attempt at suicide by firearms of small caliber, the stomach being in a fasting condition, there was absence of severe hemorrhage and a marked peritoneal reaction; and when the pulse remained good and the temperature normal it seemed that the best method of insuring recovery was by complete rest and strict diet. Ice should be placed over the abdomen and subcutaneous injections of artificial serum should be given. After this presentation, Potherat, Reclus, and Delbet declared that they did not agree with the conclusions of Reynier; judging from facts and statistics, they believed, on the contrary, in laparotomy practiced as quickly as possible in all cases of penetrating wounds of the abdomen.

The next question considered was the therapeutic value of lumbar puncture in fractures of the skull. Tuffier remarked that the therapeutic results of lumbar puncture in cases of fracture of the skull were not constant. Sometimes the results were not permanent and sometimes they were nil. Potherat in one case of fracture of the skull practised lumbar puncture for several consecutive days, and at each operation there was noted a distinct amelioration in the condition of the patient. Terrier had seen a fracture of the skull complicated by violent headache which was very much ameliorated after every lumbar puncture. Guinard had seen only a temporary attenuation of morbid symptoms under the influence of lumbar puncture and never a recovery. Rochard had always noted an amelioration after lumbar puncture which he used systematically in all cases of cranial fracture.

At the Academy of Medicine, Chantemesse presented a communication on the spread of cholera in Europe and its propagation by flies. According to Chantemesse, the spread of cholera presented itself under three very different aspects, each of which demanded the employment of special methods of prophylaxis. The three methods of extension of cholera were transportation to a long distance, propagation from city to city, and, finally, the dissemination from house to house and from individual to individual. The transportation of cholera to great distances did not take place by means of merchandise and luggage, but by means of patients who came from the midst of the epidemic. A great number of these patients showed symptoms of their disease only after their departure. They were affected by a latent microbism, the duration of which might be from six to seven weeks. This fact showed how extremely dangerous were these individual explosions and what an important rôle they played in the transportation to a distance of the cholera germs.

The propagation from city to city was likewise brought about chiefly by those individuals who looked well, but who in reality were charged with a latent microbism. As to the dissemination from house to house and from individual to individual numerous factors were to be considered. Water and variations of temperature certainly played an important rôle in the propagation of cholera. But, according to Chantemesse, there existed a factor more important still which, in the transmission of cholera, played a rôle analogous to that of the mosquito in the contagion of yellow fever. This factor was the fly. The fly, he said, carried about the vibrio of cholera, and his experiments had proved that one could obtain cultures of cholera after seventeen hours from the tubes of the feet of flies and from their intestinal contents. He stated that the house fly could very easily infect food, and so become a powerful agent in the dissemination of cholera.

At the Hospital Medical Society, Garnier and Lebret spoke concerning the renal, intestinal, and hepatic function in myxedematous patients. They said that although the intestines, the kidneys, and the liver did not present any apparent disturbance, they nevertheless performed their functions irregularly. The elimination of methylene blue was slow, tardy, and feeble. The passage of food through the digestive tract took a long time although the patient was not constipated. Finally a dose of sugar syrup, not very large, produced glycosuria. Under the influence of thyroid treatment, instituted during fifteen days, the diverse functions were ameliorated. Methylene blue was eliminated normally by the urine. The carmine given in a test meal was evacuated in twenty-four hours. Glycosuria alone persisted longer, for about twenty-five days.

A communication from Belin concerning the action of xylol in the treatment of smallpox followed. It was interesting to note—after the recent recrudescence of smallpox in Paris—the different therapeutic results obtained in the various treatments of this disease. Belin had, in addition to the classical treatment, administered internally xylol in a dose of from one hundred to one hundred and twenty drops in the twenty-four hours to adults, and from fifteen to forty drops to children. The current mortality fell under this treatment from twenty-four per cent. to twelve and five-tenths per cent. The complications were much reduced and the formation of scars consecutive to smallpox were avoided. The results already obtained by those who have employed xylol internally have confirmed Belin's work and have demonstrated the superiority of this treatment over the preceding methods. Teissier had also proved the good effects of this method of treatment. The period of suppuration of smallpox he declared was decreased, the dessication of pustules was rapid, and did not leave scars behind it. Teissier, nevertheless, made reservations concerning the influence of this medication over the general severity of this disease.

At the Society of Internes of the Paris Hospitals, the Prince of Monaco gave an interesting talk on marine biology. After explaining the scope of oceanography, to the study of which he has devoted himself for a number of years, and after showing what methods and what apparatus were demanded by this work, the prince showed pictures representing most clearly the specimens of the submarine flora and fauna. He then spoke of his work from the bacteriological point of view. He explained the researches which had taken place in recent years in regard to the poison of the sea anemone and of the sponges, the hypnotic effects of which are so curious. He also described the researches of Bertrand concerning the constant existence of arsenic in animal tissues. All of these were based on the experiments made on animals which were taken from great depths in the sea.

Mirman has been appointed general director of Public Assistance and Hygiene in France. He succeeds Henri Monod, who held his place for so long, and who, at his own request, has been allowed to resign.

## Progress of Medical Science.

*Post-Graduate and Special Journal, Items, etc.*

Operative Treatment of Old Fractures at Lower End of Radius.—An elaborate paper, freely illustrated with skiagrams is contributed by H. A. Lothrop. He considers surgical intervention as usually indicated in cases presenting an unsatisfactory result. During the first three weeks any union which may have occurred can usually be broken up by manipulation under an anesthetic, and suitable apparatus can then be applied as for a recent case. After the third or fourth week the best results are obtained by an osteotomy in the line of fracture, followed by treatment appropriate for a recent case. In fractures which have existed for from two to six months osteotomy should always improve the position and frequently improves the function, although special consideration should be given each case; but after the expiration of six months it is more difficult to correct the deformity. The backward and upward displacement of the lower fragment can always be overcome, but the correction of the lateral

displacement is more difficult and usually requires an osteotomy of the ulna. The function is rarely improved at this time. Hence, interference should be limited to selected cases.

**A Case Illustrating the Value of Persistent Conservatism in the Treatment of Ununited Fractures of the Lower Leg.**—The patient of G. H. Monks was a man of twenty-eight years who, as the result of explosion of chemicals, had extensive loss of bone and soft parts of both legs. Repeated operations were undertaken and bony union was secured about three years after the original injury. Restoration of function did not come until somewhat later. The case is reported for the purpose of showing (1) that union is possible in ununited fractures of the shafts of the bones of the lower leg after very long periods of time and, (2) that even in cases in which the bones are considerably shortened (in this case, fully two inches) the muscles will sufficiently contract to enable the patient to balance himself on his legs.

**A Study of the Gastric Contents in Twenty-One Cases of Tabes; in Three Cases, During Gastric Crises.**—M. P. Smithwick finds that in tabes gastric motor power and HCl and pepsin secretion are depressed more commonly than exalted. No degree of activity of these functions characterizes the disease. In gastric crises of this series reported, HCl secretion and motor power were more depressed than usual, and in the severe painful crises depression of acid secretion was extreme and continued for hours. In one instance there was probably hypersecretion of gastric juice.

*New York Medical Journal, December 9, 1905.*

**A Few Remarks on the Treatment of Puerperal Infections.**—R. W. Holmes' conclusions may be summarized in the following propositions: The battle against puerperal infection is practically won by asepsis and antisepsis and skilled assistants, the same as in general surgery. True autoinfection is rare. Puerperal infection is not a specific disease. Various bacteria may cause it and it may arise in any portion of the parturient canal. Local treatment of febrile conditions without a localization of the seat of infection is an obstetrical crime. At the present time there is absolutely no method of adequately reaching the offending germs in the uterine submucosa or muscularis. The curette cannot discern the locality of the retained remnants of secundines; the finger alone can ascertain this; a placental forceps more easily, more certainly, and with infinitely greater safety, can remove them, under guidance of the finger, and it is a grave error to neglect digital revision of the uterus after any instrumentation for the purpose of cleaning the uterine cavity. Shreds of tissue found in the uterus are not as dangerous as is generally supposed. The use of saline purges, administration of ergot, hydrastis, etc., removes much of the danger or necessity for active therapy; in a day or two the danger is often past, for, like a baby, the lying-in woman is often subject to evanescent febrile elevations.

**Pyelonephritis and Ulcer of the Esophagus Complicating Pregnancy.**—The patient of L. T. Le Wald was a woman of twenty-nine years in the sixth month of the first pregnancy. Extracts from the daily bedside notes are given from which it is learned that her illness began four weeks before death with nausea and vomiting, followed by epigastric pain. Then appeared irregular chilly feelings, sweating, pain in the back, and prostration. The temperature ranged from 99° to 103.5°; the morning temperature being generally low, the afternoon one high. No chills were noted after the first week. Vomiting was present throughout the illness; so was persistent pain beneath the sternum after the first few days. The pulse remained of good quality and under 100 until the second week of illness, after which it remained most of the time above 100. Constipation was present, but yielded to daily enemata. The immediate cause of death appears to have been exhaustion following uncontrollable hematemesis. Autopsy revealed an acute purulent inflammation of the right kidney. The esophagus presented a circular ulcer, one and a half centimeters in diameter, on the posterior wall, about five centimeters above the diaphragmatic opening. It had nearly perforated the posterior wall of the tube, and a small artery on its floor had been eroded. The cause of this ulceration could not be made out. It may have been due to infection coincident with that of the kidney or to a septic embolus. Lessons to be drawn from the case are: (1) Examination of the urine drawn by catheter should be made in all cases of suspected pyelonephritis, to be followed by cystoscopy and catheterization of the ureters in cases which still remain doubtful. (2) Examination of the blood for leucocytosis, its presence favoring a diagnosis of pyelonephritis. (3) Early consultation, with a view to operative interference in cases not yielding promptly to medical treatment. Choice of operation to be directed to the affected kidney rather than to the interruption of pregnancy. (4) Continued pain located in the chest just beneath the sternum in its lower third part, plus persistent vomiting, appear to be indicative of ulcer of the esophagus. (5) The combination of esophageal ulcer and pyelonephritis seems to have been simply coincident. The pyelonephritis is believed to have been dependent upon compression of the ureter by the pregnant uterus aided in this case by an anterior and lateral curvature of the spine in the lumbodorsal region.

*Medical News, December 9, 1905.*

**The Frequently Malign Nature of Chronic Hoarseness.**—This point in the diagnosis of malignant disease of the larynx is discussed by Chevalier Jackson, who states that success in thyrotomy is conditioned directly on early diagnosis. Endolaryngeal methods of operation are worse than useless, for they induce local spread and metastasis unless they result in radical extirpation which by this method is often impossible. Two cases are related in one of which a total laryngectomy was done with fatal cervical pulmonary and hepatic metastasis eight months later. In the other a thyrotomy was done and the patient is now alive after an interval of four years. In both the special symptom, when the cases came under observation, was hoarseness. The first patient refused operation until late, while the second one was operated on early. Jackson observes that the early curable stages of cancer of the larynx are characterized by nothing but hoarseness, which may come and go. Cough, odor, pain, odynphagia, glandular involvement, external swelling, emaciation, cachexia, etc., are present only after the curable stage is passed.

**The Relation of Incontinence of Urine to Neurasthenic Symptoms, and Its Treatment by the Isolated Induction Shock.**—A. D. Rockwell calls attention to the unsatisfactory results of treatment of this annoying malady. He has therefore employed electricity and gives his results in fifteen cases. Of these, seven completely recovered and without relapse, four were greatly benefited but have suffered various relapses and cannot be claimed as perfect recoveries, while four disappeared from observation before the remedy was given a fair trial. He prefers currents of low tension but of appreciable magnitude to those of high tension with a magnitude altogether negligible. The positive electrode may be applied to the sacrum and the nagative in the shape of an olive-shaped bulb may be passed through the urethra to the sphincter vesicæ. Isolated induction shocks (secondary current) may be given about once every five seconds. Sittings are given at first on alternate days; later less frequently. If the contractions of the abdominal muscles following the current interruption are not objectionable, the positive electrode may be thus employed. A slowly interrupted faradic current does not answer the purpose at all, but we must employ the isolated induction shock.

**Syphilitic Fever.**—J. A. McKenna gives the history of a child of nine years, sick for three weeks, the diagnosis being typhoid fever. The author, when called, noted on the tongue lesions suggesting inherited specific disease. Evidences of bone pain were located in the forehead and shins. Five days' administration of mercury and the iodide brought the temperature and pulse to normal, and two days later all the pains in the head and legs had disappeared. The only evidence of inherited specific taint brought out on tracing the family history was that the paternal grandfather had had necrosis of the tibia. The author thinks that if evidences of syphilis were more often looked for in continued fevers of a doubtful character, or, as a chance, specific treatment given the patient, doubtful diagnosis would frequently be speedily made definite.

*American Medicine, December 9, 1905.*

**The Comparative Study of Various Forms of Tuberculosis.**—Mazyck P. Ravenel states that (1) the division of mammalian tubercle bacilli into two types, human and bovine, first proposed by Theobald Smith in 1898, has been amply confirmed. These types have cultural, morphological, and tinctorial characteristics by which they may usually be recognized. The chief point of difference, however, is found in the very much greater pathogenic power of the bovine type. Bovine bacilli are, however, met which have low pathogenic power. (2) No other species of mammal has been shown to harbor a variety of tubercle bacillus so constant in its characteristics as to justify its classification as a third type. (3) Other species suffering from tuberculosis derive their infection from man or from cattle. (4) The human tubercle bacillus, as a rule, has a low pathogenic power for cattle, but cultures are not infrequently found which are virulent for the bovine race. (5) The bovine tubercle bacillus has the power of invading the human body and producing the lesions of tuberculosis. (6) We are at present unable to

state the exact proportion of cases in which bovine tuberculosis is transmitted to man, but in view of the evidence at hand we must regard the disease in cattle as the source of a certain part of human tuberculosis, and any relaxation in our laws and precautions against bovine tuberculosis would be most unwise.

**Cerebral Hereditary Syphilis.**—William J. Butler says the nervous system is attacked by hereditary syphilis in a considerable proportion of cases, sometimes without cutaneous lesions, the disease remaining latent until puberty or later. The pathological conditions include cranial osteosclerosis, periosteitis, meningitis, endarteritis, thrombosis, as well as atrophy, sclerosis, and softening of the cerebral cortex. The symptoms are recurring convulsions, severe headache, worse at night, and impaired intelligence. Later the epilepsy may disappear. Hemiplegia frequently develops and the patients may become paralytic idiots. Partial motor paralyses, aphasia, and disturbances of the special senses may occur. Mental deficiency, occasionally congenital, usually develops at a later period of childhood. Prognosis is unfavorable unless the condition is recognized and treated in its early stages. Congenital syphilis should be vigorously treated with mercury during the prevalence of cutaneous manifestations and, when nervous symptoms develop, potassium iodid, or if this disagrees, iron iodid, should be added.

**The Restriction of Contagious Diseases in Cities.**—Charles V. Chapin states that during the last twenty-five years health officials have been striving to make more and more stringent the measures adopted by them to prevent the spread of infection. This has been done in the belief that it is possible to control all infected persons. Evidence is presented that this is entirely impracticable. The most important discovery of modern epidemiology is that the principal mode of extension of infection is by means of well persons who are the bearers of the germs of disease. These unrecognized sources of infection we can never hope o control, and hence we can never hope to stamp out these diseases by isolation and disinfection, but only somewhat reduce their prevalence. This can be done by milder measures than those now in vogue. The specific measures to be adopted in different diseases are then discussed.

*Journal of the American Medical Association, December 9, 1905.*

**Landry's Paralysis.**—R. McGregor reports a case of Landry's paralysis, and discusses its etiology and pathology. While he considers it to be due to a toxemia, specially involving the anterior spinal horns, he thinks it probable that in very virulent intoxication the peripheral nerves may also be implicated in a secondary way, and a multiple neuritic condition coexist. These are the cases that, perhaps, give most trouble in their diagnosis. The very high mortality of this disease, however, is in striking contrast with those disorders, multiple neuritis and anterior poliomyelitis, with which it is most liable to be confounded. In the case reported, the attack seemed to follow vaccination, it was preceded by chilly sensations, fever, sweatings and vertigo, and the rapidly ascending paralysis within a week from its first appearance had involved all four extremities, the muscles of speech and deglutition and the ocular muscles. There was also cardiac irregularity and dyspnea, but there was no pain or nerve tenderness, and no fever after the stage of onset. The patient slept well and took a fair amount of nourishment. The bulbar symptoms began to improve after two months, but recovery was not approximately complete until after two years, and the patient has not yet attained his former weight by thirty pounds. There is still a slight footdrop, most marked on the right and the knee jerks have not returned. In the treatment the best results seemed to follow the use of a simple solution of the glycerophosphate of iron with small doses of strychnine.

**Multiple Neuritis.**—D. I. Wolfstein gives reports of four cases of multiple neuritis illustrating the main etiologic types; *i.e.* those due to toxic agents, such as alcohol, mercury, and lead; those due to acute infections; those connected with general diseased conditions of the body, such as rheumatism, diabetes, and syphilis; and last, cases due to exposure to cold or developing apparently without determinable cause. He remarks on some points in the differential diagnosis, such as the involvement of motor fibers, the symmetrical character of the paralysis, the usually simultaneous affection of the legs and forearms, usually not extending to the thighs and upper arms and never except in fatal cases involving the abdominal and respiratory muscles. The prognosis, save in the acute grave cases, is relatively good. In patients with chronic alcohol or lead intoxication, with impaired constitutions, we can hope for only a partial recovery if any. Rest and appropriate nutrition are the principal indications in treatment. In the early stages the salicylates are useful. Light wrappings and soothing applications for the hyperesthesia are also of use. Special causal affections and intoxications, of course, call for appropriate treatment. Judgment is needed in case of alcoholism as to the continuance or withdrawal of the stimulant. With chronic cases strychnia, arsenic, gentle massage, and the galvanic current may be useful in aiding repair of the nerve and in keeping up the nutrition of the muscles.

**Proprietary Medicines.**—H. P. Loomis calls attention to special objectionable features of proprietary medicines, the secrecy, the commercialism, the dressing up of old remedies with new names, and sometimes the fraudulent recommendations. He sent circulars of three proprietary medicines, widely distributed and pretending to give concise details involving chemico-physiological facts, to three well-known physiological chemists asking for a simple explanation of the reading matter. The answers were essentially the same in each case that the pretended concise descriptions were largely mere jumbles of words without meanings. He asks how the average physician can discern the truth when the expert fails.

**Proprietary Remedy Nomenclature.**—C. S. N. Hallberg criticises the unscientific and unsystematic nomenclature of proprietary medicines, illustrating his points by lists of names showing the imagination, or lack of it, on the part of the originators, and also by samples of names of entirely distinct preparations that are so similar as to be liable to cause confusion. He further shows that some of these names so prominently before the profession and the public are practically only synonyms of regular pharmaceutical preparations, and therefore deceptive. Thinking physicians would better appreciate these remedies if they were sent out under their proper designation, and the name of a reputable manufacturer is the best possible trademark for the protection of the public.

**Tinnitus Aurium.**—W. S. Bryant discusses the propriety of dividing or destroying the auditory nerve trunk for the relief of specially severe cases of tinnitus when it can be determined that this nerve is the seat of the disturbance. He describes a method of procedure suggested by Dr. Carlton Flint, which he has followed a number of times on the cadaver and which he considers has certain special advantages; he also reviews the reported cases, reproducing some of them in rather considerable detail. He has reached the following conclusions: "1. Carefully selected cases of tinnitus, with nerve stimulus located in the peripheral end of the auditory nerve, offer a good prognosis for cessation of the tinnitus after the section of the eighth nerve. 2. A technic which offers little inconvenience from hemorrhage, no danger from bony spicules and a minimum of evil from compression of the cerebrum, or especially of the cerebellum, gives a good prognosis of recovery from the operation and in selected cases a cessation of the tinnitus. 3. If, after appropriate general and local treatment, grave tinnitus still exists, we are called on to recommend the section of the auditory nerve, provided the source of the tinnitus is believed to lie in the peripheral portion of the auditory nerve. 4. Section of the acoustic nerve will be as effective for the cure of aural vertigo as for peripheral tinnitus."

*The Lancet, November 25, 1905.*

**Opium in Cases of Spasm with Hypertrophy of the Pylorus in Infants.**—N. Neild reports two cases which tend to support the theory that congenital hypertrophic stenosis of the pylorus is the rapidly acquired result of frequently recurring pyloric spasm. His patients were aged five and eight weeks respectively. In the first case the characteristic gastric waves were plainly evident after feeding. On account of the marked action of opium on the spasm of unstriped muscle, this remedy was selected, though the author had fully in mind the susceptibility of infants to this drug. One minim of the tincture was added to ten ounces of water and one teaspoonful of this was given twenty minutes before each feeding. Improvement at once set in. The dose was diminished one-half, and complete recovery ensued. A second case was treated in an equally successful manner, though it was necessary to double the initial dose mentioned above. The author, while loath to claim too much from this limited experience, advances the following propositions: (1) Some cases of spasm with hypertrophy of the pylorus may be successfully treated with opium in the ordinary routine of the hospital out-patient department. (2) In some cases modification of the diet, stomach washing, and tube feeding are not necessary to the cure. (3) No case should be subjected to an operation until opium has been tried, unless, possibly, some other antispasmodics, such as the belladonna group, have been found to be equally efficacious.

**Ethyl Chloride as an Anesthetic for Infants.**—A plea for the use of ethyl chloride in pediatric practice is made by F. Murray, who has administered it for anesthesia to 150 infants under a year old. A large proportion were only a few weeks old, and one only five days old. It is of service in cases of respiratory embarrassment. Em-

pyema, pharyngeal abscess, tenotomy, sounding adenoids, polypi, circumcision, etc. The effects of the remedy are described in full, together with the special form of apparatus the author prefers. The periods of induction of and recovery from the narcosis are so short as to lessen the tendency to shock, and they greatly improve the chances of a patient in a bad condition. It is considered superior to and less dangerous than chloroform for use with babies. The smell of the drug is not obtrusive, and it is such a strong respiratory stimulant that the patient does not require to make any effort; on the contrary, it promotes respiration against his will. Herein lies its chief danger, for if large doses overstimulate the respiratory center and cause a tonic contraction of the diaphragm the patient may die from paralysis of the respiration. This event is liable to occur soon after induction, the heart remaining unaffected.

**Traumatism as an Exciting Cause of Acute Appendicitis.**—The histories of four cases are summarized by F. A. Southam. Case 1 was a boy of nine years, struck on the abdomen by a playfellow. Operation on the fourth day, perforated appendix, pus in the abdomen, and death twelve hours after operation. Case 2: A boy of seven years who fell on the abdomen; operation on the third day; foul pus in the peritoneal cavity, appendix not seen; general condition too grave to search for it; recovery. Case 3: A boy of twelve years fell on the abdomen at a swimming bath, striking the water flat. Was admitted to hospital on the fourth day. In the course of three or four days the abdominal symptoms, suggestive of appendicitis, subsided. In the course of two months all abdominal induration had disappeared. No operation was done. Case 4 was a boy of fifteen years who strained himself at jumping. On the evening of the third day symptoms of general peritonitis were present. The next day the abdomen was opened and found full of pus. Death followed in twelve hours. Southam notes that if violence is applied to the abdomen over the region of an appendix which contains a fecal concretion it can readily be understood that the wall of the appendix at this spot, probably already somewhat damaged by the presence of the concretion, then becomes so injured that it suddenly ruptures or an attack of acute inflammation is set up, which may quickly terminate in ulceration and perforation. It is also possible that an appendix which is completely stenosed at some point in its course and distended beyond with a mucoid or mucopurulent fluid—a condition which is not at all uncommon—may suddenly rupture as the result of violence applied to the abdomen and its contents become extravasated into the peritodeal cavity.

*British Medical Journal, November* 25, 1905.

**Dyspepsia.**—Robert Hutchison declares that the only satisfactory classification of the diseases of the stomach or any other organ must be either anatomical or physiological. The positive functions of the stomach are secretion and movement; its negative function is not to feel, that is, insensibility. The secretory functions of the stomach can be investigated by means of a test meal and the stomach tube. The tube is also useful in studying the motor functions of the stomach. For the presence of food in the stomach when this organ ought to be empty indicates impaired motility. Percussion and auscultatory percussion with or without preliminary inflation, will aid the physician to gain a fair idea of the condition of the motor function. Any increase in size of the stomach is the result of interference with its motor power. In order to test for "atony" a dose of 75 grains of tartaric acid followed by 120 grains of bicarbonate of sodium is given. If the vertical diameter increases by more than 4 c.m. some degree of atony exists. As to the third function, it must be remembered that the stomach is normally insensitive to all ordinary degrees of stimulation. If when there is no lesion of the mucous membrane any real pain is felt during digestion this must be taken as evidence of increased sensibility. In speaking of the treatment of dyspepsia the writer mentions four methods. General measures such as rest, exercise, massage, hydrotherapy, and electricity may be indicated. Cases in which the function of the stomach is disturbed are much affected by nervous influences. Mental and physical rest are most important in such instances. Many times a dyspeptic patient is relieved at once of most of his complaints by rest in bed. Exercise is far less useful than rest, riding being probably the best of all forms of exercise. Walking, especially in a mountainous country, and golf are very helpful. Especially abdominal massage is of great aid in promoting motility of the stomach. In hyperesthesia, however, it is positively harmful. The writer believes that dietetic errors play but a small part in the production of dyspepsia. As to drugs, he states that one has merely to determine what function is perverted and how, and then to make use of the drugs which are known to act on that function. He believes that in purely functional dyspepsia surgery can be of little if any use.

**Portal Pyemia and Pylephlebitis.**—W. Langdon Brown presents the following conclusions: A collection of pus within the portal zone is the principal cause of portal pyemia. Ulceration of the alimentary tract is important only as being a frequent precursor of such a collection. Signs of portal obstruction are the exception in suppurative pylephlebitis. There are no signs by which we can distinguish with certainty cases of portal pyemia with suppurative pylephlebitis from those in which the vein is not involved. In "adhesive pylephlebitis" the essential feature is the occlusion of the vein, and this may be produced by a variety of causes, among which sepsis is not an infrequent one. Therefore, if our terminology is to accord with pathological conditions so far as they can be determined during life, we ought to speak of two conditions, portal pyemia and portal occlusion, remembering that we may meet with cases of portal pyemia with occlusion.

**A Hitherto Undescribed Change in the Urine of Patients Suffering from Nephritis.**—Marc Armand Ruffer and G. Calvocoressi define a weak hemolytic serum as one which in an 83 per cent. solution does not hemolize a given quantity of red blood corpuscles, but produces slight hemolysis in more than one hour. A strong hemolytic solution is one which added in the same proportions, dissolves blood corpuscles completely in less than one hour. In the experiments of these writers, however, when added in such proportions, all the strong (control) hemolytic serums but four dissolved the blood in less than five minutes. Even when diluted they acted very rapidly, generally in less than five minutes. The object of the investigation recently undertaken by the writers was to ascertain whether pathological urines contained more or less lysogen than normal urines. They have previously shown that the substances (lysogens) producing a hemolytic serum dialized slowly, were totally insoluble in ether, almost insoluble in alcohol, were precipitated from urine by saturation with ammonium sulphate or lead acetate, showed great resistance to the action of heat, but were quickly destroyed by acids or alkalies. A report of the results obtained in sixteen patients is given here. All but two of the patients, whose urine was injected into rabbits, were typical cases of chronic nephritis. The two exceptions were cases of acute diphtherial nephritis. The urine of one patient produced a strong hemolytic serum. The urine of four patients produced weak hemolytic serums. The urine of eleven did not produce hemolytic serum. There were sixteen control experiments, and in every case the urine produced a strong hemolytic serum. The only conclusion drawn at present by these investigators is that the physiological action of the urine of cases of chronic and diphtherial nephritis is, in the large majority of cases, very different from the action of the same quantity of healthy human beings.

**Injuries to the Eye After Paraffine Injections.**—Uhthoff reports two cases in which serious results followed the injection of paraffine for the purpose of correcting saddle nose due to trauma. The first case was that of a young woman who in the space of thirteen months received three injections of paraffine having a melting point of 43° C. Immediately after the injection she suddenly found that she was unable to see anything out of the left eye, and this unilateral blindness remained permanent. Ophthalmoscopic examination has left no doubt of the fact that it is due to an embolism of the central artery. The author supposes that a particle of the paraffine must have slipped through the pulmonary capillaries while still in the fluid condition, and have thus reached the arterial system. He refers to several other cases of the same accident, one of which was explained on the supposition that there was a patent *foramen ovale*, but considers that this explanation is rather improbable. In some of the reported cases the resulting lesion apparently was a thrombosis of the ophthalmic vein rather than a blocking of the central artery. The author's other instance of blindness following the use of paraffine occurred in a middle-aged man who after an injury to the nose, caused by the kick of a horse, received several prosthetic paraffine injections, presumably of low melting point. After working out of doors on a very hot day he complained of an itching about the eyes, and soon became unable to open them on account of swelling of the upper and lower lids. This finally reached such a point that only by forcible separation with the fingers could he cause sufficient opening to permit any vision at all with the right eye, while with the left even this was impossible. On excision of the tumors some months later they were found to consist almost entirely of dense fibrous tissue containing many giant cells and but

little paraffine. The *orbicularis* and the *levator palpebræ* muscles had also been largely replaced by fibrous tissue. The author believes that the irritation due to the presence of the paraffine gave rise to this severe production of inflammation with its resulting disastrous consequences. By the operation sufficient space was gained to permit of satisfactory vision, but the resulting deformity was very great. While not condemning the use of paraffine injections altogether, the author urges the necessity for the exercise of every possible precaution to prevent the occurrence of such unfortunate accidents.

**Prostatic Hypertrophy and Diabetes.**—Posner states that during the past ten months in examining thirty cases of prostatic hypertrophy from his private practice he five times detected the presence of sugar in the urine. This leads him to the conclusion that it is highly important to examine all prostatics for glycosuria and also to investigate the condition of the prostate in all diabetic patients. He believes that the two diseases occur together much oftener than is ordinarily supposed. This is not alone because they are both common diseases but also because he believes that there is a special connection between arteriosclerosis and diabetes, and prostatics, it is well known, are usually arteriosclerotic. If a patient who is being treated for diabetes complains of bladder symptoms they are usually ascribed to the constitutional disease, while an excessive secretion of urine or the existence of a high specific gravity in a prostatic is apt to be credited to the account of the local lesion. In this way the joint existence of the two diseases is easily overlooked, and the author calls attention to a recent instance in which a case of prostatectomy died of coma immediately after the operation as an indication of the great importance of detecting the complication when it exists.

*Münchener medizinische Wochenschrift, November* 21, 1905.

**The Relation of the Concentration of Photodynamic Substances to their Effectiveness.**—Jodlbauer and Tappeiner report on the results of some studies undertaken to determine the concentration at which a maximum of effect may be obtained from solutions containing photodynamic substances. Solutions of potassium iodide and invertin containing known graduated amounts of fluorescent bodies were subjected to the action of sunlight for definite lengths of time. On estimating the amount of chemical change produced it was found that at a certain concentration a maximum result was obtained, and that stronger or weaker solutions proved less effective. For eosin the most favorable strength was 1-2000 of a normal solution. From these observations the authors conclude that in making therapeutic use of fluorescent substances the effort should be made to bring the fluid into the tissues in its optimum concentration. With eosin, whose molecular weight in grams is 692, this would be a .04 per cent. solution. If the tissues were simple fluids the required dilution would be obtained by applying the eosin solution in double strength. Owing to the laws of osmosis, however, the protoplasmic cells can be more rapidly acted on by stronger solutions, but their use is contraindicated owing to the absorption of effective rays that takes place in thicker layers of the fluids. Therefore, more concentrated solutions are suited for local applications only when thin layers of tissue are to be treated, and the solution is used sparingly.

**Changes in the Clinical and Operative Point of View Regarding Uterine Myomata.**—Sippel says that of recent years uterine myomata have come to be regarded in a somewhat different light. It is being recognized that although of themselves benign, yet they can give rise to more serious conditions than was formerly supposed. Accordingly, the operative indications are constantly being broadened, especially for patients in the poorer walks of life, who are dependent on their own exertions for a livelihood and cannot afford the time or expense required for palliative treatment. He formulates the indications for operative intervention as follows: Every myoma causing symptoms of any sort demands medical observation and treatment. If it causes profuse hemorrhages, which give rise to persistent and notable diminution of the hemoglobin, if it grows rapidly, particularly if intraligamentary in position, if it causes pain or serious discomfort, if it leads to compression of structures in the pelvis, gives rise to severe damage of the heart muscle, or should become broken down, it should be made the ground for prompt operation. The age of the patient is an important factor to be considered, for in a woman near the menopause expectant therapy for a time is justifiable, while with a woman in the child-bearing period, radical intervention should not be too long deferred. The author gives the statistics of twenty-seven cases of myomata operated on during the last eighteen months. Five were dealt with by the vaginal route, the others abdominally, and all made uncomplicated recoveries.

**The Processes of Self-purification in Water.**—Hofer describes the results of a series of investigations undertaken to determine the manner in which self-purification takes place in the isar, which receives a large amount of sewage from the city of Munich. From an analysis of the conditions present, he concludes that the factors to which considerable importance is usually ascribed, such as chemical changes and the action of bacteria have but little influence on the disposal of the organic matter contaminating the stream. He attaches a much greater significance to the presence of the huge numbers of minute animal forms of many sorts which occur close to the river bottom below Munich, whereas, they are rather scanty in the stream above the city. He furthermore believes that in contradistinction to the usual view self-purification is not most active in rapidly flowing cold waters, but is more effective in sluggish or stagnant warm bodies of water. In conclusion he suggests for the disposal of sewage the establishment of huge ponds in which the processes of sedimentation, etc., could go on undisturbed, and from which a certain amount of useful return could be obtained in the shape of the large production of fish that could easily be secured.

*Deutsche medizinische Wochenschrift, November* 23, 1905.

**Preliminary Observations on the Results of a Journey of Investigation to Eastern Africa.**—R. Koch was able, in addition to pursuing his investigations on the coast fever of cattle, which were the chief object of his trip to Africa, to study the nature of several other blood infections in man and animals. In this preliminary report he briefly describes first, his observations on the African form of relapsing fever. The spirochete of the disease is transmitted by the bite of a tick which is found in the earth floors of the native huts. It emerges only at night and then feeds on human blood. Koch was able to detect an increase in the number of spirochetes within the body of the tick, the multiplication apparently taking place on the surface of the ovary of the insect. Another part of his studies was concerned with the development of the *Piroplasma bigeminum*, the inciting agent of Texas fever. On studying the stomach contents of ticks fed on the blood of infected cattle, a number of different phases of development of the protozoon could be traced and are described and illustrated by the author. Somewhat similar developmental stages were also detected in the parasites of coast fever, although these do not appear to be true members of the group of piroplasma. Further observations on the tsetse fly and the trypanosomes of cattle revealed the manner by which the infection is transmitted. It appears that the infected flies extrude in the act of biting a minute drop of fluid, which on microscopical examination was found to be swarming with trypanosomata. As the organisms were much more numerous in this fluid than they ever are in the blood, it was evident that the organism goes through a developmental stage in the fly, and is not merely transmitted from one animal host to another through the agency of the insect as was formerly supposed. Koch also describes and figures the results of his study of the various phases through which the parasite passes, one of the most interesting of which observations is the fact that there is a possibility that microgametes are formed as with the malarial organism, though it is not certain whether or not copulation takes place.

**The Obstetrical Management of Placenta Previa.**—Fritsch says that in his thirty-five years of obstetrical practice the cases of central placenta previa form conspicuously the most terrifying recollections. In spite of experience, practice, and carefully considered treatment, one is always likely to encounter cases that end unfavorably, yet in which the prognosis appeared good. Obstetric art has not yet reached the point at which as soon as the diagnosis of placenta previa has been made the calculable dangers of vaginal cesarean section are to be preferred to the uncertainties of the older treatment. In cases of sudden hemorrhages of considerable size, from the genitals placenta previa is always to be suspected. A distinction must be made accordingly as the blood appears to be fresh or old; if the latter, the immediate danger is over and expectant therapy is permissible, but if the hemorrhage is still persisting active intervention is necessary. Usually, even today, vaginal tamponade is the proper measure, but this must be properly carried out. The patient must be placed in the lateral position and the entire vulvar district be thoroughly disinfected. The packing material must be moist, and is best introduced only with the fingers, as the tissues of the genital canal are so friable in pregnancy that the use of instruments is always attended with great danger. The packing must be carried out so as completely to fill the pelvis; the rectum and

bladder, of course, having been emptied before the operation was begun. The thighs are then bound together, the pulse is watched, and the onset of pains is awaited. Usually the pressure of the tamponade causes this to occur without much delay, and if the packing is expelled by the patient's bearing down the cervix will be found sufficiently dilated. If the child is dead or is not viable, extraction is performed with the cranioclast in order to avoid cervical tears. The most difficult cases are those in which the hemorrhage is severe, the child is living and the cervix is undilated. If the membranes can be reached, they are ruptured and the onset of pains is encouraged by massage of the abdomen; if the case is one of central placenta previa, however, the cervix must be dilated either instrumentally or by hand until the placenta can be perforated and version performed. The danger of cervical tears is always great and the utmost care in extraction is necessary to avoid the deep lacerations that so easily give rise to fatal hemorrhage.

*American Journal of the Medical Sciences, October,* 1905.

**Surgical Intervention for Intracranial Hemorrhages of the Newborn.**—Harvey Cushing says a newborn child with regard for hemotasis and careful avoidance of exposure will stand a cranial operation well. He points out the immense amount of traumatism that every child has to undergo while making its entrance into the world. He adds that it would seem reasonable to expect that a careful operation, provided there is no loss of blood, would be no more serious. He believes that coagulation is as rapid in the newborn as in the adult. In all of his cases the effused blood was found to be clotted. He reports four cases in which he has operated. In one of these cases there seemed little question as to the presence of an intracranial hemorrhage though there was considerable doubt as to its exact situation. As the writer states the history of a sudden non-pulsating protrusion of the eyeball with great edema of the lids and conjunctiva—a condition rarely if ever met with except after cavernous sinus thrombosis—made it seem most probable that there was a basal fracture with resultant laceration of this vessel which had not thrombosed and produced proptosis until the third day. Craniotomy appeared to offer the only hope of recovery. An osteoplastic flap which included most of the parietal bone was elevated. The cerebral tension was so great, and the brain was so soft and easily injured that it was impossible to elevate the temporal lobe enough to discover whether or not a clot was present at the base. However, the numerous old blood clots were washed off from the cortex. A parietal flap was turned down in like fashion on the left side followed by a similar washing away of blood clots and the escape of cerebrospinal fluid. The tension was much diminished. The scalp wounds were closed without drainage. Immediate improvement took place. The circulation from the eyeball became reestablished and the exophthalmos gradually disappeared. Although it is difficult to tell at present what will be the future mental status of the child it now seems to be developing normally and is a natural and healthy appearing baby with no evidences of motor disability.

**The Permeability to Bacteria of Surgeons' Rubber Gloves.**—Herbert Fox and Edward A. Schumann as a result of their experiments conclude that rubber gloves are absolute barriers against wound infection by the hand of the surgeon in so far that they are absolutely bacteria proof. Any infection which occurs must be introduced into the wound from some point not protected by a glove. In one of these xperiments whole gloves were placed in bouillon about half-way to the wrist and bouillon poured into three to the same height. The gauntlet was turned over the edge of the flask and tightly tied; a beaker was inverted over the cotton stopper to avoid any risk of external infection. Unless the glove is greased at the surface which comes in contact with the cotton, the rubber will pull up when the stopper is removed. Sterilization was accomplished in the Arnold apparatus, three days being devoted to this process. The bouillon within the gloves was then inoculated with *B. coli communis* and *Staphylococcus pyogenes albus* and allowed to grow forty-eight hours. Cultures were then made from within and without the gloves. Those from within showed a pure culture of the germ. The latter were sterile. Like results followed the repetition of this experiment.

**Preventive and Remedial Treatmemt of Acute Rheumatic Endocarditis.**—Beverley Robinson believes that while salicin and members of the salicyl group relieve rheumatic symptoms in a remarkable manner in many instances, in other apparently similar cases they fail to do so. The reason for this is not yet positively known. The writer feels confident that in just such cases the rheumatic poison is still present and active; but we are unable to neutralize it, at leas with our ordinarily most effective remedy. The writer calls attention to the fact that although in many cases of acute rheumatic endocarditis the symptoms may not appear very grave it is often the results of the affection which are so serious. The larger number of all chronic cardiac disorders are a direct outcome of this affection. In speaking of the preventive treatment, the writer states that a primary and essential factor is to keep the throat in a very healthy condition. Not only is acute endocarditis thus prevented but in case of the presence of chronic endocarditis resulting from rheumatic infection a renewal of endocardial inflammation can be prevented. Even if in some cases there is failure in preventing the development of tonsillar disase and the resulting rheumatic attack, at least the heart may be helped to some extent to withstand the invasion. Besides appropriate local treatment general conditions must be considered. The gastrointestinal tract should be kept in an aseptic and fluent condition. The underlying rheumatic toxemia must be considered, and to this end attention to diet, clothing, habits, surroundings and occupation is important. Wet and cold should be avoided. By the use of salicin the poison of rheumatism may be neutralized, the disease shortened and thus there will be less likelihood of the development of endocarditis. The writer believes that patients with sub-acute rheumatism will often prevent the development of an attack of endocarditis by taking a complete rest for a while.

**Chylous and Chyliform Effusions Into the Serous Sac.**—J. G. Wilson declares that the frequency of chylous and chyliform effusions is far greater than is indicated in the literature. Quincke first pointed out the distinction between these two effusions. Bargebuhr recognized the fact that in all cases it is not possible to make a nice distinction between these two forms of effusions. Quincke's division of the fatty effusions included two groups: First that consisting of chyle from the thoracic duct, or the lacteals—transudates—and, second, that resulting from fatty metamorphosis of the cellular elements in inflammatory effusions—exudates. In general, the pathological causes of milklike effusion into the serous sac are: Trauma; tuberculosis; malignant disease; filariasis; thrombosis of the left subclavian vein; disease of the liver; and syphilis. In certain cases the milky effusion is found both above and below the diaphragm. These milky effusions do not always owe their characteristic appearance to fat. The writer describes a case in which the effused fluids, though fatty, were neither chylous nor chyliform, or chyloid, but a mixture of both. It was a case of sarcoma of retroperitoneal and thoracic lymph glands. Fatty ascites was discovered on operation for hernia. There was double pleural effusion, fatty on the left side and presenting the same appearance at repeated aspirations which were made at intervals extending over a period of many months. On the right side the effusion was circumscribed and seropurulent.

**Report of a Case of Metastatic Endothelioma.**—Edward Jenner Wood reports this case. The patient first complained of a small nodular mass on the surface of the right testicle. The testicle became painful and began to increase in size. It was finally removed. The tumor was unquestionably a large round-celled sarcoma. The patient in about two years noticed the same condition in the other testicle which in turn was almost removed. Again the trouble was pronounced to be a large round-celled sarcoma. Improvement followed for a time, but again his health became impaired and from the symptoms a provisional diagnosis of malignant disease of the left kidney was made. An exploratory incision showed a nephrectomy to be impracticable and the wound was closed. A few days later the patient died from a large pulmonary hemorrhage. Large cells evidently of the endothelial variety were found in the mass of the left kidney; there was also a nodule on the anterior surface of the liver which consisted of a mass of endothelial cells. The lung tissue showed hemorrhagic infarction. It is a question what rôle the tumor cells played in the fatal occlusion of a blood vessel. But it is certain that the lung was invaded by the tumor before the fatal accident occurred. The lung was probably the last organ invaded and still, as the writer declares, in many respects it gave the most typical demonstration of endothelioma. There is no question but that the tumor of the testicle was a large round-celled sarcoma. It is also most likely that this was the original source of the disease. If this is true, then the metastatic tumors offer another evidence that endothelioma is a pure sarcomatous tumor.

**A Procedure for Opening the Pericardium.**—J. H. Bacon believes that the treatment of the pericardium should be the same as that of other serous cavities. When there is no reaction to the treatment by rest and local application of ice-bag or heat, it should be aspirated when there is simple effusion and opened when pus is present. The writer describes his procedure for entering the pericardium. A skin incision is made parallel to the mid-line of the sternum and ½ cm. to its left, from the level of the upper border of the fifth costal cartilage to the sixth. On exposing the sternum a circular window is made through the bone with a trephine

2 cm. in diameter. The præcordial fat is dissected away and the anterior surface of the parietal pericardium is exposed. Two mouse-toothed forceps raise the pericardium and an incision is made between them. The pericardial cavity can then be readily explored and necessary treatment instituted.

*French and Italian Journals.*

**Tuberculous Parathyroiditis.**—P. Carnot and Delion report a case interesting on account of the coexistence of convulsive crises and parathyroid lesions in a young woman twenty-four years old who was tuberculous. The convulsive crises, subintrant, developed brusquely. These crises lasted eight hours and were terminated by death. The movements recalled at the time those of chorea, of athetosis, and of tetanus. At autopsy on account of the convulsive phenomena the parathyroids were carefully examined. The internal organs showed no special change but the right external one was completely lacking while the left was caseous. Since there were no changes in the meninges or in the kidneys, it seemed logical to attribute these convulsions to parathyroid insufficiency. The writers believe that this case is related to those in which tetanic convulsions are observed in patients after certain total thyroidectomies, and to those which occur in animals after parathyroidectomy. It also recalls those recent clinical researches concerning the parathyroid origin of certain tetanics and of certain eclampsias. The writers believe that in any case it is the first reported example of a spontaneous anatomo-pathological lesion localized in the parathyroids and accompanied by fatal convulsions.—*Le Bulletin Médical, November* 8, 1905.

**Extraperitoneal Rupture of the Bladder with Septic Urinous Phlegmon of the Cavity of Retizus. Hypogastric Incision on the Twelfth Day. Recovery.**—Loumeau describes a patient forty-four years old who suffered a rupture of the bladder. This was caused by the strain of vomiting and was followed by septic infiltration of the cavity of Retizus. The patient, whose condition was septic, was operated upon. A hypogastric incision was made. Recovery both from the infection and from the vesical perforation rapidly took place. The latter could be seen by means of the cystoscope as a small pink scar on the right anterolateral wall of the bladder. The reason that the rupture of the bladder occurred under the strain of vomiting was due to the existence of an old fibrous adhesion which had formed in the cavity of Retizus after a hypogastric contusion suffered by the patient when fourteen years of age. The pain of this injury was extreme and was distinctly located above the pubis a little to the right of the median line. Of late years the pain had been complicated by retention of urine and vesical paresis which could be explained only by the adhesion of the bladder to the abdominal wall. This adhesion was the outcome of a circumscribed sclerous pericystitis which had been caused by the organization of a bloody infiltration due to contusion of the bladder.—*Journal de Médecine de Bordeaux*, November 5, 1905.

**Identification of Cadavers by Means of the Teeth.**—Oscar Amoedo emphasizes the importance of this method of identification. It is only in comparatively recent years that the value of identification by means of indications furnished by the teeth has been appreciated. Many observations have been reported, which prove that these cases could be identified by means of the peculiarities of the teeth only. Many recent catastrophes such as that of the Opéra Comique, the Bazar de la Charité, and so on, have shown the importance of this means of identification. When the body is otherwise so disfigured that it is unrecognizable, the dental system is generally still in a condition to yield up its secret.—*Journal de Médecine de Paris*, November 7, 1905.

**Experimental Intestinal Occlusion.**—Roger has caused occlusion of the small intestine by means of a ligature which, at the end of twenty-four hours, has brought about a distension of the segment above the obstacle. Into this segment was introduced a cannula curved at a right angle, a kind of manometer capable of registering the compressions of the intestinal liquid. This liquid is agitated by oscillations which are synchronous with the respiratory movements and which are due to the compression caused by the play of the respiratory muscles. There was observed at the same time, every three or four minutes, a large peristaltic wave, which began from fifteen to twenty centimeters above the point of ligature and which caused the liquid in the manometer to rise. These large movements which represented an energetic effort to overcome the obstacle kept up as long as life lasted; that is, until that part of the intestine which was near the point of obstruction had lost its contractility. These experiments prove that fecal vomiting is not due to retrograde contraction; it results from compression exercised by the abdominal muscles on a loop of intestine which is closed and which is distended by liquid. —*La Tribune Médicale*, November 4, 1905.

**Early Diagnosis of Tuberculosis.**—Mariani gives as early symptoms in those predisposed to tuberculosis loss of flesh without known cause; adenoid vegetations in the pharynx; neuralgia; arthritis and herpes zoster, with anemia in women; dyspepsia with hyperchlorhydria; swelling of the thyroid; tachycardia without fever, and arterial hypotension, and orctuberculous splenomegaly; miosis or mydriasis, especially if unilateral; gingivitis; subjective bronchophony; easy elevation of temperature after slight fatigue, or injection of physiological serum; tendency to perspiration; spasmodic dry cough; dyspnea on slight exertion; hemoptysis; amiotrophy of the sternocleidomastoid and scapulothoracic muscles. Physical examination in such cases will bring to light physical signs of value to the diagnostician. —*La Riforma Medica*, October 8, 1905.

**Examinations by the Spirometer in Affections of the Circulatory Apparatus.**—Guido Castelli has examined seventy-five cases of various heart and lung affections, as well as some general diseases, and many cases of arterial disease, with the spirometer. His conclusions from his observations are as follows: 1. Diseases of the circulatory apparatus vary as to their effect on the respiration; some produce a marked diminution of power, others are normal in that respect, still others increase it. 2. There should be a marked distinction made between diseases of the heart of endocardial and of arterial origin. 3. Among those of endocardial origin, mitral stenosis most diminishes the respiratory power; next comes stenosis with insufficiency, last mitral insufficiency. 4. Aortic insufficiency of endocardial origin does not decrease respiratory power; when it exists in such cases it is due to arterial changes such as interfere with the pulmonary circulation. 5. Sclerosis and other affections of the arteries decrease respiratory power; after these come renal arteriosclerosis, arythmia, aortitis, miovalvular affections, and insufficiency of the aortic valve of arterial origin. 6. Angina pectoris coronaria alone produces no lessened respiratory power 7. Cardiac eretbism, even when accompanied by sensation of oppression, has no effect on respiration. 8. Respiratory power is increased, in troubles of endocardial origin at the mitral orifice, by the use of digitalis in small doses; if of arterial origin improvement in respiration follows a milk and vegetable diet and renal diuretics. —*Rivista Critica di Clinica Medica*, November 4, 1905.

**Differential Diagnosis between Exudates and Transudates by Dilute Acetic Acid.**—Fabio Rivolta gives us the following conclusions from his experiments in differential diagnosis between transudates and exudates by the use of dilute acetic acid: 1. Acetic acid used by the author's method has great diagnostic value, as well as simplicity, only a single drop of the fluid being needed for the test, which reacts immediately. 2. The test depends on the precipitation by acetic acid of two globulins from the blood. 3. This same reaction occurs in normal blood, in plasma, and in serum of plasma. 4. The transudates do not give the reaction with minute amounts of acetic acid because of their smaller content of globulin. 5. In fluids from malignant tumors, exudates or transudates, the acetic reaction may be lacking, or is slight in the last stages of the disease. 7. Traces of blood do not destroy the test. 8. The test is useless post mortem.—*Il Policlinico*, November, 1905.

---

**Artificial Leucocytosis as a Therapeutic Measure.**—Hubert Allison Becker states that it is well demonstrated that in all of the infectious diseases, excepting typhoid fever and influenza, there is a leucocytosis more or less marked in proportion to the severity of the infection. The leucocytes first surround the area invaded by the germs. Disintegration of the polynuclear cells takes place by which a new substance is set free in the blood serum. This material not only counteracts the bacterial toxin, but also influences the germs in such a way that the hyaline leucocytes become capable of ingesting and destroying the invading microorganisms. Since the leucocytes liberate an antitoxic substance, it follows that the larger the number of the leucocytes the larger will be the amount of antitoxin set free, and consequently the more powerful will nature become to combat infection. The writer considers nuclein the most convenient and satisfactory of the various leucocyte-increasing drugs. It must be used hypodermically as it is decomposed by the gastric juice. He recommends the five per cent. solution of nucleinic acid. It may be used in doses of from five to twenty minims. If the first dose is large enough it is rarely necessary to give more. Improvement begins in from six to twelve hours. There are no harmful results. The writer believes that artificial hyperleucocytosis is one of the most powerful and wide-reaching of life-saving measures. Its full possibilities are not yet comprehended.—*The Therapeutic Gazette.*

# Book Reviews.

L'Acide Formique et la Force Musculaire. Par le Dr. Clément, médecin des hôpitaux de Lyon. Paris: Vigot Frères. 1905.

In this book, written unfortunately for the laity as well as for medical practitioners, the author lauds formic acid and its salts as a sovereign prophylactic against fatigue and a remedy by means of which the capacity for physical labor may be greatly increased. Its action in increasing muscular strength is shown by numerous ergographic tracings. One of the chief benefits to be derived from the routine employment of this substance is, in the author's opinion, the removal of a desire for alcoholic stimulation; the laborer, no longer feeling fatigue, will have no impulse to resort to alcohol as a "bracer." It is questionable, however, whether it is wise to recommend the habitual use of a remedy which, if it is as potent in its effects as Dr. Clément asserts, is almost sure to be found on more extensive trial to have a deleterious action in certain directions. Fire is good, but if we play with it carelessly we are apt to get burned. It is curious that one so enthusiastic in his praise of formic acid should practically ignore the statements of other writers concerning its efficacy as a remedy in rheumatism. His attention seems to be have been directed solely to its action as a stimulant to normal muscular action.

Algiers as a Winter Resort and Its Therapeutical Indications, together with Notes on Hammam R'Irha and Biskra. By Alfred S. Gubb, M.D. (Paris), M.R.C.S. Eng., D.P.H. Lond., etc., Author of Aids to Gynecology; Editor of Griffith's Materia Medica; Late Editor of the *Medical Press and Circular*. London: Baillière, Tindall & Cox, 1905.

This is a short descriptive guide which will be found useful to anyone contemplating a visit to Algiers. The author has passed many seasons in the country, engaged in the practice of his profession, and has learned by practical experience what maladies are most benefited by a residence in this soft climate. Algeria is rather too far away to attract many invalids from this hemisphere, especially as we have many equally favored spots nearer home. However, many who contemplate a winter in Italy or the Riviera may find it to their advantage to pass the couple of months in which Rome or Naples is apt to be chilly and disagreeable on the other side of the Mediterranean, and to such this little book will prove to be serviceable.

The Inn of Rest. Divers Episodes in Hospital Life Relative to the Doctor, the Nurse, and the Patient. Edited by Sheldon E. Ames. New York, Akron, Ohio, Chicago: The Saalfield Publishing Co., 1905.

In this, the seventh volume of the Doctor's Recreation Series, we have a collection of tales, essays, poems, and historical sketches relating to hospital life and nursing as a profession. The selections are made from many different sources, among the writers drawn upon being Walt Whitman, Edgar Fawcett, Isabel allmpton Robb, Frederick Langbridge, A. B. Ward, Elizabeth G. Jordan, Eliza Priestley, and Joseph Hatton. One of the most entertaining of the pieces is "The Gibson Play," by Marguerite Merrington, a comedy based upon Charles Dana Gibson's well-known series of pictures of "A Widow and Her Friends." Of interest also is an historical article on "Pre-Christian Dispensaries and Hospitals," in which the impression, based largely upon the statement in Canon Farrar's "Life of Christ" that "amidst all the boasted civilization of antiquity there existed no hospitals, no penitentiaries, no asylums," is very conclusively shown to be erroneous. The get-up of the book is in conformity with the others of the series, and the typography, paper, and binding combine to make a handsome volume.

Therapeutics: Its Principles and Practice. By Horatio C. Wood, M.D., LL.D., Professor of Materia Medica and Therapeutics in the University of Pennsylvania; Member of the National Academy of Science. Twelfth Edition. Thoroughly revised and adapted to the eighth (1905) edition of the United States Pharmacopeia by Horatio C. Wood and Horatio C. Wood, Jr., M.D., Demonstrator of Pharmacodynamics in the University of Pennsylvania. Philadelphia and London: J. B. Lippincott Company, 1905.

The present revision of this widely used treatise has been somewhat more radical than most of its predecessors, for the reason that the changes made in the eighth edition of the Pharmacopeia have been incorporated, so as to bring the volume into harmony with the new official guide. Besides the changes involved in reorganizing the text in this respect, radical alterations have also been made in other directions. The chapters on Expectorants and Disinfectants have been rearranged and the more recent advances in anesthesia, including local, spinal, and neural anesthesia, have been briefly considered. A footnote is devoted to the subject of scopolamine-morphine anesthesia, and through a typographical slip the index reference to this is page 104, instead of 103, as it should be. Numerous other changes in arrangement and interpolations of new matter are to be noted; the scope of the additions may be estimated from the fact that 70 new drugs receive discussion, some of which we fear will be of only ephemeral interest, however. The enviable reputation the work has gained for itself in the past is the best guarantee that in its present form it will continue to stand in the front rank of books on this subject.

Memoranda on Poisons. By Thomas Hawkes Tanner, M.D., F.L.S. Tenth Revised Edition by Henry Leffmann, A.M., M.D., Professor of Chemistry in the Woman's Medical College of Pennsylvania, etc. Philadelphia: P. Blakiston's Son & Co., 1905.

This volume is small enough to be kept permanently in the emergency bag to serve for ready reference, and yet it contains a large amount of information on toxicology. It must be admitted that at times its language and counsels have a somewhat antiquated flavor, but on the whole it is fairly satisfactory. The sections on the purely chemical aspects of the subject are by far the best, and the paragraphs on treatment might with advantage be amplified somewhat.

Clinical Methods, A Guide to the Practical Study of Medicine. By Robert Hutchison, M.D., F.R.C.P., Assistant Physician to the London Hospital, and to the Hospital for Sick Children, Great Ormond street; and Harry Rainy, M.A., F.R.C.P.Ed., F.R.S.E., Examiner in Medicine and Clinical Medicine, St. Andrew's University, Formerly University Tutor in Clinical Medicine, Royal Infirmary, Edinburgh. With upwards of 150 illustrations and 9 colored plates. Ninth Edition; Seventeenth thousand. Chicago: W. T. Keener & Co., 1905.

This volume contains an account of the various methods of clinical investigation that are used in making a correct diagnosis. It begins with a chapter on case-taking, and includes a general scheme for the examination of all medical cases. In subsequent chapters this scheme is expanded, and the different procedures are described in more or less detail. The alimentary, circulatory, respiratory, urinary, nervous, and locomotor systems are each considered in separate chapters; special sections are further devoted to examination of the skin, the eye, ear, nose, and throat; and also to the clinical examination of children. The book concludes with chapters on the examination of pathological fluids and clinical bacteriology. The volume contains much useful information in a small compass, and can be recommended to the student and practitioner as a reliable and up-to-date *vade mecum*.

Dissecting Manual, Based on Cunningham's Anatomy. By W. H. Rockwell, Jr., M.D., Formerly Assistant Demonstrator of Anatomy in the College of Physicians and Surgeons, Columbia University, New York. New York: William Wood & Co., 1905.

In this book the body is divided into five parts, to conform to ordinary dissecting-room usage. Under the first part, the head and neck, the spinal cord is also included. In each section there is a brief yet sufficient description of the bones, articulations, fasciæ, muscles, nerves, arteries, veins, lymphatics, and viscera or other structures to be found in the given part. Throughout the volume the descriptions follow closely the new edition of Cunningham's Anatomy, and references at the end of each paragraph refer to the pages of that standard work. To all first and second-year students this little volume will be useful; to those reciting from Cunningham's Anatomy it is indispensable. The book is well and clearly printed, is of a handy size, and is bound in a limp and waterproof cover.

The Blues (Splanchnic Neurasthenia), Causes and Cure. By Albert Abrams, A.M., M.D. (Heidelberg), F.R.M.S., Consulting Physician Denver National Hospital for Consumptives, the Mount Zion and the French Hospitals, San Francisco, etc. Illustrated. Second Edition, enlarged. New York: E. B. Treat & Co., 1905.

Dr. Abrams' theory of the dependence of some cases of mental depression on dilatation of the splanchnic vessels through relaxation of the abdominal muscles, is now pretty well known and has found many adherents. That it has at least excited the interest of medical readers is evident from the prompt appearance of a second edition of the work, which apparently is unchanged except for the addition of four more sections to the appendix. These deal respectively with massage of the liver, human metabolism, chemical demonstration of the action of sinusoidal currents, testing intraabdominal tension, and percussion of the stomach. We are rather surprised not to find a chapter devoted to the aortic reflexes that have been described by the author. The volume is one that may safely be recommended to the medical man; he will find in it much of interest and ample food for reflection, even if he does not in all cases agree with either the author's premises or his conclusions.

# Society Reports.

## NEW YORK ACADEMY OF MEDICINE.

*Regular Meeting, Held December 7, 1905.*

DR. CHARLES L. DANA IN THE CHAIR.

THE evening was devoted to papers on experimental medicine.

**Methods of Studying Fatigue, with Demonstration.**—Dr. FREDERIC S. LEE, Professor of Physiology, College of Physicians and Surgeons, said that the study of fatigue offered an unusual opportunity for the application of exact physical methods to the investigation of physiological and pathological processes, for muscle was an excellent indicator of the fatigue of the organism, and since the prominent feature of the activity of muscle was the performance of mechanical work, it was only necessary in studying fatigue to make use of the methods of the physicist in investigating mechanical work. Fatigue of frog's muscle was then demonstrated by stimulating the muscle at regular intervals and recording the curves of all the contractions by the author's newly devised methods. By means of lantern slides some of the results of an extended research on the subject were presented. Dreser's method of demonstrating the production of acid during muscular activity by the use of acid fuchsin was shown.

Dr. GRAHAM LUSK said that there was nothing to criticize but everything to admire in Dr. Lee's presentation, and that the curves shown were the most beautiful he had ever seen.

Dr. R. BURTON-OPITZ also discussed the paper briefly.

**Some Properties of Indol, Skatol, Methyl Indol, and Tryptophan, with Demonstrations of the Color Reactions.**—Dr. C. A. HERTER showed the results of his investigations in the detection of certain putrefactive substances formed during the course of normal and excessive fermentative changes in the intestinal tract, interest in which was aroused last summer when doing experimental work with Ehrlich aldehyde reaction, the dimethyl-amido-benzaldehyde. He showed the typical reaction with this agent with human urine. The reaction was seldom shown in a child's urine. The urine was slightly warmed and a few drops of the reagent added; then dilute hydrochloric acid was added and the mixture brought almost to a boil. In child's urine there was hardly any color reaction noticed, but in other urines there appeared an unusual degree of intensity. The addition of chloroform took away the color. In normal persons with very little digestive disturbances, the reaction was apt to be present, although slight, and it might be absent. On the other hand, in those suffering from digestive disorders the reaction would be striking. As a result of this work Dr. Herter said that it occurred to him that some products of putrefaction or proteid decomposition in the intestines might be responsible for this color reaction, and he began experiments. He first experimented with blood, introducing large quantities of hemoglobin into the circulation in the intestines; the results as to the reaction were negative. As a result of putrefactive changes in the intestines there were developed indol and skatol. He fed indol to animals by mouth, as well as subcutaneously, and found that it produced no effect upon the intensity of the color reaction, or changed it in any way. But when he used skatol he got different results, usually by a marked increase in the intensity of the reaction. Experiments were performed upon monkeys. He presented a monkey's urine taken after it had received a dose of skatol; the reaction was marked. This showed one of the ways that Ehrlich's aldehyde reaction resulted. He then instituted investigations to determine whether the quantity of indol and the quantity of skatol that could be found in the intestinal contents corresponded to the presence of Ehrlich's aldehyde reaction in the urine, and observations up to the present time indicated an association or relationship of this sort. The question then arose how to recognize these substances in the intestinal contents. It was not such a difficult matter, so far as the mere recognizing of indol was concerned; but the recognition of skatol was more difficult, especially its quantitative determination. He devised a better method of detecting these substances than the one customary. Both these substances, indol and skatol, exerted a detrimental effect upon the nervous system and when present for long periods of time were capable of giving rise or contributing to the development of functional disturbances of the nervous system which was of considerable importance. He then told of the method he had devised for separating indol and skatol from the feces, a method which he claimed was applicable to clinical requirements. He took three test-tubes; in one he introduced indol; in another, skatol; in the third, β-naphthalquinone-sodium-monosulphonate. Caustic potash was then added to each. Then part of the contents of tube 3 was poured into each of the other tubes; a reaction formed in the tube containing the indol, but none in the skatol solution. This new compound was of a perfectly definite character and separated into clearly defined acicular crystals of peculiar color. This new compound was one which was helpful in the quantitative estimation of the substances, because, when chloroform was added, the substance went over to the chloroform and made this determination of the substance possible with a considerable degree of exactitude. He next made a solution of skatol, added some of Ehrlich's aldehyde solution, warmed it a little and the color reaction developed, but of a peculiar sort. It was of a violet or purplish tinge, which developed on heating. The addition of hydrochloric acid produced a distinct violet reaction. From this solution he shook out a substance which was blue and which, on the addition of chloroform, dropped to the bottom of the vessel. This demonstrated the possibility of separating the two substances, indol and skatol. Dr. Herter then spoke of the practical applicability of the determination of these substances, and said that from a case of pernicious anemia he had been able to obtain 60 grms. of indol from 100 grms. of the material. No skatol reaction was to be had, although there was a strong indican shown with Ehrlich's reaction. In another case, skatol in considerable quantities had been obtained from the feces, but little or no indol. In summing up his remarks he said there was without doubt a distinct relationship between the presence of skatol and the development of the Ehrlich's aldehyde reaction. He did not claim that this was the only cause for this reaction, because further experimenting showed that other factors were concerned. He believed that by means of certain methods, to be further developed, it would become easy to separate indol and skatol, and to estimate with a considerable degree of accuracy the quantity of both indol and skatol.

Dr. P. A. LEVENE said that there were two pigments in the urine, one due to faulty metabolism of the blood pigment, the other due to faulty metabolism of proteid bodies, and it was the general opinion that Ehrlich's reaction indicated faulty metabolism of the hemoglobin, or blood pigment. This was a very important thing to establish for diagnostic purposes. The most common pigment in the urine was urobilin, which was derived from hemoglobin, the blood pigment; by the disintegration of this pigment in the organism in excessive quantities, and the appearance of large amounts of urobilin in the urine made it possible to diagnose hemorrhages, such as cerebral, etc. Therefore, Dr. Herter's method made it possible to distinguish faulty hemoglobin metabolism from faulty proteid metabolism, and was very important. It should be borne in mind that the blood pigment was very closely related to the pigment derived from proteid bodies.

**Dysentery Toxin and Mercury Colitis, with Demonstration.**—Dr. SIMON FLEXNER said that there was one particular type of organism which was described by Shiga which was more intensely toxic than any others belonging to the group of organisms causing dysentery, and which was capable of yielding a toxin which grew outside the

body. He was particularly interested in the light that was thrown upon the genesis of dysenteric lesions in man. If this toxin be introduced in animals, and death followed, there would be found in the intestines, localized in particular places (about the cecum), lesions which were comparable to dysenteric lesions found in man, and the growth of these lesions varied in intensity. After studying the manner in which these lesions could be developed, facts were learned which were of great interest. Small quantities of the toxin in the circulation produced lesions which were not lesions of contact but probably lesions of elimination. Not only was the poison eliminated by the intestines, but at particular parts of the intestines. It was also determined that when the organism got into the circulation a certain number of them were influenced by the bile, and it therefore occurred to him that possibly these lesions might be more or less controlled by the biliary secretions. He then studied the effects after ligating the common duct and also by making a biliary fistula in rabbits. By so doing great changes could be brought about in the character of the lesions. It was found that this poison was eliminated into the intestine with the bile. When the poison was introduced into the intestines by injections these lesions were not produced; only when they were brought there by the circulation and permitted to be excreted with the bile could such lesions be produced. If bile was prevented from entering the intestines the lesions would disappear, or else become very much reduced in intensity. Studies with mercury were also made. The lesions here also could be much modified by ligaturing the common duct, or the formation of a biliary fistula. An interesting and very important fact was that this poison, which was made by the dysenteric bacilli and which produced these lesions, was in some way modified by the liver so that it passed through the liver into the intestine with changed character and capable of producing lesions which otherwise it could not do. If this poison was permitted to reach the liver, but prevented from passing into the intestines by the closure of the duct, the lesions produced were much reduced in intensity. The bearing of all this experimental work on human dysentery was very important. It was true that the dysenteric bacilli developed throughout the intestinal tract, and yet the lesions produced were localized in one particular part of the intestine. It seemed to him highly probable that the intestine afforded a place for the dysenteric bacilli to grow with the production of a poison which was absorbed and eliminated with the bile, producing these lesions in the intestines indirectly, as shown by the experiments an animals with the toxins and with mercury. There was developed a neurotoxin and certain lesions in animals were produced, chiefly located in the cervical portion of the spinal cord; the changes first produced were in the gray matter of the cord, particularly hemorrhages. In animals there followed paralysis of the extremities, and then a complete paralysis of the entire body. They were subject to convulsions, with retracted head, etc. The animal would live for a few days and die, and lesions would be found chiefly located in the cord. The brain would show lesions as well. A rabbit was shown completely paralyzed, with retracted head, with convulsions occurring from time to time. He believed that not only did they have to do with two substances, but that these two toxins were independent of each other, and one was far more resistant and enduring than the other. Further experimentation was contemplated in order to determine, if possible, if further light could not be thrown upon the genesis of human dysentery. Lesions in the intestines did not take place where the bacteria developed, but in parts where in elimination they were common. Such poisons as mercury produced lesions which corresponded to those produced by the dysenteric toxin.

Dr. James Ewing said that Dr. Flexner's contribution had very important bearings on the nature of dysentery. The toxins of the bacillus of Shiga and other members of this group seemed to have special affinity for the cells of the intestinal tract, and, if true, this seemed to have important bearings on the pathogenesis of the disease, especially the power of the colon to inhibit the growth of certain bacteria. A kind of vicious circle seemed to be formed, the more the bacteria increased, the more toxin was produced and absorbed, and the more of this poison was to be excreted.

**Inhibitory and Anesthetic Properties of Magnesium Salts, with Demonstration.**—Dr. S. J. Meltzer read this paper (see page 965).

Dr. George B. Wallace, after referring to the application of laboratory findings to practical therapeutics, said that he had had occasion to determine the exact value of Dr. Meltzer's discovery. Many who would use this method would no doubt be over-enthusiastic in its praise. He asked, Was this method a safe one? From an experimental standpoint the margin between the dose producing anesthesia and the fatal one was narrow. He asked, again, had this method many advantages over the more common ones? There was the absence of the stage of excitement, the lack of salivation, of an effect upon the respiratory tract, and of injury to the heart and kidney, all of which pointed to the desirability of this method. But as opposed to this method, the manner in which it was to be given was a serious drawback. Spinal injections were always more or less dangerous. On the whole, it seemed to him as if magnesium was a very suitable anesthetic in certain selected cases, but expert anesthetists would feel less comfortable with this method than with the ones in common use.

Dr. Herman A. Haubold said he had placed at the disposal of the writer of the paper a number of cases, and the procedure was justified because of the statements made to him by Dr. Meltzer regarding the outcome of similar injections made on the lower animals, together with the conviction that the method of employment was consistent with the procedure of spinal anesthesia. Dr. Haubold had used this method in seven cases. Complete anesthesia was obtained in two cases, although in only one was there no chloroform used; in this cases 8 c.c. of the solution was injected at 2.30 P.M., and the operation was performed at 3.30 P.M. The case was one of deep-seated abscess in the anterior aspect of the thigh, and two incisions were made about three inches in length, together with a counter-opening with scissors forcibly pushed through to the posterior portion. The patient at no time made any outcry and stated that he did not feel any sensation whatever. In the other case, 4 c.c. of the solution was used. The injection was made at 1.50 P.M., and at 3.30 P.M., although sensation was absent, it was regarded as wiser to administer a little chloroform. Only in two cases did no impairment of sensory conduction obtain. Motor paralysis, to a greater or less extent, occurred in all of the cases. In six cases it was necessary to give small amounts of chloroform, and, although the patients moved their arms and eyelids, there was no motion of the pelvis or lower extremities, thus permitting of unresisting surgical manipulations in these regions.

Dr. Joseph A. Blake said he had used this method in four cases. One was a patient with marked shock following traumatic amputation of the thigh, and it was given with the idea of combating this shock. The shock did not diminish and the patient died one or two hours later. The fourth case was one of acute tetanus. In one patient anesthesia was not produced to any marked extent, the motor being inhibited more than the sensory nerves. One patient had appendicitis, with much contraction of the abdominal muscles; after the use of the magnesium sulphate these muscles completely relaxed. Dr. Blake could not state how great a value should be placed upon this method at present, but he believed it would be of value in properly selected cases, cases in which the general anesthetics, as ether or chloroform, were contraindicated. In such cases, for instance, as diabetic amputation, he would prefer magnesium sulphate to either eucaine or cocaine. Again, it might be used in cases of great shock. The value of this

method was amply shown in the case of acute tetanus. A boy of 15 years was admitted to the hospital with a traumatic amputation of two fingers. On the seventh day following the accident he entered into a state of opisthotonos, with almost constant convulsions. The boy was given antitoxin the first day and without any apparent effect. The temperature was 104° and convulsions constant. The magnesium was given and the convulsions immediately stopped and the boy seemed conscious in two hours. The motor nerves were completely inhibited. He lay in bed and took nourishment. The temperature gradually came down. At the end of thirty-six hours the convulsions started again, another injection was given, and the temperature came down further. Four injections were given and improvement continued. At the end of another week the convulsions became worse and the temperature ran up a little, but another injection made the boy quiet. The boy had been in the hospital four weeks and was now perfectly well.

Dr. Willy Meyer continued the discussion and said that Dr. Meltzer's and Dr. Auer's latest discovery was, to his mind, very fascinating indeed. A salt of one of the four inorganic elements found in our system, sulphate of magnesium, if introduced, in solution, into the gastrointestinal tract, the latter being lined by a normal mucous membrane, produced frequent watery evacuations; but the same solution, if placed around the living motor nerve, exerted an inhibitory effect upon its conductivity, which effect was annulled upon washing the nerve with saline solution; furthermore, if introduced into the body in larger quantities, by means of intravenous injection, it invariably produced death by respiratory paralysis, and if injected into the subarachnoid space in the shape of the 25 per cent. solution, it produced not only temporary motor paralysis of the lower extremities, bladder, and rectum, but also analgesia of the entire lower half of the body—at times, as it seemed, also of the upper half. These new facts were evolved step by step with Drs. Meltzer and Auer's original work, following up logical conclusions drawn from former experimental work along these lines. Having been especially interested in spinal anesthesia ever since its introduction into practical surgery by Prof. Bier, he was very glad indeed to try the 25 per cent. sterilized solution of sulphate of magnesium, when asked to do so by Dr. Meltzer some five weeks ago. He had since used it in three cases and was satisfied that it did all Dr. Meltzer claimed for it. He could, for instance, in a case of extensive tuberculous fistula in ano, cut and burn with Paquelin's cautery around the anus and within the rectum without producing the least pain, only the stretching of the sphincter muscles seemed to be slightly painful. The same satisfactory result was noticed in the other two cases. In none of the three was any additional general anesthetic used. In contradistinction to the drugs thus far used for spinal anesthesia, viz., cocaine, tropacocaine, stovain, and the newest drug, novocain, sulphate of magnesium did not produce an immediate effect, after a few minutes, as did the drugs just mentioned, but only after one or two hours, and it then continued with equal strength for many hours. Thus, it was possible to have the lumbar puncture and injection carried out by a member of the house staff at, say, 12 o'clock, and then have the patient ready for operation at about 2 o'clock. According to his experience, the dose so far used, namely 1 c.c. to every 20 lbs. of body weight, was larger than necessary. The right dosage for the human being would, no doubt, soon be found by further experimentation. Naturally, the intraspinal application of sulphate of magnesium also had its disadvantages, the principal one being the temporary paralysis of the bladder, which, in cases of urethral stricture or in the presence of prostatic enlargement, might give rise to trouble. Personally, he had always been of the opinion that spinal anesthesia should be carried out on strict indication only, and this he believed to be true also when it was induced by sulphate of magnesium; but he fully agreed with Dr. Blake, that in cases of diabetic grangrene, for instance, sulphate of magnesium appeared to be preferable to cocaine and its derivatives, inasmuch as it did not affect the heart, but the respiratory center only. Dr. Meltzer's advice, to have ready in every operating room an O'Dwyer-Fell apparatus for artificial respiration, was, therefore, a very important one. In conclusion he begged to say that he believed this new discovery placed us at the threshold of finding out many new and important facts relating to medicine and surgery. It spoke for the genius of Dr. Meltzer and added materially to the glory of American scientific research.

**Election of Officers.**—The following officers were elected: *Vice-President* (for two years), Dr. George Ryerson Fowler; *Vice-President* (for full term), Dr. Robert Abbe; *Treasurer*, Dr. Reginald H. Sayre; *Trustee*, Dr. A. Alexander Smith; *Member of Committee on Admissions*, Dr. David Bovaird, Jr.; *Member of Committee on Library*, Dr. Herman L. Collyer.

## THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

*Stated Meeting, November* 13, 1905.

The President, Dr. Thomas E. Satterthwaite, in the Chair.

**Report of the Committee on the Death of Dr. Warren Schoonover, Jr.**—Dr. P. Brynberg Porter, the secretary of the association, read this report.

**Symposium on Clinical Pathology: the Relation of Clinical Pathology to Actual Practice.**—Dr. Louis Faugères Bishop read this paper. He stated that the problem was to make clinical pathology available to the men who actually did the bulk of the practice. At present clinical pathology was too much in the position of a consultation branch rather than a help in everyday work. Too many men invoked the aid of a technical examination only when the case seemed obscure or when the patient was very ill. Laboratory work was really only an extension of the physical examination, employing the microscope as we employed the stethoscope, and testing the composition of the blood as an extension of the same operation that was begun when we looked at the color of the mucous membranes. The bacteriology of the human body in health and disease should become a matter of routine observation rather than one laid aside for special occasion. The systematic examination of patients over a considerable period of time, thus ascertaining the physiological and bacteriological habit of the individual should become a more common practice. The most obvious solution of the problem that immediately presented itself to every physician was that he should take a course in the laboratory, and then make a practice of carrying on those observations for himself; but as a matter of fact the practice of medicine was too complicated an occupation to allow of the proper atmosphere for laboratory work. There was too much of the social and personal required to allow the combination of the two kinds of work in the general practitioner. The only element in practice that interested the patient was the one factor of treatment and recovery from disease, and the most successful men, from the point of view of having satisfactory practices, were those who concentrated most of their attention upon the treatment of their patients, keeping the rest much in the background. Dr. Bishop said his own conclusion was that the relation of clinical pathology to private practice had not been satisfactory, and the cure for the present unsatisfactory condition was found, first, in dissemination among practitioners of the knowledge of the actual value of the findings of the laboratory as an aid to treatment; second, in building up the confidence of the profession in the work of the younger graduates of the pathological services of our hospitals, and in separating routine work, such as those men were perfectly capable of doing, from the higher class of work which called for the expert knowledge and opinion of established specialists in clinical pathology.

**Laboratory Aids in the Diagnosis of Disorders of the Gastrointestinal Tract.**—Dr. Ernest E. Smith discussed this phase of the subject. He stated that the examination of the stomach contents, either vomited, obtained in gastric lavage, or removed after a suitable test meal, was of unquestionable value and should be more generally practised, especially in chronic gastric disease. There was one class of cases, however, which emphasized the value of the systematic examination of patients, even though they might present pretty well localized symptoms, namely, cases of persistent vomiting due to a condition of acid intoxication. For several years this had been recognized as the exciting cause in some cases of persistent vomiting of childhood, and evidence was accumulating to show that not infrequently it was the cause of persistent emesis in adults. Riegel had emphasized the value of differentiating between the gastric conditions of hyperacidity, alimentary hypersecretion, and continuous hypersecretion. The term hyperacidity was used to indicate hyperchlorhydria without hypersecretion; the term alimentary hypersecretion to indicate an increased flow of gastric juice as a result of gastric stimulation; and, finally, the term continuous hypersecretion, to indicate a flow occurring without the stimulant of the presence of food. The differentiation was made from the amount of stomach contents removed after the test breakfast, the acidity, and the absence of gastric secretion during starvation. The conditions of increased acidity and secretion constituted a large proportion of the gastric disorders with which the physician had to deal. The stomach normally passed a portion of its contents into the duodenum, even during the first hour of digestion. Failure to do so might lead to the presence in the stomach of an abnormal amount of contents, this occurring in pyloric stenosis and dilatation and in gastric motor insufficiency. Those conditions, then, must be excluded before assuming that the increase in volume had resulted from an increase in the gastric secretion. Having concluded that the secretion was increased, the question of whether it occurred only under the stimulus of food or without such stimulus was determined by examining the stomach contents after fasting. This was accomplished by gastric lavage at night and the withdrawal of any contents the following morning. In continuous hypersecretion it would be found that the stomach contained a goodly amount of liquid containing hydrochloric acid and gastric ferments. The aid afforded by laboratory examinations was probably as well, and possibly better, appreciated in gastric than in intestinal conditions. Many physicians made much of the microscopical inspection of the stools, but comparatively few realized the value of extending the examination further. The speaker suggested that the microscopical examination of the stools might well have a place in the routine of the practising physician. Examined directly, the feces rarely showed the presence of pathological admixtures unappreciated by the naked eye, but it might reveal the presence of a parasitic invader. In cases where the digestive functions were overtaxed, either because of excessive eating or because of diminished functional ability, the presence of abnormal amounts of undigested or partially digested food residue was readily recognized, even without resorting to the special methods advocated by Schmidt and Strassburger. A procedure which had attracted much attention in clinical diagnosis during the past two years was the recognition of the so-called occult blood in the feces. By means of a delicate chemical test it was possible to detect blood so modified by the gastrointestinal processes that it could not be recognized under the microscope. The patient's diet must be free from meat and fish. The test should not be limited to a single specimen, but a series of observations should be made. It was thus possible to determine whether occult blood was constantly absent, constantly present, or occasionally present. The lesion might be in any part of the alimentary tract. Occult blood had the same significance as visible hemorrhage. It was constantly present in cancer, intermittently in ulcer, and was absent in gastritis, hyperacidity, hypersecretion, and the gastric neuroses. Its occurrence was an aid in the diagnosis of a suspected case of typhoid fever. Aside from the diagnostic value of the test, it was of value in indicating the therapeutic action of remedies in gastric ulcer. In closing, Dr. Smith emphasized the importance of the histological examination of all suitable material, whether connected with the alimentary tract or from other parts of the body. The diagnostic value of such an examination was at times unexpected and considerable.

**The Present Attitude of Blood Examination for Diagnostic Purposes.**—Dr. Frederic E. Sondern read this paper. He stated that the evolution of hematology during the last decade had been so pronounced that at the present time an accurate knowledge of the blood condition was considered essential in the diagnostic and prognostic conclusions in all but the most trivial cases. The present more intimate knowledge of the minute differences, as well as of the relative changes noted in the various forms of anemia, had unfortunately shed little or no light on the etiology of these diseases, but had greatly facilitated their diagnosis, as well as the differential diagnosis. Thus, simple anemia, secondary anemia, pernicious anemia, splenic anemia, and Hodgkin's disease could be differentiated with greater precision than the former less accurate knowledge of the blood changes allowed. It was not only in the blood diseases proper, if they might be so termed, that the examination of the blood was useful. In acute febrile conditions, when the clinical picture was not yet sufficiently pronounced to justify a diagnosis, a routine examination of the blood was often a guide and always a comfort. This examination showed the degree of anemia, if any, and a search for plasmodia, a Widal test, an enumeration of leucocytes and a differential count of the latter, while they might not establish the diagnosis, at least confined it within narrower limits, and often excluded feared grave conditions. The value of finding the characteristic organisms in malaria, filariasis, trypanosomiasis, and relapsing fever needed mere mention. The increase in the relative number of large lymphocytes in malaria was an additional stimulus to repeated search if plasmodia were not found at once. In the event of coma, the knowledge that meningitis and brain abscess were always accompanied by a leucocytosis and relative polynuclear increase; that uremic, postepileptic, and diabetic coma sometimes showed leucocytosis, and that narcotic or alcoholic poisoning, hysteria, and tumor had no accompanying leucocytosis was also of diagnostic value when combined with the clinical observation. The early stages of scarlet fever often presented diagnostic difficulty, but when it was recalled that this disease always showed a pronounced leucocytosis and relative polynuclear increase, it was more readily distinguished from several other eruptive conditions most easily confused with it which did not present that characteristic. In typhoid fever we had hoped that the early diagnosis would have material aid from the Widal serum reaction. While that anticipation had been but partly fulfilled, owing to the delayed response to that test in many cases, the fact that uncomplicated typhoid fever showed no leucocytosis and a relative lymphocytosis on differential count of leucocytes was an aid not to be overlooked. In pneumonia a consideration of the blood picture was often of the greatest value in both diagnosis and prognosis. In the prognosis of that disease it had long been known that the absence of a leucocytosis was a very grave and unusual fatal sign. For several years, the speaker said, not only the leucocyte count, but also the differential count of leucocytes in pneumonia had received his particular attention, and his results seemed to justify the conclusion that the increase in the relative number of polynuclear cells was a direct indication of the severity of the toxic infection, and the degree of leucocytosis an absolute indication of the body resistance toward the infection. Blood-serum reactions, agglutinations, Pfeiffer's phenomenon, and similar work on which scientists were at present engaged were among the most important researches in medicine to-day, but the results were not yet sufficiently precise

to find application here. In surgery, as in medicine, the examination of the blood had found application in diagnosis and prognosis. The arbitrary rule that no surgical procedure was to be undertaken when the percentage of hemoglobin was below 30 should no longer adorn our text-books. Cryoscopy of the blood was a recognized method for determining the functional activity of the kidneys, and in conjunction with a proper urine analysis was decidedly useful. Blood cultures as diagnostic and prognostic aids had also increased very much in value, and the physiological changes in the blood due to pregnancy and parturition were somewhat better understood. To prevent an accusation of undue reliance on any one aid, Dr. Sondern said he would close with this motto: "The man who makes every diagnosis in the laboratory is as short-sighted and liable to grave error as the man who ignores the microscope and test tube."

**Some Recent Advances in Urinology.**—Dr. Louis Heitzmann said that of all the laboratory methods employed by the general practitioner there was probably none used as much as the examination of the urine. While to a certain degree it was true that the general practitioner did not fully realize the importance of laboratory work, he was beginning to appreciate more and more the value of making his own urinary examinations. It was only within the past few years, Dr. Heitzmann said, that we had heard so much about the estimation of the functional efficiency of the kidney and its extreme importance. Many different methods had been suggested in order to determine the working power of the kidney, and one of them had been referred to by Dr. Sondern, namely, cryoscopy of the blood and urine. This test, in trained hands and with a good instrument, was doubtless of much value, but otherwise it was apt to give rise to wrong impressions and leave one in the lurch. The electrical conductivity of the urine, which was another test that had been recently introduced, had not given satisfactory results. The same might be said of the methylene blue and the fluorescin tests, and the toxicity test. Not one of these methods was really satisfactory. If they were, investigators would not be constantly on the lookout for new ones. The speaker said that one of the reasons why urinary examinations were as a rule unsatisfactory was that they were not carried out correctly. A drop of urine was placed on the slide, and oftentimes left uncovered; it was then examined under a low power, and various forms of casts, hyaline, granular, and epithelial, were apparently found, whereas if that same drop of urine, properly covered, was examined under a high power, many of the castlike bodies would prove not to be casts at all. It was not always necessary to find casts in nephritis, and a positive diagnosis of that disease could be made without a single true cast in the urine. With our modern methods of cystoscopy and ureteral catheterization the working condition of each kidney could be fairly well determined.

Dr. Eugene Coleman Savidge said that while all recognized the importance of pathological investigation, and resorted to it to a greater or less extent, they did not do so sufficiently. The reason for this was obvious. The man who was engaged in clinical work could not burden his attention with laboratory routine, while on the other hand he frequently could not afford to send his specimens to the pathologist. Dr. Savidge said that greater freedom of laboratory resort had given him (1) renewed faith in certain forms of therapeutics; (2) an almost iconoclastic conviction that we had been making errors after certain laboratory findings; and (3) an insight into conditions which had proven themselves to be observable long before there were laboratory findings. In other words, the laboratory was both confirmatory and non-confirmatory. It clarified as much by what it did not tell as by what it told.

Dr. Max Einhorn said that while the laboratory methods that had been discussed were of great aid in some instances, the clinician, first of all, had to study the symptomatology of the patient, the history, the physical findings, and so on. These, in the greater majority of cases, would enable him to arrive at a correct diagnosis, although there certainly were instances where every possible aid, including the laboratory tests, had to be invoked. The speaker said that over twenty years ago he had called attention to the fact that the percentage of lymphocytes in their relation to the other white elements of the blood was diminished in anemia and septic conditions, and he stated that Dr. Sondern deserved great credit for the work he had done in this field of pathology, and for his recognition of the importance of the differential count of leucocytes, and the relation of the number of polynuclear cells to the leucocytosis. Taking up Dr. Smith's paper, Dr. Einhorn said that in order to determine the presence of continuous hypersecretion, he was opposed to the method of gastric lavage at night and the examination of the stomach contents the following morning. Instead of washing out the stomach at night, he gave the patient a light meal, preferably of rice, and then resorted to lavage the following morning. By this means we could determine whether there was any obstruction at the pylorus, and it would also indicate the presence or absence of continuous hypersecretion.

Dr. Robert Coleman Kemp said that in addition to the laboratory aids in the diagnosis of disorders of the gastrointestinal tract, the gross examination of the stomach contents by means of a test meal and subsequent aspiration of contents was very important. Such an examination would show the degree of maceration of the food, the presence or absence of mucus, the odor, and the quantity found after a definite time, and would give us a pretty accurate idea of the degree of motor insufficiency of the stomach. Such a microscopical examination of the stomach contents could be made by the average physician just as intelligently as he now made an examination of the urine, and if this was done as a matter of routine, grave pathological conditions of the stomach would more often be detected at an early stage. Careful attention should also be given to the stomach in the treatment of tuberculosis, as various changes occur in the gastric secretions during different stages of the disease. The speaker said that while he was in favor of the "stuffing" process in tuberculosis, it should be done in a commonsense and scientific way if we expected to get the best results. The examination of the gastric functions and contents was important in epilepsy and in certain nervous diseases, especially in neurasthenia, where there were symptoms pointing to fermentation or autointoxication. In such cases he had seen marked benefit follow treatment directed to the gastrointestinal tract.

Dr. E. Libman called attention to the importance of an accurate blood examination in the diagnosis of acute leukemia. In cases of suspected typhoid fever in which the Widal test gave no reaction in the customary low dilution, a number of higher dilutions should be tried. The best results in bacteriological examinations of the blood would be obtained by those who had not only a knowledge of bacteriology, but also a large clinical experience. Otherwise the reports would be apt to be misleading. Certain microorganisms would grow well in highly diluted blood; others would not grow well excepting in a large quantity of blood. The speaker said there was a question whether in every case of infection by bacteria there were bacteria present in the blood, and he was of the opinion that bacteria did not multiply very often in the blood. There were certain types of infection; for example, suppurative thrombosis of the portal vein, in which bacteria could not usually be found in the blood, while in malignant endocarditis they were usually present. Personally, Dr. Libman said, he had never found bacteria in the blood in appendicitis, but he believed they did occasionally occur there.

Dr. Frederic Bierhoff said he had always held that clinical microscopy and urinology were two branches of medicine that were entitled to be classed as specialties just as much as were any of the other well-known specialties. They required, in order to be of real value, a degree of skill and exactitude which the average general practitioner

did not possess on account of the lack of time that he had to devote to them. When these examinations were properly and carefully made the findings were often of the greatest value; when they were improperly made they were of less than no value, because they were apt to lead us astray. Dr. Bierhoff said the present tendency was to place less reliance upon cryoscopy of the blood and urine and more upon a very thorough examination of the urine itself; its chemical constituents, its microscopical ingredients, the quantity passed in a given time, and a comparison of the urine secreted by each kidney. The results of such an examination were far more reliable than cryoscopy of the blood or urine. In making a careful examination of the urinary tract, one point of great importance was to discover the presence or absence of gonococci. In the male they were usually found by the microscope, but in the female they often escaped detection, because the smears were generally taken from the vagina or vulva, instead of from the cervix or interior of the uterus, which were the most frequent seats of the trouble. If gonococci were present at all they would be found in the cervical secretion, or in that taken from the uterus. Preferably, the smear should be taken twenty-four hours after the cessation of menstruation.

Dr. Richard Van Santvoord said that, speaking from the standpoint of the general practitioner, he wished to emphasize the necessity of interpreting the laboratory findings in the light of the history of the patient and the clinical symptoms. He feared there was some tendency to rely too much on laboratory methods and too little on a careful examination of the patient. Clinical pathology, like everything else, had its limitations and its exceptions. A single malarial parasite in the blood did not prove that the case was one of malaria, nor did a single tubercle bacillus in the sputum prove tuberculosis. The laboratory work, in order to be relied upon, should be done thoroughly and efficiently, and a sufficient number of tests should be made to warrant reliable conclusions.

Dr. Henry Heiman said that by an examination of the blood we could not only make a positive diagnosis of malaria, but could also differentiate between the tertian, quartan, and crescentic forms of the parasite. The microscope had also taught us which forms of malaria responded most readily to the administration of quinine, and the disease could be treated more intelligently and rationally than in former years, when quinine was given in unnecessarily large doses. The value of clinical microscopy in the study of blood diseases could not be overestimated; for example, in the recognition of the various forms of splenic and myelogenous leukemia, as well as in the anemias. No one doubted the value of the Widal reaction and the presence of leucocytosis as confirmatory aids to diagnosis.

Dr. Winfield Ayres said his own experience had led him to believe that the average general practitioner, on account of his other duties, did not possess the necessary degree of skill to make a thorough urinary analysis, and that such work was best done in the laboratory.

### Philadelphia County Medical Society.

At a stated meeting held November 8 Dr. Wm. Pickett presented a communication entitled "The Morbid Physiology of Neurasthenia." He defined the affection as a disability rather than a disease, and he considered it essentially a state of exhaustibility, an undue readiness of fatigue, rather than real weakness. Dr. F. X. Dercum presented a communication entitled "The Diagnosis of Neurasthenia." He pointed out the necessity of excluding various visceral affections presenting symptoms that may be designated neurasthenoid. The inherent symptom of neurasthenia is the undue readiness of fatigue. Around this may be grouped various motor, sensory, psychic, and somatic manifestations, together with a number of secondary phenomena. The differentiation must be made especially from hysteria, hypochondria, and neurasthenoid states. Dr. Charles K. Mills presented a communication on "The Treatment of Neurasthenia." He discussed first the importance of isolation, in the more severe cases at least. The foremost indication generally is rest. This may be partial or complete, and it must be regulated in accordance with the conditions present in the individual case. In some cases it may, with advantage, be replaced by or alternated with exercise and work of one sort or another. Feeding is an important therapeutic adjuvant. Milk may at first form the basis of the dietary, which is to be gradually amplified. Massage is a most useful measure, and it may appropriately be conjoined with electricity. Drugs play a subordinate part in the treatment, and are employed to fulfil special indications, such as sleep, anorexia, and so on. Major Charles E. Woodruff, Surgeon U.S.A., spoke, by invitation, of the influence of light, particularly of the short rays, in the development of neurasthenia, and especially the severe grade observed in the tropics. The most pronounced symptom is impairment of memory, especially for recent events, and recovery quickly ensues on change to a more temperate climate. Blondes suffer more than brunettes, from the absence in the former of pigment in the skin, the pigment tending to exclude the actinic rays of light and preventing the irritation otherwise resulting. The fact, he said, had a therapeutic, as well as a hygienic, value, as it would be found that neurasthenic blondes did better in a climate with less light.

## Therapeutic Hints.

**Sciatica.—**

℞ Morph. sulph. ..... gr. ss.
Atrop. sulph. ..... gr. 1/25
Aq. destillat. ..... ♏ xx
Sig. Inject deeply into the muscle over the course of the nerve.
—Brown-Séquard.

**Follicular Tonsillitis.—**

℞ Formaldehydi ..... ♏ xx-xxx
Glycerini ..... ʒ ii
M. Sig. Apply with a brush three or four times a day.
—Jordan.

**Hemorrhoids.—**

℞ Ichthyol. .....
Acidi tannic. ..... aa gr. v
Ext. belladon. .....
Ext. stramon. ..... aa gr. 1-3
Ext. hamamel. ..... gr. x
M. Ft. supposit.
—Tuttle.

**Acute Pharyngitis.—**

℞ Ergotin. ..... ʒ i
Glycerin. ..... ʒ vi
Aquæ dest. ..... ʒ i
M. Sig. Use as a spray every one-half hour. One-tenth grain of ergotin by mouth may be used as an adjuvant.
—Perry.

**High Tension in Gout.—**

℞ Potassii bicarb. ..... ʒ ix
Potassii nitratis ..... ʒ vi
Sodii nitritis ..... gr. i
Ft. chart. No. xx.
Sig. One powder in the morning in a large glass of water.
—Lauder Brunton.

**Pneumonia.—**

Cain treated sixteen cases of pneumonia with no mortality, using guaiacol in doses of five to thirty minims, according to age. It was rubbed into the skin of the chest or abdomen every twelve to twenty-four hours, as indicated. The skin was first cleansed to promote absorption. Then the guaiacol was slowly dropped from a medicine dropper, and rubbed in, one finger only being used. If the fingers are all used, much of the medicine is absorbed by them, besides making them rough. The chest was protected by a woolen flannel jacket. The bowels were kept well opened. A soda, alcohol, and water bath was given at least once a day. The diet was light, and he insisted upon having plenty of warm, fresh air. Anodynes, expectorants, tonics, and stimulants were seldom required. In most cases no internal medication was employed except laxatives.—*Therapeutic Gazette.*

## New Instruments.

### HIGH FREQUENCY HIGH POTENTIAL CURRENT CATAPHORIC AND FLUORESCENT ELECTRODES.

By WILLIAM JAMES MORTON, M.D.,

NEW YORK.

In the issue of the MEDICAL RECORD of November 18, 1905, I published a description of a vacuum electrode provided with disks of porous material or with disks of fluorescent material which could be used respectively for the introduction of medicines, or for the treatment of disease by fluorescent light.

I wish to extend that publication by saying that electrodes of solid metal, properly constructed and provided with disks, may also be made to answer the above purposes. Similar solid metallic electrodes provided with porous disks were described by me in

my book upon Cataphoresis, published by the American Technical Book Co. in 1891, page 109, but their purpose at that time was for use with the galvanic current.

To construct an electrode which may be used with high frequency currents rather than galvanic currents a somewhat different method must be employed. The metallic portion must be without sharp peripheral edges so that the current shall not stream off at such edges.

The accompanying illustration makes plain the salient features of the present electrode. It is a brass disk two inches in diameter with rounded edges. Surrounding the metallic disk is an ebonite cap which fits it and affords a projecting lip. Into the cap and lying flat upon the exposed surface of the disk may be placed the porous material of blotting paper, asbestos, or whatever is desirable, and it is this disk which retains the medicament desired to be introduced. But if the disk is composed of fluorescent material, then the electrode becomes a fluorescent lamp which may be applied flatly upon any desired surface, and there produce effects due to the radiation from a variety of solid fluorescent materials. Among fluorescent minerals are willemite, calcite, fluorite, zinc sulphide, calcium sulphide, barium, platino cyanide, and calcium tungstate.

The metallic exposed surface is corrugated so that recesses for the retention of fluids are provided, just as in my galvanic cataphoric electrodes, drill holes into the solid metals, but not through it, exist everywhere on the surface.

The electrode is manufactured by Messrs. Van Houten & Ten Broeck, 300 Fourth Avenue, New York City.

19 EAST TWENTY-EIGHTH STREET.

---

**"The New England Alkaloidist"** is the title of a new monthly journal published at Milford, Mass., under the editorial management of Drs. J. M. French and N. W. Sanborn. Its purpose is to advocate the therapeutic use of the alkaloids and other active principles, as tending to greater accuracy and more positive results.

## Books Received.

*While the* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE PREVENTION OF SENILITY AND A SANITARY OUTLOOK. By SIR JAMES CRICHTON-BROWNE. 12mo, 141 pages, muslin. The Macmillan Company, New York. Cloth, 75 cents.

BABY INCUBATORS By JOHN ZAHORSKY. 8vo, 136 pages, illustrated, muslin. Courier of Medicine Company, St. Louis, Mo.

A STUDY IN NURSING. By Miss A. L. PRINGLE. 16mo, 98 pages, flexible muslin. The Macmillan Company, New York. Cloth, 35 cents.

SHORE LIFE. By ALFRED GOLDSBOROUGH MAYER. 8vo, 181 pages, illustrated, muslin. A. S. Barnes & Co., New York.

THE LOCALIZATION OF CEREBRAL FUNCTION. By ALFRED W. CAMPBELL, M.D. 4to, 360 pages, illustrated, muslin. The Macmillan Company, New York. Cloth, $6.00.

RADIOTHERAPY IN SKIN DISEASE. By Dr. J. BELOT. Translated by W. Deane Butcher, M.R.C.S. 8vo, 463 pages, illustrated, muslin. Rebman Company, New York.

PHYSICIAN'S VISITING LIST FOR 1906. P. Blakiston's Son & Co., Philadelphia.

PRÉCIS DE LARYNGOLOGIE CLINIQUE ET THÉRAPEUTIQUE. By Dr. P. LACROIX. 12mo, 627 pages, illustrated, paper. F. R. de Rudeval, Paris. Paper, 8 francs.

AUTOINTOXICATION IN DISEASE. By CH. BOUCHARD. Translated by Thomas Oliver, M.A., M.D. Second Edition. 8vo, 342 pages, muslin. F. A. Davis Company, Philadelphia. Cloth, $2.00, net.

STOFFWECHSEL UND STOFFWECHSELKRANKHEITEN. Dr. PAUL FRIEDRICH RICHTER. 8vo, 389 pages, paper. August Hirschwald, Berlin.

THE ART OF MASSAGE. By A. CREIGHTON HALE. Second Edition. 12mo, 144 pages. The Scientific Press, Ltd., London.

SURGICAL DIAGNOSIS. By ALBERT A. BERG, M.D. 12mo, 543 pages, illustrated, muslin. Lea Brothers & Co., Philadelphia.

LIFE AND MATTER. By SIR OLIVER LODGE. 12mo, 175 pages, cloth. G. P. Putnam's Sons, New York.

MATERIA MEDICA AND THERAPEUTICS. By J. MITCHELL BRUCE, M.D., LOND. 16mo, 632 pages, muslin. Revised and enlarged edition. W. T. Keener & Co., Chicago. Price $1.75 net.

PHYSICAL DIAGNOSIS. By EGBERT LEFEVRE, M.D. 12mo, 479 pages, illustrated, cloth. Second edition. Lea Brothers & Co., Philadelphia.

TEXT-BOOK OF MATERIA MEDICA FOR NURSES. Compiled by LIVINIA L. DOCK. Fourth Edition. 12mo, 330 pages, muslin. G. P. Putnam's Sons, New York.

ORGANOTHERAPY OR TREATMENT BY MEANS OF PREPARATIONS OF VARIOUS ORGANS. By H. BATTY SHAW, M.D., LOND. 12mo, 256 pages, illustrated, muslin. W. T. Keener & Co., Chicago. Price $1.75 net.

TEXT-BOOK OF MEDICAL AND PHARMACEUTICAL CHEMISTRY. By ELIAS H. BARTLEY, B.S., M.D., Ph.G. Sixth edition, 8vo, 734 pages, illustrated, cloth. P. Blakiston's Son & Co., Philadelphia.

PATHOGENIC MICROORGANISMS. By WILLIAM HALLOCK PARKS, M.D. Second Edition. 8vo, 546 pages, illustrated, muslin. Lea Brothers & Company, New York and Philadelphia.

MOVABLE KIDNEY. By C. W. SUCKLING, M.D., M.R.C.P. 12mo, xii, 127 pages. H. K. Lewis, London.

THE BLUES (NERVE EXHAUSTION). CAUSES AND CURE. By Dr. ALBERT ABRAMS. Second Edition, Enlarged. 8vo, 246 pages, illustrated, muslin. E. B. Treat & Company, New York.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending December 9, 1905.

| | Cases | Deaths |
|---|---|---|
| Measles | 572 | 7 |
| Diphtheria and Croup | 334 | 40 |
| Scarlet Fever | 187 | 6 |
| Smallpox | .. | .. |
| Chickenpox | 222 | .. |
| Tuberculosis | 429 | 177 |
| Typhoid Fever | 94 | 13 |
| Cerebrospinal Meningitis | 34 | 15 |
| Typhus Fever | .. | .. |
| Yellow Fever | .. | .. |
| Cholera | .. | .. |
| Totals | 1,872 | 258 |

**The Etherization of Children.**—Walter G. Elmer declares that the administration of anesthetics to children is an art which requires an unusual degree of skill and tact on the part of the anesthetizer. Very great care should be taken to prevent the overdosing of the little patient, with the resulting increased shock and lowered vitality. Children are very susceptible to anesthetics. The writer advocates the use of ether as the safest and best of the anesthetics for young subjects; the vitality of children is easily affected even when ether is properly given, the shock to the nerve centers from a prolonged anesthetization being very considerable. There are a few instances in which ether is not the choice anesthetic for children, the most important of which is an abnormal state of the respiratory organs. Ether, for example, should never be given to children during an acute bronchitis, pulmonary congestion, or pneumonia. In such cases, when an emergency operation arises, as for virulent appendicitis, strangulated hernia, and so on, chloroform should be used. For short operations, ethyl chloride is of value. If ether is properly given, its use need not be considered of unusual danger in cases of nephritis. The greatest care must be observed in etherizing a patient with heart disease. Cases of profound anemia are more than ordinarily susceptible to shock. The most favorable time for operation upon children is in the morning. The preparation of children for an operation and for the anesthetic does not materially differ from that of adults. An absolutely pure ether should be used, and that from the can. The open method of administration should always be adopted. The eyes should always be left uncovered, therefore the smaller size of inhaler should be used. In weak children subjected to a long or dangerous operation, the vital forces should be preserved as much as possible; the body should be swathed in cotton batting, or an electrothern may be used. If the child is old enough to understand, it is well to talk to him a minute or two about things that interest him before beginning the anesthetic. No one should be in the room but the nurse and the anesthetizer, who should tell the child to clasp his hands tightly together, holding the fingers closely interlocked. The child should never be deceived in any way. As a rule, children are ready for operation in six minutes. Now and then children can be etherized while asleep, but this method is hardly advisable, for the chances are that the child will be awakened and frightened, with consequent unsatisfactory results. If children are carefully and tactfully treated, etherization is robbed of much of its distress.—*Archives of Pediatrics.*

**Local Action of Antidiphtheritic Serum.**—Dopter describes the results of Martin's method in the local application of antidiphtheritic serum, which are infinitely better than those from the use of the liquid serum. His results are antimicrobic, not antitoxic, and are obtained by the use of dried serum incorporated with gum and administered in the form of pastilles. In the great majority of cases this method insures the disappearance of the diphtheria bacillus at the latest in five days; a greater delay is exceptional, and relapses are rare. Certain details are necessary in order to obtain these results: The patient must not chew the pastilles, but should let them melt in the mouth; the contact of the serum with the mucous membrane is thus more prolonged. The patient ought to such the pastilles regularly, one each hour. Every gargle or mouth wash which would dilute the serum in the throat should be omitted. The writer has employed the serum in the form of a dry powder on the mucosa of the nasal fossæ. The patient uses this like snuff. It has an undeniable action on the nasal bacilli, although the results are less satisfactory than in the case of the throat pastilles. The diphtheria bacilli rapidly disappear from the throat with the use of the throat pastilles, and the patient is quickly freed from the injurious action of the toxine, which is constantly elaborated by the germs. The writer thinks also that by this treatment there is hope of preventing the prolonged varieties of diphtheria, the relapsing forms, and the severe toxic accidents which occur after the casting off of the false membranes. He also thinks that the paralyses and pareses of the velum palati are avoided. The period of contagiousness and thereby of isolation is notably diminished. Hospital expenses are greatly decreased.—*Annals of Gynecology and Pediatry.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended December 9, 1905:

### THE NEURASTHENIC STATES CAUSED BY EXCESSIVE LIGHT.*

By MAJOR CHAS. E. WOODRUFF

SURGEON U. S. ARMY, PLATTSBURG BARRACKS, N. Y.

The new knowledge as to the powerful therapeutic effects of light in the case of superficial infections or atypical growths is so recent that the medical profession has not yet had time to realize the full significance of the facts so far published. It has long been known that light destroys practically all the bacteria in their vegetative stages and that it is one of our best disinfectants, so that it was quite logical to apply it therapeutically to the bacteria which had invaded the tissues. The success has been phenomenal and has been duly recorded in current literature. Briefly it might be stated that almost every local infection, if not too deeply seated, and practically every superficial atypical growth, whether malignant or benign, is curable by concentrated rays. Some operators use blue and violet, a few use the shorter ultraviolet, though as a rule these rays are filtered out by the cooling apparatus such as that used in the Finsen system. Still others use the shorter and more irregular *x*-ray, and in some instances the exceedingly minute waves set up by the corpuscles flying off from radium. Naturally there are differences of opinion as to which is the best, and these details are not yet worked out. There is some evidence that tubercle bacilli are killed more easily by the blue-violet rays than by the ultraviolet, while the cancer cells are more damaged by the *x*-ray or radium rays. In time there will be differentiation of treatment and every case will receive the wave length of most efficiency for it. Even concentrated red has been found efficient in some conditions. The new uviol lamp of Dr. Schott of Jena is a modification of the Cooper-Hewitt mercury vapor light and is made of glass which is transparent to ultraviolet rays. It has no red or infra-red and is practically cold. Its fatal effects upon living protoplasm are said to be extraordinary and it may become a powerful therapeutic agent and as dangerous as the *x*-ray.

Now, all this knowledge has had a curious result. We wholly fail to realize that the effect of short waves is always destructive and never constructive. Even in plants, they are used to break up the carbonic oxide of the air, being transformed in some way to another form of energy, possibly electric, by the chlorophyl. Hence the opinion was universal that light was a most beneficent agent of which we could not get too much, and the profession to a man has been advocating excessive exposure to the sun's rays and the admission of great streams of light into our living rooms, schools, and workshops, utterly oblivious of the fact that if it can destroy bacillary protoplasm it can do the same to the cells of our bodies. In addition light almost invariably hinders growth while darkness favors it both in plants and animals. Even men tend to be big in dark climates and little in the light ones, with some exceptions.

Botanists have long recognized the fact that the living growing cell always functions in the dark, under the bark, and that the protoplasm in the leaf must resort to all sorts of schemes for protection from too intense a light. Zoologists also have shown that animals pass all their time in the dark, or if they must expose themselves to the sun's rays they are invariably protected by an opaque covering of hair, feathers, or skin pigmentation. It is only within a decade that anthropologists have discovered that the same law applies to man. It is now proved that in every part of the world the native type of man, who is adjusted to the climate, has an amount of pigmentation strictly in accordance with the amount of light to which he is exposed. The degree of heat is immaterial, for we find that Arctic natives and those of the subtropics are equally pigmented, the former for protection from the reflected snow glare and the latter from the direct rays. Only in dark cloudy climates where there never is intense light, do we find the blonds at home, and in this cold northern part of Europe the blondness is an actual advantage in conserving heat. White surfaces radiate less heat than dark ones. Consequently blonds are perfectly adjusted to dark cold climates, and when they migrate to lighter countries they are more or less damaged according to the excess of light to which they are exposed. This fully accounts for the fact that though there has been a succession of streams of blond races, flowing southward in Europe, they do not permanently survive.

It is now necessary to find out the manner in which this extinction takes place. Since America is peopled entirely by European types, many of whom are far south of their natural habitat, it is evident that the same process of extinction is now going on under our very eyes, but so slowly that it has never been noticed. Anthropologists have repeatedly called attention to the fact that Americans are becoming more and more brunet, so as to approximate the complexions of people of similar latitudes in Europe. The ordinary explanation has been in the direction of a belief that our children are becoming darker than their parents. No one seems to have noticed that the blonds are suffering a greater mortality than the brunets, yet that is the real process. It has already progressed considerably in our South, whose vigorous types of white men are notably brunet. America then should be a good field for the study of this process of extinction.

The main result of excessive light which is not of sufficient degree to cause necrosis of protoplasm is some kind of a chemical breaking up which renders it paretic. We see a typical illustration in the low vitality of tissues damaged by the *x*-ray. Another instance is the prolonged and often incurable neurasthenia following sunstroke, and it might be said that the short sun's rays are one of the factors

*Read at the Annual Meeting of the Northern New York Medical Association, at Malone, N. Y., October 24, 1905.

in some of these cases, though thermic fever may be due to the dark infra-red rays alone. It might also be explained in passing that in the therapeutic use of these short rays it is found that invading organisms and atypical new cells are more easily killed than the normal tissue, but that if the light is too strong it kills both normal and abnormal. Indeed normal cells, from repeated damage of minor degree, may be so changed as to take on malignant growth themselves. It may not be necessary even to kill the bacteria, say in lupus, for if they are injured, the healthy tissues can dispose of them. The matter is more fully explained in my work on "The Effect of Tropical Light on White Men" (Rebman Company, 1123 Broadway, N. Y.), but is entirely too big a topic to treat properly in this place.

It has been proved that under the influence of excessive light which is not strong enough to be fatal, metabolism goes on at an increased pace and carbonic oxide is excreted in larger amounts. It is easy to see that this process cannot have any other ultimate result than exhaustion, and this is what we find in the tropics where neurasthenia is a very common condition among those who are careless in exposing themselves to the sun. Dr. L. H. Fales (*American Medicine,* April 1, 1905,) mentions that this condition is particularly common in the women, though several British India physicians believe that the men are the greater sufferers. I have found it quite common in both sexes. In men it is apt to be concealed owing to their greater musculature and better blood conditions, and the disease is rarely mentioned, as there is sure to be some coincident infection or organic trouble for which treatment is given—indeed these conditions invariably magnify the neurasthenia.

In the first few months of a tropical residence the stimulation causes an increased feeling of well-being and greater activity, so that new arrivals are capable of more work than at home. With few exceptions they are deceived as to the climate, and write glowing descriptions of its excellence. There are many curious letters in existence written by these stimulated men who have subsequently been killed by the climate or its infections. This fact will explain some of those remarkable discrepancies published as to the climate. For some reason the obese or those of great musculature suffer from neurasthenia in the tropics to a more marked degree than the little frail people, unless the latter were neurasthenic beforehand. I have been informed that the big Englishmen who go to India are quite apt to break down, while the little men more often pull through for many years.

The most important facts are found in relation to complexion. It has been particularly noticed that blonds suffer in the Philippines more than brunets, have higher grades of neurasthenia, break down in larger numbers proportionately, and in many ways prove their unfitness for the climate. This is the great point in regard to America, and particularly the cities in which the light glare is so intense in Summer. It is known that the inhabitants of European cities are more brunet than those of the surrounding country and the same phenomenon is now taking place here.

This process of the death of blond families of our larger cities, particularly in the South, is very slow, to be sure, and is not generally noticed, but is a painful fact nevertheless, and perhaps the main reason for that other fact, so long noticed, that cities are consumers of population. Growing or germ cells are more easily injured than differentiated adult cells. That is the reason *x*-ray workers are so often sterilized, why the ovary also can be made inert, and why young animals or ova are killed by exposures to radium, *x*-ray, or light in amounts which are harmless to adults. It is why also men who are raised in the country can move to a city and stand the light which kills off all their children or makes them so nervous that they are not fit to procreate a healthy third generation. It is also why we find dreadful neurasthenic states in children in the cities, even babies, when the parents are strong, and it is also why white children in the tropics begin to fade at seven or eight, or about the time they begin to run about. Infants kept indoors and protected from the light apparently do well in the Philippines, though I have seen them very sick, particularly blond children.

I have been informed by a Philadelphia neurologist that most if not all his neurasthenics are from the South, and blond at that. The Northwest corner of the United States is the cloudiest and rainiest. Not only do blonds flourish there, but the report of the Surgeon-General shows that the soldiers in that region have the lowest sick and death rates of any place in the country. As soldiers are all of one type and live under identical conditions, the result must be due to the cloudy climate. It may be remarked in passing that slight degrees of pigmentation are quite good light-screens. The tanning is due to a sunburn prevents a repetition of the damage, and *x*-rays can be applied very strongly after previous applications have tanned the skin. An olive skin, such as is found in the Mediterranean basin is a protection permitting exposures harmful to Scandinavians, so that such dark types show less damage here in America.

Physicians should find more neurasthenic conditions among the city blonds than among the brunets, omitting the Jews, of course, who are notoriously neurasthenic the world over. It will also be found that all conditions having a basis in a weakened nervous system are apt to be more frequent in the blonds, but to particularize would require a very long list of diseases of this nature. In the tropics we have noted that apepsia is very common, and so is amnesia, which may go even to the point of complete loss of memory of recent events. There are a host of other neuroses which can have no other origin than neurasthenia.

It has long been known that suicides and insanity are more frequent in the lighter months of the year than in the darker—phenomena noticed in every part of the world. It seems that the pain or irritation due to the light is the last straw, which forces melancholics to the final act. Chronic manias are reported to be worse after several days of intense light, and school children are known to be better behaved in soothing dark days, but irritable and hard to manage after several days of bright light streaming into the school room. Their sufferings can be imagined when it is known that there is an actual sun-pain, or a curious blinding headache, resulting from light glare in the Philippines, even when there is not an excessive heat. I have found these cases so bad that life was hardly worth the living, and yet complete relief could be obtained through darkening the house with appropriate window shades and verandas. It is a dreadful pain, which is more marked in the blond, the neurasthenic, and in women. Hence it is true that dark gloomy weather has a soothing effect and reduces crime, insanity, misdemeanors, and suicides, and has the exact opposite result of what popular opinion gives to it. (See Dexter's "Weather Influences.")

Dr. Milliner of Buffalo read a very interesting paper last June on the neurasthenic conditions found among electricians who work with high tension currents. It is known that there are streams of cor-

puscles thrown off from these currents, setting up tissue changes similar to those due to light. Many writers have noticed similar conditions in *x*-ray workers. Both of these instances are merely exaggerations of what every blond American is liable to get if he is too far South.

The practical point following from all this is the important matter for the medical profession. If it is true that excessive light is one of the many causes of neurasthenia, it follows that this condition in America should be worse in blonds than in brunets, should be worse in the cities than in the country, and should be vastly benefited or cured by a removal to dark cloudy climates. As a matter of fact severe cases are known to be remarkably benefited by removal from the city in the Summer, and are made worse by remaining; are damaged by a trip to lighter climates and benefited or cured by a sojourn in northern cloudy ones. It is not the heat, for the fact is the same even if the sufferer escapes the heat. Of course cases can arise in cloudy places if there are other causes. It is merely proof that light is one of the causes of this trouble.

The remarkable success of santoria in such places as the lower mountains of New York has been very marked in cases of neurasthenia sent to them from southern cities. No one has ever given an explanation of this phenomenon, and there is a constant tendency to belittle sanatorium treatment because of this ignorance of the reasons. Of course there are very many advantages in getting a patient from his home environments and giving him a complete rest and a relief from all the things which have been injuring him. Nevertheless no one has ever suggested that some of the good might be due to the relief from excessive light. It has been suggested that perhaps the rest treatment of Weir Mitchell has a partial explanation in the fact that the patient is removed from light irritation.

One of the phenomena of our Rocky Mountain tablelands is the neurasthenia which so often compels the sufferer to seek a lower level. All sorts of explanations have been given for this state of affairs, but upon investigation they are found inadequate. The only difference between those elevated regions and lower places, which we can surely accuse, is the excessive light. The ultra-violet rays in particular are exceedingly powerful, and in mountain climbers they cause the well known glacier burns which are actual ecchymoses. It has been found that cloudy days in Denver bring great relief, and an equal relief is found by removal to lower levels to which the ultra-violet rays do not penetrate in such amounts. It has long been known that American women, and particularly the blondes, do not flourish in such parts of the United States as Arizona and New Mexico where the streams of light are excessive. In the course of some years neurasthenia makes its appearance and if the patient does not move to darker places she is liable to go under through some coincident infection. To be safe from such light, one should be as dark as an Apache Indian.

The degeneration, through nervous instability, of the blond families of our Western plains, is a phenomenon which is bound to receive attention in the future. The curious hysterical outbursts, religious or political, which characterize certain of these Western States, has an explanation in a pathological state of the nervous system. It is not the normal slowness of the Baltic breed.

We have, then, in this Northern part of New York, the dark conditions suitable for the care of neurasthenics from the South. We are in the latitude of the Northern Alps, to be sure, where the mountaineers tend to brunetness, so that it is not nearly so well suited as a latitude of 50° or 60° in Norway or Scotland. Nevertheless it is vastly better than that of 30° or 35° which is the zone of our Southern tier of States and of the Northern part of Africa where the real blonds are never found, though there are a few men of light type in the dark valleys of the Atlas Mountains.

In my tours of service in various parts of the country, I have been particularly struck with the fact that neurasthenias are worse in the light parts than in the dark, and am quite of the opinion that the profession could not do better than to send such cases to these Northern latitudes either here or on the Northwest coast, where it is so cloudy and where the people are so enthusiastic over their climate in spite of its clouds.

The slow phlegmatic nervous system of the people of the Northwestern corner of Europe is the normal, and our immigrants from that section become in one generation just as nervous as the rest of us. There is no doubt that these American "nerves" are pathological phenomena due to climate and not due to the strenuous life. On the other hand, this excessive activity, push, energy, and excitement are all not only due to the pathological condition of the nervous system, but act no doubt to increase the existing exhaustion. What better advice then can we give our patients than to tell them to go North to the woods, particularly in Summer. It is regrettable that it is not possible to send more of them, and it is to be hoped that every Summer we shall find a greater and greater migration to the North. There are many conditions, no doubt, for which we should send patients to the South for a short stay—but that is a large matter, requiring much explanation.

For those who cannot afford to travel it is possible to give advice as to protecting themselves from excessive light. Our cities in the Summer do not differ much in sun glare from those in the Mediterranean basin, where the natives themselves are very careful to avoid the light as much as possible, particularly at midday, and it is very wrong not to give such advice to our nervous patients in a city Summer. In other words, we in America can gain considerable practical knowledge from tropical experience, which should put an end to the sun worship which is causing us to advocate too much of a powerful agent. Some light is no doubt essential, its stimulation is beneficial, and we all enjoy a sunny day after a week or two of clouds, but the excessive amounts to which we are exposed in Southern climates, particularly the cities, can do great harm.

In the case of tuberculosis we can all recall the old idea of the scrofulous diathesis—a general tendency to blondness. Since we gained the knowledge of the great tendency of negroes to tuberculosis, the old conception has rarely been mentioned. Nevertheless there is considerable evidence that the white population of any sanatorium in the long run shows a markedly less pigmentation than the population from whom it is taken. This also fully accounts for the growing conviction that there is some nervous element as the basis of susceptibility to tuberculosis. At any rate, the infection in white men in the tropics is so rapid as to be fatal unless the patient is removed to the North at once.

We are now in a fair way to explain the remarkable discrepancies in our views as to the benefits of climate in the treatment of tuberculosis. Blond cases should not go South, as they are so apt to become neurasthenic wrecks. The extreme South has long been known to be very inappropriate for all cases and has been abandoned for the same reason probably that we send the cases out of Manila. I

have been informed that at Dannemora prison it was discovered that in patients prone to hemoptysis, sun exposure was almost certain to cause a hemorrhage. Patients became irritable when so exposed, and bedridden cases did best in a certain shady corner of the ward. Finally we find that there are excellent results in sanatoria situated where there is a minimum of sunshine, both here and in Europe. There is room for investigation of certain bad results in sunny climates which have the greatest popularity. It is quite possible that the worst results will be found more often in the blonds than in the brunets.

Dr. S. A. Knopf, in an address on the sanatorium management of tuberculosis, while demonstrating "the curability of the disease independently of climate" (MEDICAL RECORD, October 21, 1905), has even stated that "while all modern tuberculosis therapeutists now freely confess that there exists no specific climate for the treatment of pulmonary or laryngeal tuberculosis, and that even the so-called best climate can only be considered an adjuvant, it would almost seem safe to say that in the treatment of tuberculous and scrofulous affections in children the sea coast climate in moderate zones is more nearly entitled to the name of a specific than anything thus far known in tuberculo therapeutics." And cures obtained in our ordinary home climate, while often requiring a little more time, seem to be more lasting than those obtained in more congenial climes."

We shall probably be compelled to revise our old estimates of the value of light in the treatment of tuberculosis. It is, of course, proved to be efficient locally at superficial infections, and there is even evidence that if concentrated it can be made to penetrate to the larynx or apices of the lungs and assist the cure, but whether the prolonged sun exposures often advocated are not of more harm than good, is a proper question to ask ourselves—particularly in the case of blonds.

In the case of insanity, it is said that there is a tendency to brunetness because of the large number of our foreign element who are notoriously brunet to begin with, but in the old families it is said that the blonds suffer more than the brunets in this respect as well as in all nervous conditions.

Consequently it is desirable to know whether the proportionate numbers of dark and blond types in any disease are the same as among the healthy population from which they are drawn. To determine this we should first know the complexions of the general population, native born and foreign. This can easily be done in the schools, and it is a valuable work in which the teachers can be of vast benefit to medical science. The matter is strongly commended to the school boards throughout the country, as it is easy of accomplishment by a little co-operation, and it will take but a few minutes of a teacher's time.

In gathering statistics of complexions, it is necessary to have some kind of a system so that we can compare results. I have prepared the accompanying scheme, in the hope of having complexions stated in regard to their protective power or opacity. We do not care whether the skin is yellow like a Chinaman or red like an Indian, as both colors are at the lower end of the spectrum and exclude the ultraviolet and upper colors. If an Albino has zero opacity, and the darkest man of southern Europe has ten (10), the others grade in between somewhere. The estimate is determined from the skin, hair, and eyes combined. The skin of the face is apt to be tanned and give a false idea of the real degree of pigmentation. The real complexion is determined by the skin color where it is protected, say on the upper arm. The eyes and hair vary, but they help materially to determine the matter. The total of the three will give a fair approximation of the degree of pigmentation in mixed types; thus, if the skin appears to be light (3), but eyes brown (7), and hair dark (8), the pigmentation would probably be about 18, or if the skin is dark olive (9), but the eyes dark gray (5), and hair lightest brown (6), the total would be 20 or brunet, like those Mediterraneans usually called blond from their contrast to the prevailing type. Some of the Scotch and Irish brunets have very white skins, and grade low in the scale, though they have dark eyes and hair.

GRADES OF EUROPEAN COMPLEXIONS

| | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
|---|---|---|---|---|---|---|---|---|---|---|---|
| *Skin.* | Albino. | Very white. | White. | Light. | More or less dark. | | | Muddy. | Light olive. | Dark olive. | Light brown. |
| *Eyes.* | Albino | Very light blue. | Light blue. | Dark blue. | Light gray. | Dark gray. | Hazel. | Lightest brown. | Light brown. | Dark brown. | Very dark brown (black). |
| *Hair.* | White | Yellowish white. | Yellow | Light blond and brick red. | Dark blond and sandy. | Chestnut and auburn. | Lightest brown. | Light brown. | Dark brown. | Darkest brown. | Black. |
| *Types.* | Albino | Blonde and Scandinavian types. | | | Medium and Central European and Mixed types. | | | Brunette and Mediterranean types. | | | |

All other races, as a rule, have black hair (10) and dark brown eyes (9) or (10), the skin pigmentation varying from deep olive (9) to jet black or about (50).

On the coast of Norway there is quite a percentage of so-called brunets who have migrated there from the Continent, though it is probably safe to assert that most of them are not real brunets with a good pigmentation, but are light-skinned types with rather dark hair and eyes, which in contrast to the prevailing blondness make them appear very brunet. It is the opposite mistake to consider many swarthy Italians as blond because their gray eyes and chestnut or red hair afford such a contrast to the prevailing brown eyes and black hair.

If we go a little inland the Norwegians are said to be very blond, with very few brunets, consequently the center of blondness of the world is in this region of central Norway. If a straight line is drawn in any direction from this area, we find along that line an increase of the proportionate number of brunets and their pigmentation. The blonds who have migrated have perished more or less quickly, according to the distance they have traveled, particularly in a southern direction. Those who have gone due west to Scotland and its northern islands have survived in the best condition, but even as far south as England they disappear. In other words, the different types of men are adjusted to the climates where we find them, and every climate on earth is perfect for its own types and injurious to all others. We must study the type of patient as well as his disease. "It is quite as important to know

what kind of a patient the disease has got as to know what sort of a disease the patient has got." (Moxon.) Anthropology is thus an essential part of modern medicine.

Two French writers have recently taken up the question of harmfulness of light—Dr. G. Bohn, of the College of Science, Paris, and Francis Marre. The latter published his remarks in *Cosmos*, and the former in *La Nature*. As the ideas of both these gentlemen are evidently taken bodily from my own work, "The Effects of Tropical Light on White Men," it is a satisfaction at least that the matter is being given the attention it deserves. But it is certainly disheartening that medical and lay writers in America are ignoring the matter almost entirely, while the same ideas, after floating to Europe, are taken up by the lay press as European thoughts and not American. It's a queer world—particularly the part so far south as we are.

Since this paper was read, an interesting article by Dr. Geo. H. Kress on "The Tuberculosis Problem of Los Angeles," has appeared in the *Journal of the American Medical Association* for November 25, 1905. Complaint is made of the tremendous death rate of that city from this disease—greater than any other place in the United States. It is shown that a very great number of the deaths—nearly half—are of people who have resided there less than a year, and complaint is made of the habit of Eastern physicians sending incurable advanced cases to that city. Since he also speaks of the great amount of sunshine, we are quite justified in asking if that is not really a factor in this great mortality, and whether it wouldn't be better to keep all patients further north, particularly if blond. Surely we must injure some of them. The statistics published rather indicate this. The relative tuberculosis mortality of Italians and French in Los Angeles is far less than in the rest of the United States, but the northern races suffer a far greater mortality there than in the rest of the United States—Scandinavians, Germans, Canadians, English, and Russians. The Irish are an exception to this rule, but the figures prove what is indicated from other data, that only tuberculous patients of the types of Southern Europe should be sent south.

It is noted that the least mortality is in July, and that the rate rises gradually to a maximum in the following March, when it drops quickly to the summer minimum. As the damage due to light is cumulative and slow, it would not show its effect until some months had elapsed, yet it is quite likely that there are also other factors to account for the high spring rate—possibly it is due to the fact that many patients go there for the winter and a very large number die within a few months of arrival. Observations of their complexions is greatly needed.

The last report of the Surgeon-General of the army shows that the healthiest spot in the country is the northwestern corner, the Department of Columbia having the lowest sick and death records. As the soldiers are under identical conditions everywhere, this result must be due to the climate, and as this spot is more cloudy and rainy than any other, it certainly shows that we must revise some of our old estimates of the excellence of sunny climates.

---

**Post-Partum Eclampsia and Glycosuria.**—J. B. Waters reports this case. The patient, thirty-five years old, was delivered normally of a healthy child. She gave no cause for anxiety until the fourth day, when she had typical convulsions. After treatment with morphine injections, hot packs, and saline enemata, she made a good recovery. The urine showed a trace of albumin and reduced Fehling's solution freely. The writer suggests that the cause of her disturbance may have been lactose, for her breasts were very full and hard.—*British Medical Journal.*

## THE CURATIVE TREATMENT OF PNEUMONIA; WITH POINTS ON HYDROTHERAPY AND THERAPEUTIC FASTING IN FEVERS.

By CHARLES E. PAGE, M.D.,

BOSTON, MASS.

It is hardly worth while to describe minutely the non-curative, not to say killing, treatment for pneumonia, which is the prevailing one; the results tell the awful story: a death rate of 50 per cent. in hospital practice, and 15 per cent. in private (Medical Record, October 28). This is the natural result from the regular medical treatment—drugs and forced feeding, to clinch the mischievous but natural effects of hot poultices on hot lungs, so to say, which would tend to produce the disease if applied over the chest of a robust man in high health. This statement of fact would not appear at all strange or overdrawn to any one who fully appreciates what is going on in the lungs of a patient suffering from pneumonia. We see, for example, a young man with every evidence of a powerful chest and of great muscular strength, altogether laid down helplessly ill by a failure of the lungs. Even when he was at the worst there was no lack of power in the muscles of the chest, which were lifting powerfully, but in great measure in vain, so far as getting air into the lungs was concerned. The lack was in the lungs themselves, which were allowing the blood to flow in and to remain gorging the vessels so as to forbid, in great measure, the entrance of the vital air into the air-vessels, which have no room for expansion. When all is going well the air-vessels of the lungs on one side and the blood-vessels on the other keep time, so to speak, with the motions of the breathing muscles. As the diaphragm closes upwards, and the muscles of the chest press inwards, so as to expel the breath that has got charged with carbonic acid, the blood-vessels prepare on their side to receive the blood which is in need of the oxygen that should meet it in the next breath. The air-vessels also prepare to open to that air, when the muscles expand the space in which the lungs act and allow the air to flow in. The moment that space is expanded blood and air flow in and meet so as to exchange elements and promote the process of life.

To describe the condition is to suggest the true remedy, viz., local cooling; not chilling by means of ice-packs, but persistent cooling in and in, by means of the cold compress over the entire chest in front, the compress to be freshened as often as it gets hot, until the walls of the engorged blood-vessels have been braced to the point of resuming their normal caliber, thus allowing the air-vessels to open up and receive the air as in health. When this stage of the curative treatment is reached the patient is convalescent and all danger is passed, providing that his therapeutic fast is not prematurely broken.

No greater folly can well be conceived than feeding any patient critically sick with any acute disease, during the progress of the disease, since all the energies of the vital organism are fully engaged in its efforts to "throw off" the disease, by eliminating the disease-producing matters, or, so to say, its efforts to recover "that just balance which we call health." In every such crisis the functions of digestion and assimilation cease for the time being, and for a time all food, save water, is ingested solely for putrescence and blood-poisoning, and to add terribly to the diseased condition.

The disastrous effects of forced feeding have been vividly portrayed by the late Dr. William Jenner.

Twenty years ago Sir William Jenner, in an address before the Midland Medical Society of Birmingham, England, referring to the vicious effects of forced feeding, said: "I have seen the patient restless, sleepless, his temperature raised several degrees above what it had previously been, vomit, eject a quantity of curd, and at once the restlessness cease, the temperature fall, the skin become moist, and the patient drop into a quiet sleep. All the threatening symptoms vanish with the ejection of the offending material. Or, the undigested curds may accumulate in the bowel, inducing flatulent distention, pain, restlessness, and increased febrile disturbance. Under these circumstances I have seen an enema bring away a large vesselful of offensive, sour, undigested curds. Or, again, the undigested curds may themselves (and this has not been an uncommon consequence of milk diet in my experience) irritate the bowels, and produce, keep up, or greatly increase diarrhea."

Hippocrates was a wonderfully wise man, and one of the wisest things he ever said, as it seems to me, was that it is best to withhold food during the progress of all fevers; and therapeutic fasting has from his day to ours been the sheet-anchor of every expert sick-room dietist in all acute diseases.

It must be evident to the most superficial student that this sort of thing fully accounts for perforation of the intestine and all the distresses of a long-drawn illness, and for the excessive mortality. Moreover, food ingested under such conditions sets up or keeps up an inflammatory state of the stomach, which is readily communicated to the lungs by continuity of tissue. Indeed, there is every reason for believing that this constitutes the primary lesion, often, in what finally results in pneumonia.

Dr. Frederick P. Henry has declared ("System of Practical Therapeutics," Hare) that during the progress and at the height of fever, water is the only nutriment we have. He says: "The blood is of a dark, blackish-red color, and is generally obtained by needle puncture of the finger with more than ordinary difficulty," indicating conclusively a deficiency of water." But shall we not nourish the fever patient? Assuredly, yes; but," as Dr. Henry remarks, "the question of nourishment is a relative one, depending upon the immediate wants of the system. To a person perishing from thirst nothing is so nutritious as water. The strongest argument for the cold-bath treatment in typhoid fever is that it prevents tissue degenerations, especially of the heart, which are generally ascribed to long-continued drought. We do not attribute the desiccation and decay of vegetables during the torrid heat of summer so much to the presence of heat as to the absence of water, and the facts with reference to our own tissues during the heated term of a fever are precisely analogous. In a word, our bodies, in health, are more fluid than solid, and cannot perform their functions unless this fluidity is maintained."

The thickly coated tongue, sordes, and the generally parched condition of the mouth indicate quite clearly the utter lack of all the dissolving and preserving juices absolutely essential to the digestion of solid food, or any other food but water. To call milk a liquid food seems to me absurd, when it is stated on high authority that the casein of a pint of milk is equal to a good-sized mutton-chop, and is vastly more difficult of digestion; yet we know that as much as two or three quarts of milk are often swallowed by a pneumonia or typhoid fever patient in twenty-four hours.

When convalescence is fully established and the condition of the stomach such as to indicate the possible digestion of food, and the patient normally hungry, the time has come when food will prove a nutriment instead of a drug. The fasting patient will shortly have no movement of the bowels; there is a normal closure, so to say, under these conditions. There is never any occasion for purging in these cases, and we may well take to heart the dictum of Hippocrates, that "physic is the hardest medicine for the system to withstand." After a few days of feeding, the patient out of bed and exercising, the bowels will get in condition for a natural movement. The diet should be plain and frugal. Until this condition has been reached there is usually no appetite and there is often a feeling of disgust for food. To compel such a patient to take food, or to tempt the appetite with palate-tickling dishes, or to employ "tonics" to excite a fictitious appetency, or to run down a lot of milk (an unnatural food for human beings, and one that many persons in high health are unable to digest)—all this sort of thing is a play for prolonged illnesses and a heavy mortality.

In incipient pneumonia, at the very beginning of malaise and difficult breathing, the application of a heavy cold compress over the entire chest in front, well covered with dry folds of towel, very soon aborts the disease. The procedure is very simple, indeed. A large towel, coarse linen or cotton, is folded lengthwise in the middle, then folded crosswise in the middle, and one-half the length of this four-ply towel is wrung tightly from ice-water, or the coldest water obtainable, and again folded crosswise, so as to give four thicknesses of damp towel next the skin, and the same, dry, outside. This for a robust adult. For a delicate person or a child I use two thicknesses only of damp towel and two, dry, outside. A single towel of right size, folded lengthwise, one-half wrung tightly from ice-water, and folded crosswise, and applied as above directed. Or, a smaller towel may be folded two-ply, and wrung out and applied with another dry, two-ply, as a wrapper. Two sets of damp towel may be employed, one kept on ice while the other is getting hot; thus the changes can be made more readily.

As already remarked, the damp folds should be freshened as often as they become at all hot, whether this be in ten, twenty, or thirty minutes. At first, in severe cases, the changes will be as often as every eight or ten minutes, the intervals lengthening more and more as the inflammation subsides, and breathing consequently becomes deeper and easier. When the patient is able to breathe naturally, and the compress no longer becomes hot, and before it is felt to be an uncomfortable treatment, this local cooling should cease. When applied nicely and in a proper manner, the treatment is in the highest degree agreeable to even the tender infant, though, of course, each first touch of cold is more or less disturbing. When this treatment is indicated, the compress very speedily gets warm and is in every way soothing. It has a good effect upon the general temperature, finally, though no hydrotherapeutic or other treatment should ever be given for the purpose of directly "downing the temperature" of a fever patient, no matter what the disease may be called. While directly lowering the temperature by water is less devitalizing than by means of potent drugs, it is still bad treatment, and is never resorted to by the skilled hydrotherapist, whose aim in all treatment is to banish the cause of the fever, when the high temperature (which is the organism's means of eliminating the disease-producing waste and effete matter, and not at all the disease to be combated) goes down of its own accord, so to say.

Reducing fever directly by means of drugs has been fitly characterized by Dr. Simon Baruch, as

follows: "The chief advantage of the coal tar derivatives seems to be that their use enables the fever patient to die with a fairly normal temperature." Thus is the doctor the ally of the disease. The vitality of the patient goes down with the temperature when influenced by antipyretic drugs.

Pneumonia, as it seems to me, is properly classed among the filth-diseases; the body is ill-conditioned, and the local disease is at the patient's weakest point, the lungs. Along with the local treatment, as above described, therapeutic fasting should always be employed and continued until breathing is easy and the patient absolutely convalescent, and all cause for anxiety passed. It is difficult to decide, as between forced feeding and drugging of such patients, which does the most harm; nor is it worth while to discuss the point, in face of the fact that there is no call for either, and that both are harmful and fatal in their tendency. The fact that both of these procedures are employed as the routine treatment in pneumonia, and that, added to such unphysiological treatment, the pneumonia jacket, hot poultices and skin-irritating pastes are usually employed, fully accounts, in the present writer's opinion, for the terrible mortality in a disease which, rightly treated, is in its earlier stages readily aborted, often within a few hours, as I have proved over and over again in my private practice.

Dr. Simon Baruch's mortality in pneumonia of about 2 per cent., which I judge refers to his private practice, and Dr. Thomas May's mortality of less than 5 per cent., in hospital and private practice, together, may very properly be regarded as the normal death-rate in this disease under wise management. The chief element is chest cooling with both of these gentlemen. We do not lose sight of the fact that some cases as they come to us, especially in hospital practice, are necessarily fatal, such as (to employ the language of the editor of the MEDICAL RECORD) "the old, the social wrecks, those broken down by excesses of all kinds, by exhausting labor, and by privations, and the actually moribund." Some of these patients have, so to say, a right to die; but even these are entitled to a fair chance for their lives, and to die, if die they must, in comparative comfort, as they will if happily they are saved from the stock treatment, the results of which are so fearful as to lead up to the dictum that "pneumonia is a disease which can neither be aborted nor cut short by any known means at our command," which is the sentence which opens the section on the treatment of lobar pneumonia in one of the most popular of American textbooks of medicine. ("Is Pneumonia Incurable?" MEDICAL RECORD, October 28, 1905.)

Between the two extremes—the simple cases, taken at the very onset of the attack and readily aborted, on the one hand, and, on the other, the very worst cases, some of which are necessarily fatal—we have cases of all degrees of severity, but most of them curable, only demanding in the most serious cases the most extreme care and skill of the expert, who knows where, when, and how to cool, and also, where, when, and how to apply genial moist heat, as explained elsewhere in this article.

If ever there is a demand to have "every feather to the good," in the treatment of a patient, it is in pneumonia. In the first place, there should be the freest ventilation of the sick-room. The bugbear of too many, in and out of the profession, is "catching cold"; it is a sort of scapegoat which tends to throw us off the track; that is, when forced feeding and drugging have given a patient a setback, and from apparent convalescence (the product of stimulation) a physician finds his patient in condition of relapse, the change is apt to be attributed to the patient's having "caught cold." The fear of catching cold is mischievous in the extreme, since it operates to shut the patient up to an insufficiency of fresh air, in spite of the fact that, as Dr. Benjamin Franklin long years ago declared, "colds, so-called, are utterly independent of either wet or cold," and as I—the "pigmy on a giant's shoulders," if you please—have urged upon the attention of the profession in numerous articles* during the past twenty-five years. It was the dictum of the eminent Dr. Juergensen of Germany that "a fever patient cannot catch cold." I have caused the almost instant revival of a babe in pneumonia in midwinter by throwing wide open the windows in the stived den in which it was being smothered, though the home was of the palatial order. It is usually in such a close room that the oxygen treatment is employed, a treatment which I have never felt moved to use, feeling no occasion for such artifice, since the fresh cold air supplies oxygen in just the right dilution for the best effects.

In absence of drugging, absence of forced feeding, whether with "predigested food" or not; absence of heating appliances over the chest, and with persistent cooling over the region of the lungs, the use of a small half-cupful of moderately hot water every hour or two when the patient is awake, for an adult, or a few teaspoonfuls, at frequent intervals, for the young child—this kind of treatment will in most cases suffice to bring the patient out all right. Taken early, in the majority of cases, the disease is speedily aborted, often within a few hours; and in a majority of cases it is the only treatment demanded.

In severe cases, as those coming late under treatment, or that have been badly treated before coming under this management; frail and delicate patients, the aged, alcoholics, etc—in these cases, to "stimulate" and counteract effects of local cooling, there is apt to be a demand for a full hot fomentation of the feet and legs by means of a small, clean, woolen blanket, folded and lightly saturated with hot water, and applied as hot as it can be without danger of scalding the flesh, wrapping this snugly with several folds of stout dry sheet to keep the heat in; and a hot-water bag may be a useful adjunct. Nothing of this kind is needed in ordinary cases. In certain cases there may be a period, after the "lung fever" has subsided, but never earlier, when a moderate hot fomentation is useful at the back of the chest, while the cold compress is over the front of it.

As for bathing, there is very little occasion for it, beyond a daily quick sponge bath with lukewarm water, in which a trace of acetic acid is added, to make it very slightly acid to the taste. Alcohol baths, so commonly employed, or alcohol in any form, inside or out, is to my mind contraindicated. How frequently we read the announcement, like one before me at this moment: "Death from heart failure, after pneumonia." It is not the pneumonia, but the "heart stimulants" employed, that play the mischief in these cases. An eminent physician, in a lecture before the Harvard Medical School Association, related the story of two "brilliant cures" of a certain form of heart disease, under his treatment, when he was a young man, by "enormous doses" of digitalis. Both patients had been taking ten-drops doses, and

*"Catching Cold," *Popular Science Monthly* (New York), January, 1884. "Therapeutic Fasting; Should It Be Called Starving?" MEDICAL RECORD, February 24, 1894. Hygienic *vs.* Drug Treatment for Typhoid Fever, *ibid.*, April 28, 1894. "Flannel Underwear and Personal Sanitation," read before the Section on State Medicine, meeting of the Am. Med. Assn., Philadelphia, Pa., June 2, 1897. "Consumption; Roughing It, *vs.* The Coddling Treatment," MEDICAL RECORD, October 20, 1894, etc., etc.

he increased the dose to forty drops. "The triumph seemed complete," said the lecturer, "and so it was for weeks; but mark the ultimate result: Mary, one morning, as she trod the doorway of the market-house, fell dead across the threshold. The banker, stretching his arm across the desk that had been to him the pathway to riches and power, fell hushed and powerless into the eternal silence."

Dr. José M. Ferrer, visiting physician to St. Vincent's and the French Hospital of New York, in writing on the treatment of pneumonia in the MEDICAL RECORD for May 21, 1904, said: "I cannot too strongly deprecate the excessive interference practised in many of the ordinary cases. I have seen patients robbed of sleep, their temperature increased, their hearts overtaxed, their respiration made more labored, and their general condition rendered miserable by pulling and hauling examinations and baths, and injections and poultices, taking oxygen and drugs, all of which seem to me largely unnecessary."

There is a lamentable lack of interest among medical men concerning all such studies as are embraced in this paper. The reason of this is not far to seek: the medical schools give their graduates almost nothing in the way of teaching in hydrotherapy, and it is the almost universal practice with the professors and the hospital physicians to feed early and often, as if the questions of digestion and assimilation, instead of simply swallowing, were not at the bottom of all true feeding. In the discussion following the reading of an essay on "Hydrotherapy, Its Scientific Basis," by Professor Putman of Harvard University, recently, Dr. Coggeshall insisted that "it is disgraceful that students should be allowed to graduate from our medical schools with practically no systematic teachings in regard to non-medicinal therapeutics," and Dr. Rogers remarked, jocosely, that "medical colleges ought to cease to graduate men who don't know the difference between a Scotch douche and a hot Scotch." Kussmaul was quoted as follows: "Of hydrotherapy the average physician knows almost nothing. Here is a great gap in the education of our physicians; here is the real cause of their inability to cope with the empirics for the favor of the public." Professor Credé of Leipzig remarks that, "if physicians were better versed in these branches, the field of operation of many quacks would be greatly curtailed," which is only another way of saying that many quacks are more efficient in practice than the average practitioner. When we speak of a death rate of 15 per cent. the prevailing idea is, that the 85 patients who escape immediate destruction, speaking of typhoid fever or pneumonia, have recovered health. But the fact of the matter is, they are left so badly off that, as the life insurance statisticians assure us, one-fourth of their number die prematurely of consumption. This amounts, then, practically, to a mortality of about 36 per cent., instead of the comparatively trifling 15 per cent., which is the nominal death rate in typhoid fever and pneumonia.

It has to be confessed—and this constitutes the chief hindrance to progress along this line—that skilful physiological, or natural, treatment is apt to be "bad business" for the family physician, especially for the young practitioner striving for a paying practice; for, if he skilfully abort a case of pneumonia or typhoid fever, or other acute disease, and has his patient shortly on the street, he gets no credit for curing a bad case. "It was only a mild attack," it would be said; or, "It wasn't pneumonia, after all." On the other hand, if one of his competitors had treated that same case, and there had been several weeks of painful, costly sickness, with a day nurse and a night nurse, and daily calls of the physician—clever fellow, so kind, so sympathetic, and so well-intentioned—this doctor, whether his patient lived or died, would have gained reputation and a big honorarium. In the one case it would be said that he cured one of the worst cases; in the other, it would be set down to "the will of God."

The late Dr. John Forsyth Meigs, in a lecture delivered at the Pennsylvania Hospital in 1879, said: "When I stand by the bedside of a severe typhoid case, and see the patient motionless, insensible, dead to all the usual senses of the living; when I look at his half-closed eyes, his gaping mouth, his dried and fissured tongue; when I brush the unheeded flies from his poor, unconscious face; and when I touch his hot and burning skin, I ask myself into what lower state the human body can fall. Not only has the patient lost all appetite for food, not only is he dead to all that surrounds him, but his hot and withered body, his dry and pasty mouth, filled with desiccated crusts and sordes, knows no longer even the sense of thirst. This has been the last sense of which he has been deprived. So long as he retained any consciousness at all he would ask for water. Now he feels not even this great want. It is in this crisis of his life that he is to be saved, if saved at all, only by the constant care of his physician, nurses, and relatives. And woe to the physician who can look on such a sight and not yearn to know all that his art has acquired through centuries of experience and study."

Typhoid fever destroys fifty thousand lives in this country every year, and, as we have observed, sadly injures the other two hundred and fifty thousand patients who are said to recover from the disease; or, more correctly speaking, the prevailing treatment does the greater part of all this fearful mischief. Outside of the practice of here and there a physician, who has learned the proper treatment for typhoid fever, there has been little or no improvement in the treatment of this disease, either in private or hospital practice, during the past one hundred years. We have the history of typhoid in the Massachusetts General Hospital for the past seventy-eight years, thanks to Dr. Fitz, whose tables from the records show that from the year 1821 to 1859 the mortality in typhoid fever was 12.75 per cent., and from 1859 to 1899 it was 15.5 per cent. Certainly, this is a very bad showing for medical progress, so far as concerns this disease.

Chrisippus won the title of "irregular" by opposing the prevailing practice of his time of active purging and bleeding, and he introduced the hunger cure (doubtless meaning abstinence till the patient was hungry), which is the dictate of good sense, as it seems to me; and Erasistratus prescribed fasting as the most efficacious remedy in all febrile and inflammatory processes; so that none, who regards antiquity as evidence of the value of a remedy, may sneer at the idea of giving the stomach a rest when this organ is in an exhausted state.

How often I have visited a fever patient day after day for a week or more, observing the tongue changing favorably, the temperature kept down well, strength steadily increasing, and all this on a diet of cold and warm water, until I have suggested at some point that perhaps the time was ripe for feeding, only to have my patient query whether it might not be safer to put it off another day or so! Finally, I will say, that so far as the question of safety is concerned in fasting a fever patient for any required length of time, I am apt to drop all anxiety regarding the outcome of the case if this part of the treatment is strictly adhered to, speaking of the great majority of cases that come under early treatment. And at no stage of any case do I hesitate to apply

the principle in question, as in neglected or badly treated cases coming under my care. The fact seems to be, that the longer the stomach and bowels have been subjected to the forced-feeding outrage the more reason for such rest as may seem to the expert attendant demanded.

In my own practice I never allow the ingestion of a morsel of any sort of food, except water, or perhaps a little orangeade or lemonade, until my patient is practically convalescent; and highly as I value the Brand bath for typhoid fever, which I have used to the limit for twenty odd years past, I would without hesitation, if shut up to the choice, trust to simple sponge bathing with fasting, rather than to the most expert hydrotherapy, with constant feeding. The "starving" plan practically prohibits "complications" and "relapses" (commonly regarded as the effect of "a cold," when, in fact, they are the product of indigestion and "reaction" from the antipyretics and stimulants so freely employed by most practitioners).

The fasting patient is scavenging on, and thereby eliminating the impurities with which his system is saturated, and which to a great degree constitutes his disease; on the excess of fat, if stout, and on the unassimilated nutritive matters which abound in the interstices of the tissues of most fever subjects. He is for the time being a sort of cannibal; but it is "Dr. Jekyll" devouring "Mr. Hyde," and the diet is well suited to his needs. With an abundance of soft water, which is best supplied for the most part at a temperature slightly above that of the blood (though the patient should not be denied a draught of fresh water when desired), he will be well sustained. For adults, from 2 to 4 ounces every half-hour to two hours, according to the amount and complexion of the urine. It is given moderately hot, and always with a placebo in some of the portions. Fasts of five, eight, and ten days have been so common in my practice that they have long since ceased to be at all novel.

## CONGENITAL STENOSES OF THE URETHRA.

By FAXTON E. GARDNER, M.D.,

NEW YORK.

With the exceptions of hypospadias and epispadias, malformations of the urethra do not awaken a vivid interest among surgeons. Some of them are considered as frequent, but unimportant; others are looked upon as anatomical curiosities, often associated with more extensive abnormalities, incompatible with life and beyond the reach of art. While this surgical contempt may be justified in a certain number of cases, there are some few exceptions. Congenital strictures, for instance, deserve a far better consideration. Until recently they had taken their share of the common disdain. No text-book on urinary diseases, even no comprehensive treatise on surgery gives them more than a brief mention. Yet, strange enough, quite a respectable number of cases are on record, and several interesting articles have been published on the subject, but all have fallen into oblivion. A special variety, though, has had better luck, viz., atresia of the meatus, well studied by Otis first, by Tédenat and Desnos later, and which has now found its place in all of the classical books. This latter variety is undoubtedly the most frequent and the easiest to observe and describe, but it is only a special localization, and all anatomical types of stenosis that have been found at the meatus may be found also in the other parts of the urethra. The attention of the profession at large has not been called yet on this fact in an explicit enough manner. Those deep strictures must be promoted from the rank of anatomical rarities, as has been the atresia meati; they are much more frequent than commonly thought, and their clinical importance is not nearly so small as might be inferred from the scant courtesy writers have so far shown them.

My attention was drawn to the subject by a case I observed a few years ago when house surgeon in one of the Paris hospitals. A boy, aged 10, had had urinary incontinence both at night and in daytime, the mother said, ever since he was born. No history of perineal traumatism, no hereditary antecedents, no external malformation. Careful interrogation of the mother and of the boy showed that there was no real incontinence in the daytime, but only an imperious miction. A *bougie à boule* No. 10 was stopped by an annular stricture just before the entrance of the membranous portion. Urine clear, good general condition. Progressive dilatation with bougies proved easy and the incontinence disappeared quickly. The patient left the hospital cured, and could not be seen afterward.

At the time I saw this case I thought it was an exceptional one, inasmuch as I could not find any information in classical books. I made some bibliographical research, and found several similar cases published by Philips, Englisch, De Semet, Bangs, Loumeau, Oraison, but no general study. Recently, Bazy has made several communications on the subject before the Paris Société de Chirurgie, and one of his internes, Foisy, has written for his thesis the so far missing general study. He collected 104 cases from the literature (not including numerous cases of valvules of the meatus, nor of partial bands without clinical history), and since his thesis was printed (May, 1905) several additional cases have been brought up to light, so as to bring the actual total of cases up to 110. The latter figure may seem small, almost trifling, if compared with the enormous number of acquired strictures, but it is by no means contemptible, and, as we see facts much better once we have been taught to see them, we may take for granted that the number of cases will in the future increase much more rapidly than it has done so far. Two and seventy-five hundreths per cent. is the only estimate of relative frequency given up to the present time (Christen), but this percentage we deem only provisional and bound to be modified in a near future.

All malformations find an explanation in embryology. But if this branch of science shows us *how* defects are produced, it does not tell us *why* they are produced. It gives us the pathogenesis of a lesion, but it does not give us the etiology. Be it said at once, we do not know anything more about the real etiology of congenital strictures of the urethra than about the etiology of malformations in general. We might rehearse here all the commonplace topics about heredity, consanguinity, maternal emotions and traumatisms during gestation, which have been used indifferently for harelip, hypospadias, or any kind of congenital deformity, but it would be perfectly idle talk. One group of causes, though, seems to have more scientific value, namely infectious diseases of the parents, especially the mother. Hereditary syphilis may play a prominent part as a determining factor of all congenital malformations, but in the particular case of urethral strictures special conclusive evidence is still lacking. Therefore, we must be contented with the pathogenesis, if we cannot reach the etiology. Let us summarize in a few lines the development of the male urethra and dwell a little longer on the points of special interest in our study.

At the end of the eighth week the cloaca is divided into two by a septum; the posterior part of the cloaca becomes later the rectum, the anterior is the urogenital sinus. The anterior wall of the cloaca is then formed by the cloacal membrane, a thin layer of epithelial cells separating the entoderm from the ectoderm. This cloacal membrane soon thickens by active proliferation of its epithelial cells and becomes the cloacal plug of the French writers, which gives rise by its anterior face to the genital tubercle. The urogenital sinus forms the posterior urethra, that is the prostatic and membranous portions and the portion of the anterior urethra which is situated just before the entrance of the membranous portion.

A little later the cells of the cloacal plug undergo partial resorption and a communication is established between the urogenital sinus and the outside. The slit which marks the opening of the sinus is prolonged under the genital tubercle by the urethral groove. During the third month of gestation both edges of this groove unite together on the median line and thus a canal is formed. But here takes place a most interesting phenomenon, and most important to remember: the canal thus formed does not persist as a canal, it is soon filled by active proliferation of the lining epithelial cells and becomes a solid epithelial tube without central lumen. Later on this solid tube becomes the definitive urethra by resorption of the central cells. The urethral groove produces the spongy portion of the urethra.

As to the balanic portion, its development is still a much discussed question. One point, though, is settled: the balanic portion is developed independently from the rest of the urethra. From the anterior part of the genital tubercle springs an epithelial bud which penetrates forward in the mesoblastic tissue of the glans. The dividing line between this bud and the end of the spongy portion is an epithelial layer, the epithelial wall of the glans. Later on, the solid bud becomes a canal by resorption of the central cells, and by resorption of the epithelial wall is connected with the spongy portion.

The points to be borne in mind by us are the following: (1) The urethra is formed by three embryological portions: (*a*) the posterior urethra developed from the urogenital sinus, and separated from the next portion by the cloacal membrane; (*b*) the spongy portion developed from the urethral groove and closed during the first stages of its development by the cloacal membrane, at its posterior extremity, and the epithelial wall of the glans, at its anterior; (*c*) the balanic portion developed independently. (2) The spongy and the balanic portions, *i. e.* the whole anterior urethra, are not derived as the posterior, from a hollow embryonic organ, but on the contrary develop in a solid, continuous mass of epithelial cells. So that the continuity of the urethra is established from behind forward only by the following series of processes: resorption of the cloacal membrane, resorption of the central cells of the spongy portion, resorption of the epithelial wall of the glans, resorption of the central cells of the balanic portion.

The development of the posterior urethra is relatively simple, but the development of the anterior is complex. Other examples show congenital malformations to be more apt to occur in organs which develop by complicated processes, and at the uniting point of two embryologically distinct parts. Therefore, we may think, *a priori*, that stenoses will be much more frequent in the anterior urethra than in the posterior, and that the elective points will be the premembranous and the balanic portions. Anatomical pathology shows facts to be in accordance with those inductions. Congenital stenoses are exceedingly rare (2 cases) in the male posterior urethra; they are unknown in women who have only a posterior urethra.

In an incomplete resorption of one of the epithelial masses which at one time of embryonic life fill completely the anterior urethra, we have the explanation of most congenital strictures. We understand easily how an incomplete resorption of the central cells will leave a thickening in the wall, the length and inner projection of which may vary considerably. We understand how the non-resorption of those cells will leave a fibrous obliteration of the canal. We understand how an incomplete or a non-resorption of the cloacal membrane or of the epithelial wall of the glans will give rise to an obstructive perforated or unperforated septum. Such an explanation, however, will not hold good for the few cases on record of strictures of the posterior urethra. The latter being derived, as it is, from a hollow embryonic organ, and not from a solid epithelial tube, we must admit here, instead of an arrest of development, an excessive proliferation of the cells lining the urogenital sinus. Such a process must be much less common than an arrest of development, which is the fundamental embryonic base of most deformities, and this is one more reason why strictures of the posterior urethra are so seldom observed.

Guyon, who, in 1863, gave the first classification of congenital strictures, described two types: (*a*) Cylindrical and annular, (*b*) valvular. The small number of cases then on record did not warrant a more elaborate classification, and Guyon's division was adopted by most subsequent writers. In 1880 De Semet split the valvular group in two, because in some cases there is a typically valvular fold, just like a venous valvule, but in some other cases there is a perforated septum, a diaphragm. Recently, Foisy has proposed the creation of a fourth class for those cases in which the stricture is constituted by an incomplete band implanted on part only of the circumference of the canal. We have no capital objections against this subdivision; but hair-splitting must be avoided in nosology, and we wonder if such a complication was called for by necessity or was even an improvement. Partial bands are only diminutive and incomplete types of annular stricture, and the fact that their elective locations and embryogenic formation are exactly the same militates strongly against any artificial division in the group.

But if the annular group is homogeneous, the valvular is not. De Semet's subdivision is an improvement. Septa and diaphragms differ widely from valvules both in location and embryology. The latter is the same for septa and for annular strictures, but valvules, very improperly called "valvular strictures" by many European writers, are simply the exaggeration of a normal condition. "Valvular strictures" in the penial portion are simply hypertrophied normal small valvules, "valvular strictures" in the prostatic part are "constituted by an hypertrophied frenum of the verumontanum," "valvular strictures" of the meatus are simply exaggerations of that very frequent, if not normal, valvular fold of the newborn described, in 1823, by Stiebel under the name of male hymen.

Such valvular formations have nothing common in their origin with the arrest of development which creates annular stenoses or septal obstructions; they are the result of a formative process exactly similar to what gives Guérin's sinus. Consequently, we think it better not to link with congenital stenoses lesions anatomically, clinically and originally absolutely different. On the other hand, we think it

arbitrary to describe perforated septa as strictures, and to make a separate class for imperforated septa. The very small hole found in most cases is not enough to justify the creation of two classes in lesions which in all other respects are absolutely identical. Same reasoning holds good for cylindrical strictures and occlusion of the canal by fibrous transformation. Our conception of congenital stenoses is the following: a hierarchy of lesions all originating in an arrest of development, starting from simple defectuosities and going up to the total obliteration of the urethra. A restriction, however, must be made; obliterations of the urethra do not have the practical interest of strictures, because they are frequently associated with grave lesions and almost incompatible with life.

Incomplete bands are the least accused type of congenital strictures. As Otis and Getz have shown, such congenital bands are very common in the urethra. Professor Guyon (oral communication, quoted by Bazy) says he has found them very often without having ever called special attention on them. A slight incomplete band is almost constant in two normally narrow points of the canal, namely, behind the fossa, and before the bulb. These two points are precisely the elective points for strictural partial bands.

Cylindrical strictures show us a more marked anatomical type. The normal elastic wall of the canal is changed into a thick, dense, inextensible cylinder. But often, when divided, as in urethrotomy, such a cylinder does not give the sensation of a hard and unyielding tissue. Indeed, several operators have noticed, under such circumstances, a resistance not different from that of a healthy tissue: and besides, the section gives comparatively more blood than in the case of a common stricture. Both peculiarities are easily accounted for by the histological structure of the cylinder, which differs widely from the type found in inflammatory cases. Microscopical examination shows the lesion to be a proliferation of the connective tissue of the chorion with perfect integrity of the epithelium; in other words, it is a subepithelial sclerosis (Foisy).

There may be considerable variation in the length, caliber, and number of those strictures. When short, the stricture is termed annular; when long the term cylindrical is used, and in the latter case the length of the cylinder may vary from a quarter of an inch to the totality of the posterior canal and part of the bulbar portion, as in Stein's case, or even to the entire length of the canal as seen by Chopart and Mapather. The average length is one-half to one inch. Some strictures will allow only filiforms to pass, others will simply give a jerk with an 18 or 19 *bougie à boule*. In most cases, the stricture is single, but Englisch and Foisy have found two stenoses in the same canal, Daniels, Bangs, Oraison and Sikora have found three, Getz four, and Bardinet as many as five. In one case a cylindrical stricture was associated with an abnormal valvule. Cylindrical and annular stenoses have been found in all points from the meatus to the neck of the bladder, but the most frequent location is the meatus. Next ranks the deep bulbar portion, just before the entrance of the membranous portion. The case I have reported above belonged to the latter variety, named by Bazy and Foisy premembranous. A third location, though less frequent, is common enough, namely, the fossa navicularis, and the junction of this fossa with the spongy portion of the canal.

The highest type of lesions in that case is illustrated by the few cases of obliteration of the urethra by fibrous transformation, with or without derivative canal. Guyon has collected eight such cases from the literature. Such an obstruction is generally found in the premembranous urethra, but may extend to the entire length of the canal (three cases). There are now in all 40 cases of annular or cylindrical strictures on record.

Urethral septa are generally transparent and thin membranes. They may be perforated or unperforated. If unperforated, they are incompatible with life, on account of their frequent association with more extensive abnormalities, and of the grave lesions they determine during intrauterine life. If perforated, the aperture is generally very small, and located either in the center or in some other point more or less distant from the center. As that aperture is small, symptoms of obstruction are marked. Frequent enough at the meatus, rare in the pendulous urethra, they have been found several times in the bulbar portion. Jarjavay has found a septum perfectly iris-like in the membranous portion. Others have found an obstruction at the neck of the bladder, but such cases are exceedingly rare. In one case there were three unperforated septa: one at the meatus, one at the junction of the fossa with the spongy portion (epithelial wall of the glans), and one in the premembranous portion (cloacal membrane).

Congenital stenoses of the urethra are very frequently associated with other deformities, phimosis, hypospadias, dilatation of the urethra, diverticula, etc. The ascending lesions of the urinary tract are much the same as in other strictures.

The anatomical evolution of congenital stricture compatible with life raises several interesting points. They certainly develop, as does the fissure of a harelip, proportionately to the growth of the surrounding parts, so that the deformity is not any more or any less apparent in adult life than in childhood. But we cannot admit what has been said by some authors, that at the time of maturity strictures so far not developed enough to give rise to any disturbance may grow more rapidly than the surrounding structures and become troublesome. Such a supposition is perfectly untenable so far as normal development of the stricture is concerned. But, and this is probably the cause of the error which gave rise to such an opinion, maturity is precisely the time when extrinsic influences may come and aggravate the lesions of a preexisting stricture. Infection is the principal, if not the only, one of those extrinsic influences, and may be caused by a specific microbe, such as the gonococcus, or by non-specific common germs. The latter come generally from the canal. Above a narrow point, urinary stagnation produces a constant inflammatory condition, by which microbic virulence is exalted. But non-specific microbes may be brought from the outside. In a case quoted by Forgue, a patient used to himself dilate his narrow meatus with wooden mandrins of his own very primitive workmanship. Tédenat reports another case, in which a congenital atresia became a real cicatricial stricture after an ill-timed cauterization of the meatus and fossa.

Gonorrheal infection is more frequent and more interesting. The stricture aggravates the clap and the clap aggravates the lesions of the stenoses. The influence of a narrow meatus on the evolution of gonorrhea is well known, and there is not one physician who has not had to incise such a meatus behind which a clap was raging. But it is an evident exaggeration to say that if a canal is normally developed from end to end, and if it is entirely free from congenital stricture, gonorrhea will be light and disappear in a short time without doing any further mischief. Gonorrhea can produce a stricture by itself without being helped by an anteriorly exist-

ing congenital defect; but undoubtedly when both coexist, gonorrhea finds in the congenital stricture a *locus minoris resistentiæ* where it grafts the lesions of an acquired stricture. Numerous cases are on record in which the symptoms of a tight stricture appeared a short time after a gonorrhea. We shall have to dwell on those facts later on, when we shall discuss the diagnosis.

There is an evident gradation in the anatomical types of congenital stenoses; there is a similar gradation in their clinical symptoms. Many a man may have a congenital band in his canal without ever experiencing any ill effects; many a man has had a congenital stricture and has not felt any inconvenience until a complication, such as gonorrhea, set in; others, on the contrary, have been troubled from childhood; nay, from early infancy. The severity of the symptoms may still be greater since some strictures determine irreparable lesions of the bladder, ureters, and kidneys during intrauterine life, and cause death before birth or during the first days of extrauterine life. But the clinical gradation is not absolutely parallel to the anatomical gradation. The chief anatomical fact is the extension of the lesions: the chief factor for a clinical standpoint is tightness. Of course both extension and tightness may coexist in the same lesion, but such an association is not compulsory. For instance, a thin, transparent diaphragm, with a small aperture, will give rise to much more marked disturbances than a long cylinder with a comparatively large lumen.

When the stenosis is not tight, as in cases of partial bands and short rings, the symptoms of urinary obstruction are generally absent. No strain, no protracted miction. On the contrary, parents bring their children or youths come spontaneously to the physician's office because miction is too easy and they are incontinent. They have wet their bed every night since they were born, or perhaps with the exception of a few short periods. In the daytime micturition is frequent and imperious; if the desire is not promptly attended to, urine escapes in the trousers. Such a condition is invariably called incontinence by the complainants, but interrogation will always show that the desire is felt in the daytime, and that the young patient is able to hold his urine for a short time. Such a clinical association, nocturnal incontinence and diurnal frequency, without any pathological changes in the urine, must be considered as suggestive of stricture, and instrumental exploration of the canal should then always be resorted to. The following mechanism is given by Bazy to account for the seemingly paradoxical fact of a stricture causing incontinence without dilatation of the bladder and without retention. The stricture causes a very small quantity of urine to stay in the posterior urethra, where it incessantly incites the bladder to contract by reflex action. During the day voluntary control partly counterbalances bladder contractions, but during the sleep such a control does not exist any longer, and incontinence is produced. Only in nervous children will such an excitation give such results. Now we find all of those children to be highly nervous or of highly nervous parentage. At the time of puberty, incontinence generally disappears; sometimes, if the patient becomes infected by the gonococcus, incontinence is followed by symptoms of a rapidly growing stricture.

When the stenosis is tight, the clinical picture is much like that of an ordinary inflammatory stricture, but the symptoms appear very early in life. It is often a difficult task to interpret the urinary symptoms presented by a very young child. Often these symptoms attract the attention when the child begins to go to school. He is obliged to leave the classroom hurriedly to empty his bladder three or four times oftener than his classmates. He also stays out much longer. Sometimes a miction lasts five or ten minutes, or even more. The urine flows drop by drop at the beginning, and the stream becomes filiform when the child strains. After a miction, a few tardy drops are voided in the trousers. The little patient is well aware of these facts, but as he does not know how passing water freely feels, and as children do not like to speak about their urinary organs, he very seldom complains. As accessory symptoms, priapism and early sexual habits have been noted. Later, the stricture reveals its presence in many cases by a sudden attack of complete retention, which very often brings the patient under medical care for the first time. Such an attack occurs generally between the ages of 15 and 30 years, but it has been seen as early as the ninth day and as late as the sixtieth year. This appearance late in life of a symptom caused by a congenital lesion is very important to remember. It is one of the reasons why congenital strictures are so frequently overlooked. But is it not understood that what characterizes a congenital affection is the anatomical disposition existing at the time of birth, and not the early appearance of symptoms after birth? We all agree that a hernia in which a special disposition of the sac and the testicle is found is a congenital hernia, though it may not have acquired any considerable volume before adult age. Therefore, why should we eliminate the possibility of a congenital stricture simply because the first attack of retention has not been produced before adult life?

After one or several attacks of acute complete retention, incomplete chronic retention, with distention of all the urinary tract above the stricture, sets in. Then all sequels and all possible mechanical and septic complications may be seen. Congenital strictures then behave just as inflammatory strictures, even if no infection has ever touched them.

If properly weighed, the above-mentioned symptoms should be suggestive of stricture and direct exploration of the canal should be resorted to. We cannot rely much on inspection, except in cases of meatic stenoses, palpation is of little or no avail, instrumental exploration alone with *bougies a boule* is conclusive. The sensations given to the fingers do not materially differ from those perceived in an ordinary stricture, and we do not intend to dwell at full length on them. Though the diagnosis of an affection with such special clinical features would not seem particularly difficult, we may safely assert that the diagnosis of congenital deep urethral stricture is almost invariably passed by, and this for one very simple reason: namely, that those strictures are never thought of by the average physician, and consequently the one necessary examination is not performed.

In children, incontinence, if not accounted for by some evident external malformation as a phimosis, an atresia meati, or the like, is too often pronounced by the physician, without further examination, to be due to neuropathic disturbances, and is called "essential." Or it is attributed to "congenital irritability" of the bladder. "Essential incontinence," when used in such a way, is not a diagnosis: it is only a label pasted on a symptom, the cause of which the physician has been unable to discover. And no wonder he has not discovered that cause, since he has not been looking for it! "Congenital irritability" as a causal diagnosis does not seem to us much better even if introduced in urinary pathology on such high

authority as Thompson's. When we read the latter's description of his so-called congenital irritability of the bladder, when we notice that the principal symptom is nocturnal incontinence in childhood, followed by the development of a stricture in adult years, and, at last, when we hear Thompson declare that gonorrhea in individuals afflicted with "congenital irritability" usually runs a more severe course, and always produces a stricture, we can but agree with Foisy that the explanation which Thompson declared himself unable to give, lies most probably in the existence of a congenital stenosis.

In adults the existence of the stricture itself is generally diagnosed, but its congenital nature is not any more recognized than in children. From the physician's standpoint, a man who has a stricture must have had a clap, or must have received a perineal traumatism. The negative answers of a patient are accepted as reliable authority for the perineal traumatisms, but not for claps. There seems to be among physicians a strong tendency to consider a man with a stricture who denies all previous gonorrheal infection as ignorant or a liar. An ignorant or dull-witted patient may have had a clap without knowing it; some others, through an ill-timed bashfulness, may attempt to conceal the truth. But when we have to deal with men perfectly frank in just as delicate question as clap, who, for instance, will acknowledge unhesitatingly having masturbated, and who are keen observers of their genitourinary organs, is such a prejudiced opinion anything more than an unfair assumption? And when they add, besides, that all symptoms go as far back as childhood, are we not the dull-witted and the ignorant if we prefer to affirm a vehemently denied gonorrhea than to admit the congenital nature of a stenosis? Long ago, some authors, failing to find any apparent cause in some cases of stricture, incriminated masturbation. It is not really easy to conceive how masturbation, alone and uninfected, can produce the sclerous tissue of a stricture; but if we remember that priapism, early sexual habits, and masturbation are frequent in patients endowed with a congenital stenosis, may we not think that here again the cause has been mistaken for the effect?

But, even if a clap is to be found in the antecedents, the diagnosis of congenital stricture must not be rejected *ipso facto*. When a tight stricture is found fully developed, only a short time, say, three months to a year, after the first clap, we must consider as likely the existence of a congenital stenosis aggravated by gonorrhea. Such cases are frequent enough. We know thoroughly the histological constitution of an inflammatory stricture, and we must admit that such a tissue requires years in order to grow enough to form a tight ring around the canal. Therefore, clap or no clap, the congenital nature of a stricture is always a possibility, and investigation must always be pushed along that line.

The inverse mistake, however, is also possible. In young children, a stricture may not be congenital. Cases have been recorded in which young, very young children, have been contaminated by gonococci, and have a few years later developed the symptoms of a common acquired stricture. The consideration of time is therefore very important in all cases. If there is a congenital stenosis, a tight stricture will develop in a few months; if the stricture is really acquired, a few years will elapse before a tight stricture is found, whatever may be the age of the patient at the time of his gonorrhea. Another physical sign is important: congenital stenoses are single; acquired are multiple. In congenital cases, the wall of the canal has kept its normal elasticity except in the stenosed point; in acquired strictures, this elasticity is lost even between the strictural rings.

If the foregoing points be borne in mind, the diagnosis becomes easy. If the proper examination of the canal is made, there cannot be a confusion with foreign bodies or stones. Urethral spasm, frequent in nervous children, will be diagnosed from a congenital stenosis much in the same way as it is from an acquired stricture in the adult.

Progressive dilatation is the fundamental indication of the treatment. Bougies and sounds prove sufficient in most cases. If not, internal urethrotomy, and, as a last resource, external urethrotomy in complicated cases must be resorted to.

## DYSMENORRHEA AT PUBERTY, AND UTERINE TUMORS.*

By FRANK DE WITT REESE, M.D.,
CORTLAND, N. Y.

For twenty years I have recorded the histories of my office cases, especially of the patients who were suffering from uterine tumors. These records have prompted me to ask this question: Does dysmenorrhea at puberty sustain any relation to the uterine tumors of adult life?

I have been impressed with the fact that nearly all women with uterine fibroids gave a clear, unmistakable history of having suffered pain at the very first menstrual period, and of continuing to suffer until the tumor was developed, unless interrupted by pregnancy or relieved temporarily by some medical agent.

A few years since it was my privilege to spend a time in the clinics and laboratories of the Johns Hopkins Hospital, and while there I became interested in the original work of one of the teachers, Dr. Cullen, who with others was trying to discover the cause of uterine fibroids. I was deeply impressed with the thought that, up to that time, there had been no discovered cause of this frequent trouble of woman. Since visiting the Johns Hopkins, five years ago, I have searched every authority in the text-books and journals that have come to me, and have failed to find anyone who has yet discovered the cause or causes of uterine tumors.

Nor have I seen in text-books or journals any reference or suggestion that possibly dysmenorrhea at puberty is a symptom denoting the presence of a uterine tumor, or that dysmenorrhea at puberty should lead one to think that the patient may develop a tumor of the uterus in the future, if nothing is done to prevent it.

In answer to this question, "Please send me statistics showing the per cent. of your cases, suffering from uterine tumors, that gave a history of dysmenorrhea at puberty," Dr. Matthew D. Mann, of Buffalo, writes: "I am sorry to say that I have no statistics covering the point about which you ask." Drs. Kelly and Cabot give practically the same answer. I have written to other prominent gynecologists, making the same request, but they have not favored me so kindly with a reply, and the fact that they have not leads me to conclude that their answer would have been the same as Dr. Mann's, "They have no statistics covering the point." From the paucity of statistics on this subject it seems probable that we are developing a new field for observation.

I quote, in part, a letter from Dr. Cullen, of May 27, 1905. He says: "We have been working on

*Read at the New York State Medical Association, October 17, 1905.

fibroids for several years and have about twelve hundred cases; unfortunately it is impossible for me to give you any information as to the causation of uterine fibroids from a laboratory standpoint. Looking at the matter clinically, one certainly is forced to the opinion that the uterus must have something to do, and that if no pregnancy takes place fibroids are more apt to form." In discussing this subject, dysmenorrhea at puberty and uterine tumors, I have two propositions to submit for your consideration: (1) Is dysmenorrhea a symptom denoting the presence of uterine fibroids at puberty? (2) Are the causes of dysmenorrhea exciting causes of fibroid tumors of the uterus? My answers to these propositions are based largely upon the histories of cases that have occurred in my private practice, and upon statements of authors whom I have been able to consult.

There is no doubt that fibroid tumors exist in utero previous to menstruation and are the exciting causes of dysmenorrhea in many cases. Why do I believe this? (1) Because of all the cases of uterine fibroids that have come under my observation, and especially the last thirty-one cases, whose histories I have recently studied, all with but one exception, have begun menstruation with severe pain. That one case gave a history of a miscarriage at the third month, which was complicated with a septic condition. (2) Because of the statements of men of standing in the profession like Kelly, Mann, Warren and Gould, Reed, and others.

Howard Kelly says in regard to the existence of uterine tumors, before puberty, in his Operative Gynecology: "Although all myomata probably exist in fetal life in diminutive form, they rarely give evidence of their presence until menstruation has been established for some years." He further says, in speaking of the early signs of uterine fibroids, that among the earliest clinical signs is painful menstruation. Kelly does not say that these signs occur at puberty, but that the earliest sign of uterine fibroids is painful menstruation.

My experience does not concur with Kelly's regarding the length of time the menstrual period has been established, before there is evidence by pain of the fibroid. I believe it is impossible for a patient to have a tumor of the uterus before puberty, and not have the fact announced by pain with the first menstrual period. I am persuaded that careful observation will establish this belief.

Dr. McMurtry, speaking of uterine fibroids, says: "These tumors have been found prior to puberty, but being of slow growth they produce no symptoms until the age of sexual activity."

Reed, in his text-book on gynecology, says: "There have been reported a number of cases of this kind in children." "They may exist before puberty" is a statement taken from an American text-book of gynecology. Mann says he had a patient who never menstruated who had a tumor of the uterus.

The second proposition is of great importance, but perhaps may be more difficult to establish. Are the causes of dysmenorrhea exciting causes of fibroid tumors of the uterus? I assume such to be the case, and will try in the next few minutes to establish my claim.

Dysmenorrhea has various causes. Some of the masters in gynecology assign the pinhole os as a cause. Hewitt asserts that it is due entirely to retention. Matthew Duncan urged that it is neurotic in its origin, but a neurosis is dependent on some irritation. Anteflexion is mentioned by nearly all authors consulted. Displacements are given, but they are comparatively rare causes.

In adults, oöphoritis and tubal diseases with obstruction are prominent as causes of dysmenorrhea. Hendfeldt Jones gives spasm of the uterine muscle at the internal os as a cause.

Now, any and all of these causes of dysmenorrhea mentioned, except the one assigned to neurosis (I consider neurosis only a symptom), are capable and possible causes of uterine fibroids. MacDonald makes Bayle say that one-fifth of all women over thirty-five years of age have fibroids. About one-fifth have dysmenorrhea at puberty.

Dysmenorrhea, as we have seen, has various pathological conditions assigned as causes; every cause assigned is either an irritant or a stimulus to tissue growth. There must be in every cell a substance that has the power to reproduce itself.

Irritation brought to bear upon this substance may destroy the harmony between the cells by producing a new cell or by causing the death of a cell. The one thing a cell inherits above every other characteristic is life. Life responds to stimuli. Prof. Burke's sterilized bouillon responds to the quickening influences of radium. Loeb, by the action of cyanide of potassium on an unimpregnated ovum, has produced the early stages of growth that follow the impregnated ovum.

The cells of the gravid uterus increase and multiply uniformly from the stimulus or irritation of pregnancy. This is a normal condition. A group of cells of the uterus may increase by irritation, forming a tumor; this is an abnormal condition. The one irritation is removed in obedience to nature's laws; the other should be removed by the skilled gynecologist. The equilibrium of the cell-producing power of the uterus should be maintained free from any and all abnormal stimulating influences.

Schaper and Cohen press their theory of "growth centers" into service, to help explain the origin of atypical noninflammatory new growth or tumors. According to the *Journal of the American Medical Association*, they say that it is the persistence of a latent capacity for proliferation in these special growth centers that accounts for the phenomena of regeneration after pathologic disturbance of local correlations of cell function. It is remarkable how frequently the growth centers or places where embryonal karyokinesis persists longest turn out to be sites of predilection for the development of tumors. The growth centers of the uterus are located in the fundi of the uterine glands.

This theory of the origin of new growth accords well with that of Cohnhem Ribbert. He assumes, "First, the presence in the body of cell material capable of proliferation, and second, a stimulus which incites abnormal proliferative activity."

Dr. Mary Dixon Jones claims that all uterine myofibroma are due to a diseased condition of the uterus. In the "International Text-book of Surgery" McMurtry says that uterine fibroma is essentially a pathological condition incident to the menstrual period of woman. Gottschalk thinks that all fibromata originate by an endarterial proliferation, rapidly followed by an increase of the cellular elements surrounding the artery. He says, "Local irritation and circulatory disturbances would be the principal agents in this pathological process."

The theory of the embryonic origin of fibroids was first advanced by Durante, then by Cohnheim, and later adopted by Senn, but was rejected by Veit, who says: "So far as the common myomata are concerned, I hold that their origin from an embryonic

inclusion has not been proved. It appears, however, that heredity plays a rôle therein, and one is able also to understand that irritation acting chronically upon the uterus may give rise to the formation of myomata."

Sterility and virginity are catalogued among causes of uterine fibroids.

I could go on indefinitely enumerating the opinions of master surgeons upon this subject, but will only refer to one more, to which I give the greatest credence. It is the one advanced by Dr. Jones, who says: "For a fibroid to be developed, the tissue of the uterus must be reduced to medullary elements." I quote: "Schultz speaks against the tendency to look upon dysmenorrhea in girls and multiparous women as a functional or neurotic disturbance. It should not be forgotten that the affection may be due to structural changes of the mesometrium, such as insufficiently organized connective tissue in the external uterine layers."

I will recite the history of a case chosen from the thirty-one reported in my private practice.

Miss X. consulted me December 30, 1893, and gave the following history: Age, 30 years; occupation, teacher; always well, except had typhoid fever when 14 years of age. Father died of pneumonia, mother of consumption. Her first menstrual period appeared when she was 13 years old and was accompanied with severe pain in the back and abdomen. She also passed clots.

Examination discovered an extremely anteflexed uterus with the fundus enlarged. After an interval of six years, in 1899, she again consulted me, complaining of backache with leucorrhea, which was worse when she was pursuing her occupation of teaching. The uterus was much enlarged, with a hard, uneven surface of the fundus. At this time she received a few local treatments before she returned to her college work. I did not examine her again for two years; then she had discovered a bunch in her left side which proved to be a well-developed fibroid tumor of the uterus. This was in 1901. I referred her to a New York physician, who advised immediate removal. This was refused and the tumor was treated by electrolysis.

I examined her in 1903 and found the tumor had ceased to grow, at least it had not materially changed in size. Since then she has waited for the climacteric to work a cure.

In analyzing the brief history of this case we must be impressed with the four stages of progress in the evolution of the tumor: (1) Dysmenorrhea at puberty, which was the chief symptom, denoting that there was something wrong. (2) A deformity of the uterus (extreme anteflexion) was discovered at the first local examination, when she was 30 years old. (3) At 36 years of age there were backache, leucorrhea, and an enlarged uterus with a hard, uneven surface. (4) At 38, a tumor of the uterus had developed to such an extent that the patient detected it herself through the abdominal walls.

Is it not safe to conclude that a cause that produces dysmenorrhea at puberty may, if not removed, act as an exciting cause of uterine fibroids?

It is my opinion that the treatment for uterine fibroids should be prophylactic, and that dysmenorrhea at puberty is the pathognomonic sign for the commencement of such treatment. The importance of this treatment, which should include the hygienic care of the adolescent girl, is commensurate with the frequency of the trouble.

Emmett says: "Out of two thousand cases of dysmenorrhea, seventy-five women were sterile." Klob makes the statement that "forty per cent. of women over 50 years of age suffer from uterine fibroids."

If the statistics just quoted are correct, we are morally bound to remove the causes of dysmenorrhea at puberty. This may relieve our patients from being operated upon for the removal of fibroid tumors before and at the menopause.

## TONSILLITIS.

By R. M. NILES, M.D.,

SCRANTON, PA.

MEMBER OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA, OF THE LACKAWANNA COUNTY MEDICAL SOCIETY, EX-MEMBER OF THE NICHOLSON BOARD OF HEALTH, ETC.

TONSILLITIS, while not usually a dangerous affection, often produces much discomfort, and, at times, even threatens life. The disease naturally divides itself into the catarrhal, lacunar, and parenchymatous forms, and each of these forms may be acute or chronic, single or combined. Further, an acute exudative form may be distinguished which, notwithstanding the absence of the Klebs-Löffler bacillus, may be productive of profound depression, alarming constitutional symptoms, and sloughing of the tissues affected. Various organisms are found in the exudate,—staphylococci and streptococci probably are the etiological factors in the greater number of cases. Sloughing is due to round-cell infiltration, followed by defective nutrition and necrosis.

A differential diagnosis between diffuse exudative tonsillitis and diphtheria can be made certain only by microscopic examination. I am convinced that many cases of diphtheria are treated as tonsillitis, while a smaller number of tonsillitis cases are probably treated as diphtheria.

It should be remembered that more marked constitutional disturbance follows severe exudative tonsillitis than ordinary diphtheria; that an ashy-gray membrane, leaving a bleeding surface when detached, is indicative, but not proof positive, of diphtheritis; and that a careful investigation of the case, history, and symptoms is the duty of the intelligent physician.

In the treatment of this affection we should isolate the patient, for many times tonsillitis is contagious. Broken doses of calomel, followed by a saline should be given. If the stomach is irritable, or the patient seriously objects to the salts, one may instead give one-fourth to one drop of croton oil in combination with hyascyamus and a carminitive.

Quinine in tonic doses (gr. ii t.i.d) should be given in the majority of cases. Strychnine may be added if indicated. Aconitine controls fever, and may abort the disease. Sodium salicylate is a most meritorious drug in cases presenting the rheumatic diathesis. Guaiac is also applicable, both as a gargle and as a constitutional remedy. Anodynes may be required for pain, hypnotics for restlessness. The diet should be light, digestible, and fluid, or semi-fluid.

Hot alkaline gargles are comforting to the patient, and as they tend to free the parts from mucus and mucopus, their frequent use should be encouraged.

For years the writer has used the following gargle with the happiest results:

℞ Pot. bicarb. . . . . ℥iv
Spt. menth. pip.,
Spt. camphoræ. . . . . aā ℥ss
Aq. ferv. . . . . q.s.ad ℥iv

Sig.: Use hot, gargle every hour or two.

Atomizers are useful in the application of hydrogen peroxide, in the treatment of young children, and those unable to gargle. Gargling, when efficaciously done, is superior to spraying.

Nitrate of silver in solution, painted over the tonsils, will abort some cases, but to be effective it must be applied early in the disease.

Iodine, bichloride of mercury, turpentine, phenol, sulphur, and a host of other remedies have their recommendors. Numerous pharmaceutical houses have on the market a tablet composed of tinctures of aconite, belladonna, and bryonia, with red iodide of mercury and sodium salicylate. While this is a shotgun prescription, nevertheless the tablet, when dissolved slowly in the mouth and swallowed, gives good results.

Chlorate of potassium is of little, if any, value, its possible beneficial action upon the diseased area being more than offset by its objectionable attributes.

Often the application of the tincture or vinegar of capsicum produces the most brilliant results. Congestion and edema are reduced, the separation of sloughs is facilitated, granulations are stimulated, vasomotor inertia is overcome, and normal tissue metabolism is reestablished.

In cases presenting sluggish ulcerations, massage with cod-liver oil and capsicum has given better results in my cases than any other treatment. If the application of capsicum causes pain, apply cocaine before using. Capsicum enhances the action of cocaine, *i.e.* it tends to make permanent the temporary contractive influence of the latter. Capsicum gives tone to the muscular tissues with which it comes in contact, diminishes the lumen of abnormally dilated vascular canals by local stimulation of their muscular and nervous elements, and promotes the resumption of physiological secretion and absorption.

Tincture of capsicum, full strength or diluted with cod-liver oil should be applied to the Schneiderian mucous membranes in the treatment of the rhinitis, which is a frequent concomitant of the tonsillar involvement. The nasal mucosa is first cocainized, and the capsicum is then applied with a cotton-covered applicator.

Applied to the neck a hot camphorated animal oil may give some relief, and to this belladonna may be added to increase its anodyne qualities.

In conclusion, I would remark that, if every case of "sore throat," so-called, received the care and attention that an affection of so delicate and important a structure would seem to merit, much discomfort and suffering would be avoided, while unfortunate and dangerous complications and sequelæ would become much more rare.

414 Spruce Street.

**Syphilis Infection and Paretic Dementia.**—James G. Kiernan declares that there are two possibilities which would lead to syphilis infection of paretic dementia—the possibility of reinfection and the possibility of non-syphilitic paretic dementia. The writer reports ten cases that have come under his own observation in which syphilitic infection occurred during paretic dementia. In the majority of these cases preparetic-dementia syphilis can be excluded, while it is a bare possibility in the remainder. The writer believes that at any rate the cases show that the ordinary tests of the syphilitic origin of paretic dementia have no value unless they are carefully scrutinized. One of the cases he reports was that of an Irish hotel man seventy-three years old, whose wife and children were perfectly healthy. He began to have "fainting spells" in the warm plate room. These were followed by temporary motor aphasia and right hemiplegia. There was a decrease in the degree of urinary acidity at the time of these attacks, a few hyaline casts and very exhausting cold acid sweats. There was no albumin in the urine. After the attacks marked urinary acidity and acetonuria were noted. Some months later the patient began to manifest silly optimism, gradiose delusions, extravagance, and irritability. No evidence of syphilis could be found. Still later he showed a tendency to dissipate, and at about this time he contracted a chancre. The secondary eruptions disappeared under mercurial treatment. Another case reported is that of a respectable woman forty-two years old. At the age of thirty-nine she became very boisterous in manner and negligent of household duties. Six months later an apoplectiform attack was followed by physical symptoms of paretic dementia. During a condition of practical nymphomania she contracted a chancre. Secondary fever and eruption followed. The marked depression which developed cleared up under mercurial treatment. The case ran the usual course of paretic dementia. Death finally occurred.—*Medicine.*

**Insanity Precipitated by Pelvic Disease in Women.**—R. R. Huggins declares that the removal of healthy organs in the insane is absurd, and is often followed by an aggravation of the mental symptoms. But the insane woman who has pelvic disease has the same right to treatment as the normal mentally. Some of these cases may be cured if the pathological condition is removed before neurotic habits are established. Our success in operative treatment for pelvic trouble in such cases will depend on our ability to judge the amount of mental instability of each patient. The degree of irritation and character of the lesion must be considered, the previous and family history, and the extent of the degenerative stigmata. The acute psychoses and the chronic melancholias with little predisposing taint will give the best results. Considerable irritation may be observed in healthy women at the menstrual period and during the puerperium. This will be more marked in diseased conditions of the pelvic organs, and must cause irritation which may precipitate an attack of mental disease in one predisposed to it. The psychoses of the puerperium are due in 70 to 80 per cent. of cases to toxemia or infection, combined with psychopathic tendency. There is a greater percentage of pelvic disease among insane than among sane women. Hobbs of London, Ontario, in 1895, selected one-fourth of the female patients of the asylum for gynecological examination, including young and middle aged women who had borne children. In 1,000 patients he found pelvic disease in 25 per cent. of the whole number; ovarian disease in forty-one cases, 40 per cent. of whom recovered after ovariotomy, and ten more improved mentally. Sixty-eight uterine displacements: mental recovery in 48 per cent., improvement in 20 per cent. Sixteen cases of tumors: recovery in two cases, improvement in six. Recovery in nineteen out of sixty cases of cervical lacerations.—*Annals of Gynecology and Pediatry.*

**The Relation Between Anthracosis and Pulmonary Tuberculosis.**—Jonathan M. Wainwright and Harry J. Nichols in considering this subject, refer to the most frequently mentioned theory that has been advanced to explain the observation that anthracotic lungs are less susceptible to tuberculosis than the normal organs, namely, that it is due to the germicidal action of the coal dust. The writers have found from various tests, however, that coal dust has no germicidal action whatever. Another suggestion that has been advanced is that the rarity of tuberculosis among these workers depends upon the fact that the air of the mines is comparatively free from bacteria. This, together with the fact that tuberculous sputum cannot dry, must have some effect in diminishing tuberculosis. But these are probably not the only factors. The writers think that the coal dust in the lungs does exert a true protective influence against the tubercle bacilli, and that it is due to the stimulating effect of the coal dust on connective-tissue growth. This growth is the way in which nature overcomes the tubercle bacilli. It is well known that coal dust causes stimulation of connective-tissue growth. The writers have performed some interesting experiments on guinea-pigs in relation to the effect of anthracosis on tuberculosis, and as far as they have gone the experiments have been affirmative. *American Journal of the Medical Sciences.*

## ALCOHOLISM AND DRUNKENNESS.

DR. G. ARCHDALL REID is the foremost exponent in Great Britain of what may be termed original views as to the causation of drunkenness and alcoholism. Dr. Reid's theories on the subject have been referred to on several occasions in the editorial pages of the MEDICAL RECORD. He not only is a man of original views, but, like all earnest men, is decidedly dogmatic and is somewhat inclined to beg the argument. He believes that inebriety is a problem of evolution, and that acquired effects of disease are not transmissible to offspring. Also that men drink alcoholic beverages for three distinct reasons: to satisfy thirst, to gratify taste, to produce a direct effect on the brain. Dr. Reid is further of the opinion that men differ in their predisposition to inebriety. As a rule, men drink in proportion to their individual predispositions. Self-control is a subordinate factor in the causation of sobriety. Lack of temptation is the principal factor. Alcohol, argues Dr. Reid, weeds out the unfit, and is therefore, like disease, a selective agency, and also like disease develops resistance. For instance, practically every negro on the west coast of Africa suffers for a prolonged period from malaria, this has been the case for generations. If the environment of the germ-cell causes variations in the offspring, it should do so with these negroes. As a matter of fact, however, neither the negroes nor any race exposed to malaria has grown degenerate. Therefore from these circumstances the theory is evolved that every race exposed to disease, or to any other adverse condition, is resistant to it precisely in proportion to the duration and severity of its past sufferings. It is pointed out in support of these views that Englishmen who have suffered much from consumption are more resistant to it than Polynesians, who have no previous experience of the disease and who are exterminated by it. "Extreme cold has not rendered the Esquimaux degenerate, nor extreme heat the Arabs; they have merely been rendered, by the survival of the fit, resistant to heat or cold, respectively."

Where Dr. Reid especially begs the question is when he asserts that every race is temperate in proportion to its past experience of alcohol. A short time ago he published an article on the matter in the London *Daily Chronicle*, wherein he declared, as he has declared before, that West African savages, who have long possessed unlimited supplies of palm toddy, the Jews, and the inhabitants of the vine countries of the south of Europe are more temperate than North Europeans and infinitely more temperate than most savages, for the reason that formerly they were less temperate. The force of the foregoing argument is by no means convincing. It is denied by many authorities that West African savages, the Jews, or South Europeans were at any time so intemperate as North Europeans. The Jews were ever a temperate race, and South Europeans were not probably in far back times such a hard drinking people as, for instance, the ancestors of the British race. Again, the South Europeans of the present time consume more alcohol than do those of the North. In France the per capita consumption of spirits is greater than in many a more northern country.

The discussion regarding the drink question from a scientific standpoint has been productive of a great deal of hard hitting and mutual recrimination on the part of the champions of the various theories. The biological critic of the London *Times*, commenting upon Dr. Reid's published opinions, delivered himself as follows: "It is not by exercises of this kind that the riddle of the universe will be read, and the demand that our lives shall be compulsorily regulated by laws based on such sandy foundations is nothing short of impudent."

The Research Committee appointed by the British Society for the Study of Inebriety in part reported that they were of the opinion that the continued use, or rather abuse, of alcohol tended to render a race less innately prone to excessive indulgence than it would otherwise have been, and that this result is brought about by the elimination of those with a weak tendency to alcoholic indulgence. They thought that the widespread belief that the indulgence of the parents tended to render the offspring more innately prone than they otherwise would have been to excessive indulgence, was not warranted by the existing evidence on the subject. Many, perhaps, of those who have made a subject of inebriety hold that an inborn tendency to inebriety is most marked in races that have had little or no experience of the poison.

Dr. Reid states that there are two conceivable methods of temperance reform—the elimination of drinking and the elimination of the drunkard, which he terms Nature's method. He contends the reformers' methods have totally failed, while Nature's method has invariably succeeded, but at a fearful cost. In a few words, the doctrine is that of the survival of the fittest. The sole remedy that the champion of this theory, as applied to the drink habit, puts forward is that it may be possible to minimize its dire effects by limiting the output of children by drunken parents—as by spreading abroad a knowledge of the danger of marrying into intemperate families.

Of course the opinions of Dr. Reid and his followers are accepted by only a few scientific men. Views as to the transmissibility of acquired characteristics are by no means unanimous. A great many adhere to the theory that acquired habits can be transmitted, and it would seem to be undoubtedly the fact that the children and descendants of inebriate parents, even if they do not inherit the taste for strong drink, at any rate inherit frequently a neurotic and unstable nervous temperament, which peculiarly predisposes them to alcoholic indulgence. From Dr. Reid's contentions it might be gathered

that the more drunken a race is the stronger it will grow in the course of time. History, however, does not confirm the truth of such a view.

## THE TREATMENT OF SYPHILIS.

It may be safely assumed that mercury will constitute the specific remedy for the treatment of syphilis until a time when science has succeeded in producing a curative serum, which, like that so successfully employed in diphtheria, shall be equally effective against the pathogenic agent of the disease as well as against its toxins. The sovereign form of mercurial medication is, and will probably continue to be, the inunction, for the subcutaneous and intramuscular injections of the various solutions of mercury have by no means overcome the objections so often urged against them. Although the mercurial treatment of syphilis is usually successful, it is a well-established fact that in a certain number of cases a refractory tendency is manifested by the patient against the drug, and its administration fails to constitute an effective barrier to the later appearance of the tertiary lesions of the disease.

It is quite natural that other means of treatment for this widespread affliction should be sought for, and among those which have been most loudly proclaimed were the exclusive hydriatic procedures advocated among others by Father Kneipp, and before him by Priessnitz. The arguments advanced by these men and their enthusiastic adherents appeared most attractive to many of the afflicted, and improvements and cures were reported in many who gave up their mercurial treatment for the new method. It developed, however, that the patients of this class had already been saturated with mercury before they abandoned the use of this drug, but of the many previously untreated or incompletely treated patients who sought the institutions where this water cure was exploited, practically no exceptions were noted in the progress of the disease and in the later appearance of tertiary lesions, even after a prolonged subjection to the hydriatic procedures. The many failures constituted a sufficient basis for the severe criticism which the method met with, and the successes can readily enough be accounted for and depend, as shown by Rudnik (*Wiener klinische Rundschau*, November 5, 1905), on the favorable effects produced on the system in general by the procedure. Thus, the metabolic exchange is stimulated, the excretion of toxic substances is favored, and the number of red cells and the hemoglobin content of the blood are increased. These factors alone may not be sufficient to overcome the effects of the syphilitic virus in the organism, but they may be made to serve as an aid to the specific action of the mercury. Rudnik suggests, therefore, that they be employed as an accessory to the accepted form of medication, and gives his reasons for this recommendation.

The manner in which mercury is taken up by the system is by no means clear. It has generally been assumed that the drug is absorbed from the skin by the lymphatics, but, as Rudnik suggests, it is more likely that it enters the circulation directly through the capillaries, and in this fact is found a ready explanation why the hemoglobin is increased after only a few inunctions of mercury. The virulent character of the infection in anemic persons and alcoholics he also explains by the presence in these subjects of an insufficient capillary circulation common to these conditions, so that the mercury is not promptly enough absorbed to become effective. The arteriosclerosis of older patients presents a similar obstruction to the absorption of the remedy and accounts for the malignant nature of the disease at this time. Hydriatic measures, according to Rudnik, are therefore indicated as an accessory in the class of patients just noted as well as in those who display a refractory tendency towards mercury which defies explanation. He has employed the method with success in a number of cases which received no benefit whatever from the mercurial medication alone, and as the result of his experience recommends the following mode of procedure in a given case of syphilis: (1) From the time of infection to the manifestation of the clinical evidences of the disease, an expectant attitude should be maintained. (2) As soon as the constitutional symptoms appear, an energetic system of inunctions should be instituted, and hypodermic or intramuscular injections should be employed only in those exceptional instances in which the former cannot be carried out for individual or social reasons. (3) A course of thorough hydriatic treatment extending over a term of 6 or 8 weeks is indicated in all cases even when the clinical symptoms have abated after the inunctions have been given. This will not only obviate the possible metasyphilitic states at a later period, but it also serves to eliminate the excess of mercury from the system.

A great deal of time and thought has been accorded to the therapeutics of syphilis, and yet we meet with refractory cases and obstinate recurrences in many instances even when treatment has been most careful and thorough. An increasing amount of light has lately been shed on the etiology of the disease, and if the value of the simple recommendation advanced by Rudnik as an accessory to the usual mode of treatment is confirmed by others, we may expect better results in the future in patients afflicted with this malady.

## DEATH BY ELECTRICITY.

The enormous strides made during the last few decades in the application of electrical energy to the arts and sciences have raised a number of problems, among the most serious of which is the oftentimes fatal effect of the force on the individual accidentally projected into its path. Although we have records of fatalities due to lightning dating back to early historic times, it was not until the 18th century that scientists began to devote their attention to the investigation of death from this cause. They recognized the similarity between the natural atmospheric discharges and the frictional electricity they were able to produce, and we find that experiments were made on animals in order to determine, if possible, the manner of death by this agent. The question of death from the artificially produced currents did not, of course, assume any great importance until the invention of the dynamo with its increased generating capacity, and this also marked the beginning of the study of electropathology. Numerous opportunities have occurred to study the mode of action of the electric current with the increasing number of fatalities which have grown with the development and

expansion of electrical science, yet we are compelled to admit that comparatively little progress has been made towards the solution of the problem, for reasons, some of which will be enumerated later on.

A recent and interesting contribution to the subject of electrical death is contributed by Jellinek (*Wiener klinische Wochenschrift*, November 2, 1905), whose studies have extended over a number of years and include extensive personal experiments. It is well known that the effects of the electric current vary greatly in their manifestations. Death may be caused either by the direct or by the alternating type of current of either high or low tension. In most instances immediate unconsciousness results, although authentic cases are on record where the victims of the shock remained conscious for several minutes before death finally took place. In fatal cases there is an immediate relaxation of the muscular system, unless the individual remains in contact with the conductor; in the latter case a tonic spasm results. Respiration and heart action may cease at once, or a gradual cessation of these functions occurs. Animal experiments and the observations made on the human subject show that there is no definite symptom complex, however, which characterizes electrical death. The explanation of the wide variations which have been noted must be sought for on the one hand in the electrical conditions, and on the other in the resistance of the individual affected.

In any given fatal case the current may be said to exert a double effect. When it enters the body it acts as an enormous irritant which manifests itself as shock. It has been found that this particular effect can be eliminated to a greater or less extent, as shown by the fact that it is reduced to a minimum or absent altogether when the current enters the system during narcosis or during sleep. In addition to the psychic phenomena just noted there is also manifested a dynamic effect on the various aggregations of body cells, which probably amounts only to a disturbance or at the most to an inhibition of one or more of the vital functions. In fact, experience has shown, and this has been confirmed by animal experiments, that the threatening and seemingly fatal symptoms of impending death due to the electric current, are very often only transitory in character. Jellinek justly claims that in most instances death is merely apparent,—"Scheintod," and it is an extremely difficult matter to express an opinion as to the final outcome as regards dissolution. If we are to act on the author's suggestion, a fatal issue should not be accepted as having occurred until energetic and prolonged efforts at resuscitation have been carried out in a systematic manner without result. And this raises again the question as to when death occurs in cases of so-called electrocution—whether it is while the subject is in the chair or while he is on the autopsy table.

### Congenital Pneumonia.

The transmission of various substances through the placenta from the maternal to the fetal organism has been widely discussed in obstetrical literature and many obscure points in the physiology of pregnancy have now been cleared up by the investigations in this field. The passage of volatile anesthetics and soluble drugs from mother to child has often been demonstrated; acquired immunity against a variety of diseases can also be transmitted, and likewise apparently some of the infectious diseases themselves. Instances of intrauterine infection are infrequent, however, and this applies particularly to pneumonia, of which only a very few instances have been recorded. Bochenski and Gröbel (*Monatsschrift für Geburtshilfe und Gynäkologie*, October, 1905) present the history of such a case, where a woman developed a croupous pneumonia during the very last weeks of her pregnancy and then gave birth to a child which died within twelve hours with evidences of pulmonary disease. An autopsy showed the lungs of the infant to be in a state of gray hepatization, and bacteriological examination disclosed the presence of the specific diplococcus. A post-partum infection in this case can be excluded, for both macroscopical and histological appearances of the lungs pointed to an invasion by the disease which failed to correspond in length of time with the brief period of extrauterine existence. In attempting to trace the manner of the transmission of the disease from the mother to the fetus, the only satisfactory solution lies in assuming that the maternal circulation afforded such an outlet and a pneumococcemia existed in the mother in addition to the pneumonia. The lesions which must have been present in the placenta in order to permit the pneumococcus to pass through this barrier are believed by the writers to have resided in some mechanical injury to the placental villi, brought about possibly by the sudden increase of intrauterine pressure during a severe coughing spell which resulted in the condition designated as retroplacental apoplexy. The fact that the pneumococcus was deposited solely in the lungs of the fetus to the complete exclusion of all the other organs demonstrates quite conclusively that the pulmonary tissue is the site of predilection for this type of organism.

## News of the Week.

**Amalgamation of the State Societies.**—The new House of Delegates of the Medical Society of the State of New York met in Albany December 14, together with the Chairmen of the Standing Committees and the Joint Committee of Ten. The Secretary was ordered to notify all county societies of the fact that they should reorganize so as to amend the constitution and by-laws according to the agreement, and to notify all members of the Association of the fact of consolidation. The counsel who made application for consolidation gave the opinion that an order from the Supreme Court made all members of the New York State Medical Association in good standing members of the Medical Society of the State of New York, upon the receipt of a certificate of the President and Secretary of such Association. It was voted to continue the Medical Directory, and to retain the feature of malpractice defense for the members of the Medical Society of the State of New York. The President and Secretary were ordered to continue the *Journal* for January and February, and a Committee was ordered to be appointed by the President to select an editor and to report his name at the annual meeting of the House of Delegates. A committee of five was appointed, of which the President was one, to carry out the referendum as per Section 7 of the court order, relating to the practice of medical ethics. The Constitution of the American Medical Association provided that when any State Medical Society was reorganized according to the plan of the American Medical Association and by resolution expressed its allegiance

to the American Medical Association, it then became a constituent of said Association. Such a resolution was unanimously carried. A tentative constitution and by-laws for the county societies was submitted as being suggestive and which might be adopted with very slight alteration by the several county medical societies of the State.

The New York County Medical Association held a meeting on December 18, under the presidency of Dr. Francis J. Quinlan, in the assembly room of the New York State Medical Association's headquarters, 64 Madison avenue, when several important matters relating to the dissolution of the Association and its charter were discussed. Steps were taken to dissolve the articles of incorporation.

**Efficiency of the Army Medical Corps.**—The Secretary of War has received a letter from Major-General Leonard Wood strongly urging the passage of the bill now pending in the House to increase the efficiency of the Army Medical Corps by making provision for more rapid promotion and giving higher rank to the army surgeons. In emphasizing the urgent necessity for improvement General Wood says: "Our experience during the war with Spain should be sufficient to render a recurrence of the conditions then prevalent impossible. First-class men in sufficient numbers cannot be secured under the present conditions of promotion." He is opposed to the employment of contract surgeons, and says in this regard: "The system of employing contract surgeons is a makeshift and expensive one, as is our policy of expanding the medical department in time of war through the employment of inexperienced civilian medical men. These gentlemen, whatever their professional attainments, know little of army methods or of handling large bodies of men."

**The Southern Medical College Association** held its annual meeting December 11, at Louisville, Ky., under the Presidency of Dr. Christopher Tompkins of Richmond, Va. More stringent rules applying to the admission of students were adopted. Ten of the fourteen colleges of the Association were represented. President Tompkins read an address on "The Advancement in Preliminary Educational Requirements." The suggestions set forth in the address, after considerable discussion, were resolved in a motion which was unanimously passed. The motion provided that from the present time until January, 1908, an applicant for admission to any college of the Association must have had two years in a recognized high school, or a certificate from an acknowledged preparatory school, besides a grammar-school education. After January 1, 1908, the nine requirements for admission will be a high school diploma, or a certificate of graduation from a recognized preparatory school, and the courses at the college shall be for four years of seven months each instead of six months, as is the case with some schools at the present time. Since the last meeting five colleges, not in the Association, have either filed applications for membership or will do so within a short time. Two of the colleges which have filed applications are the Medical Department of Epworth University, Oklahoma City, Okla., and the Medical Department of the Southwestern University, Dallas, Tex. The other three colleges are in Georgia and Maryland. The following officers were elected for the ensuing year: *President*, Dr. Christopher Tompkins, Richmond, Va.; reelected; *Vice-President*, Dr. T. H. Fraser, Mobile, Ala.; *Secretary and Treasurer*, Dr. G. C. Savage, Nashville, Tenn., reelected. *Executive Committee*, Drs. J. S. Kane, Nashville, Tenn.; W. B. Rogers, Memphis, Tenn., and Stuart McGuire, Richmond, Va. The next meeting of the Association will be held in Baltimore at the same time with the Southern Surgical and Gynecological Association.

**Concerning the Registration of Births.**—In August, 1904, the Board of Health sent to every physician and midwife practising within the city limits a circular calling attention to the importance of making a report to the Department of Health of every birth occurring in his or her practice. The rules of the Department of Education require the production of a transcript of birth by the Department of Health for every child seeking admission to school. The Child Labor Law of the State requires that the applicant for an employment certificate shall produce a transcript of his or her birth record. The circular above mentioned directed special attention to these two points and stimulated for the time being the full reporting of births. Recently the births have not been fully reported. Physicians and midwives are earnestly requested to forward at once to the Registrar of the Department of Health the returns of all as yet unreported births occurring under their care during 1905. Overdue returns will now be accepted without penalty. The Board of Health intends, after January 1, 1906, to take legal action against physicians and midwives who have failed to comply with the law in this matter.

**American Association for the Advancement of Science: Section K.**—The session of Section K (Physiology and Experimental Medicine) of the American Association for the Advancement of Science, which will be held in New Orleans on the morning and afternoon of January 1, promise to be of unusual interest. The morning session will be opened by an address by the Vice-President, Dr. William T. Sedgwick, on "The Experimental Method in Sanitary Science and Sanitary Practice." The remainder of the morning session and all of the afternoon will be devoted to a symposium on "Yellow Fever and Other Insect-Borne Diseases." Yellow fever in its various phases will be discussed by Drs. J. H. White, Quitman Kohnke, James Carroll, and H. A. Veazie, and it is expected that Drs. Edmond Souchon, Surgeon General Walter Wyman, Col. W. C. Gorgas, and other specialists will also take part in the discussion. Dr. William S. Thayer will read a paper on "The Problem of Prophylaxis Against Malaria in the United States"; Dr. Henry B. Ward will consider filariasis and trypanosome diseases; Dr. Charles W. Stiles will present a résumé of facts bearing on the principles involved in the transmission of disease by insects; and Dr. Gary N. Calkins will discuss the protozoan life cycle. Dr. L. O. Howard will talk on mosquitos that carry disease, and Mr. Henry Clay Weeks, Secretary of the American Mosquito Extermination Society, will present the practical side of mosquito extermination. The Secretary of the Section is Dr. William J. Gies, 437 West Fifty-ninth street, New York.

**The St. Louis Obstetric Dispensary.**—On December 14, 1905, the St. Louis Obstetric Dispensary was formally opened in its new quarters at 711 Carr street. This institution was founded in October, 1904, under the auspices of the St. Louis University, and is at present maintained with funds provided by a Ladies' Auxiliary Board. A medical report just published by the physician-in-chief, Dr. Hugo Ehrenfest, states that the assistants and senior students on regular duty at the dispensary attended to 166 labor cases. In a speech made by the Health Commissioner, Dr. Snodgrass, the interesting fact was emphasized that this represents 1.4 per cent. of all confinement cases reported to the health au-

thorities of St. Louis during the past year. This fact certainly justifies the optimistic views expressed by all the speakers concerning the future of the St. Louis Obstetric Dispensary.

**The Philadelphia Pediatric Society.**—On Tuesday evening, December 12, Dr. Henry Dwight Chapin, of New York, read a paper on the subject of "Nutrition of Infants" before the Philadelphia Pediatric Society, which was formally discussed by Drs. J. P. Crozer-Griffith, E. E. Graham, Thompson S. Westcott and David L. Edsall. After the meeting a largely attended reception was given to Dr. Chapin at the Hotel Stenton.

**Conference of Surgeons, Illinois National Guard.**—Forty physicians and surgeons, connected with the Illinois National Guard, recently held their annual conference in Chicago to discuss ways and means of improving the physical condition of the State militia. The session began with a series of demonstrations at Rush Medical College. Captain S. C. Stanton, First Infantry, discussed the examination of recruits; Major Charles Adams, also of the First, spoke on medical treatment, while Dr. Nicholas Senn gave a demonstration of amputation on the battlefield. Lieutenant Henry W. Howard spoke on the dressing of fractures. The conference closed with a luncheon at the Presbyterian Hospital. In the evening Dr. Senn gave the association a dinner at the Rothernstein Inn.

**A New Radioactive Substance.**—O. Hahn, a pupil of Prof. Ramsey, is said to have discovered a new radioactive element. The substance, to which the name of radiothorium has been given, is so rare, however, that it possesses only theoretical interest and is not likely to prove commercially useful.

**Tuberculosis Hospital Not Wanted.**—The inhabitants of Staten Island have evinced considerable opposition to the project of building the city's new $2,000,000 tuberculosis hospital in Richmond County, alleging that it would be detrimental to local interests and health conditions. The Medical Society of Richmond County has taken the matter up, and has adopted a resolution condemning the proposition on the ground that the climate of Richmond was detrimental to the successful treatment of tuberculosis owing to its humidity and variations in temperature.

**For Repeal of Anti-Canteen Law.**—A resolution adopted by the Association of Military Surgeons, urging the repeal of the anti-canteen law, has been transmitted to the House of Representatives by Secretary Taft. The tenor of the statement is to the effect that the abolition of the canteen has resulted in an increased consumption of bad liquor by soldiers, tending to demoralize their efficiency, that it has increased the number of saloons and disreputable places just outside garrisons, has caused the spread of disease, and generally has resulted in no good. An association of women, forming an auxiliary to the German-American Alliance, is being organized for the purpose of combating the Women's Christian Temperance Union, and assisting in the restoration of the canteen.

**Gift to the Sydenham Hospital.**—Mr. Isaac Guggenheim has announced to the directors of the Sydenham Hospital in West 116th street that he will contribute $250,000 toward the erection of a new building, provided that the board secures enough other contributions to equal this amount. Mr. Guggenheim has already contributed $20,000 to assist in paying the hospital's running expenses. The hospital was established two years ago with six beds. It now has 86 beds, 70 of which are free. The city gave the hospital an appropriation of $12,500 last week.

**Bequests to Hospitals.**—The will of Mrs. Sarah H. Walker of New York directs that a friend shall have the use of a house in Charleston, S. C., during his life, but on his death it is to go to the City Hospital of Charleston, "for use of white people only." A lot in Montgomery, Ala., also goes to the City Hospital there, to found a surgical ward for white persons only. Besides this, the Montgomery hospital is to have $1,500, and Mrs. Walker's physician receives a legacy of $25,000 and a share in the residuary estate.

**Yellow Fever at Havana.**—Up to December 19 there had been 59 cases with 19 deaths from yellow fever in Havana; ten cases are still under treatment. One hundred and twenty men have been added to the yellow fever brigade, which now numbers 445 men, 325 of whom are engaged in disinfecting, twenty in inspecting tanks, barrels, etc., and 100 in putting petroleum on water where mosquitos might breed.

**Dr. William Osler** is expected to spend the holidays in Baltimore and Boston, and will lecture at the Johns Hopkins University in January.

**Immigration Figures.**—The annual report for 1905 of the Commissioner of Immigration shows that during the year ending June 30 last, 1,026,499 aliens were received into this country This is an increase of 213,629 over the figures of last year. Of the entire number, 23,925 came from Asia, all the others being natives of Europe. Austro-Hungary, Italy, and Russia, in the order named, contributed the largest proportions of the new arrivals, the sum total of immigrants of these nationalities being almost 700,000.

**New York City's Station Houses.**—In his report to the Society of Medical Jurisprudence as Chairman of a committee appointed by the Society last May to investigate the condition of the police stations, ex-Magistrate Alfred E. Ommen denounced most of them as being "pestholes unfit for habitation either by policemen or prisoners." No fewer than nine police stations were reported as being entirely unfit, and the committee declared they should be torn down. Mr. Ommen's associates in the investigation were Dr. R. W. Willcox, Dr. C. A. Ramdohr, S. B. Livingston, and E. V. M. Heermance. The most interesting remedial feature of Mr. Ommen's report was the suggestion that instead of the police-station prisons, district prisons should be established. These district prisons should be located in the center of a police district and joined to the Magistrate's Court. Under present conditions a good deal of time is wasted in first taking a prisoner to the police station, and then to the police court to be arraigned. It was also urged that at present if a prisoner needed medical or surgical attention, it was necessary to send for an ambulance and have him taken to a hospital. In the district prison there could be a small hospital, where surgeons could give emergency treatment.

**A New Medical City Officer.**—The Civil Service Commission, on the recommendation of Comptroller Grout, has created the post of Medical Examiner for the Finance Department, with a salary of $2,500. It will be the duty of this officer to investigate claims against the city for damages for personal injuries. This work is at present done by the police, and it is expected that much money will be saved by having it in charge of a medical man.

**Cerebrospinal Meningitis.**—Five cases of cerebrospinal meningitis, with one death, have been re-

ported from the naval training station at Newport. The disease appeared among recent arrivals, and all new apprentices who were quartered in the detention building have been removed to the former Spanish cruiser *Reina Mercedes*. Other precautions have been taken to prevent a spread of the disease among the remainder of the 1,500 apprentices in the station. The schools of Dunkirk, N. Y., have been closed on account of the same disease. Five cases are under quarantine and the schools will be fumigated before being reopened.

**Valvular Closure of the Gall-Bladder.**—The author of the article on this subject in the issue of November 25 was Dr. A. E. Rockey, and not H. E. Rockey, as the types would have it appear.

**Obituary Notes.**—Dr. Edwin Reynolds of Brooklyn, for twenty-two years chief of staff of the Brooklyn Home for Consumptives, died December 15. He was born in Warwick, N. Y., sixty years ago, and was descended from an old Massachusetts family. Dr. Reynolds was a graduate of the New York College for Physicians and Surgeons, and also studied at the Ecole de Médecine in Paris.

Dr. David Oldham Lewis, Medical Inspector and Fleet Surgeon of the United States Pacific Squadron, died of apoplexy on the cruiser Chicago at Honolulu on December 16.

Dr. Theodore Deecke of Utica, N. Y., died on December 15, after three years of illness. He was 69 years old. For seventeen years he was pathologist at the Utica State Hospital, during which time he brought his department to a high state of efficiency. From time to time he had figured prominently as an expert witness in criminal trials in different parts of the country.

Dr. James Elliott of Newark died on December 15, at the age of eighty-eight years. He had practised in Newark for fifty-six years.

Dr. Solomon B. Wolfe, a retired physician of this city, died suddenly of heart disease on December 13, at the age of sixty-one years. He was in a life insurance office and had asked for a blank application form, but died before it could be handed to him. He served through the Civil War as Colonel of the Seventh Kentucky Cavalry.

Dr. S. B. Sayre of Oelwein, Ia., died suddenly on December 11 at the age of thirty-five years. He attended Rush Medical College at Chicago, and Worcester Medical College at Cleveland, O., graduating from both institutions. For several years he was located in the practice of medicine at Marshalltown, but moved to Oelwein about two years ago and established himself as an eye, ear, and throat specialist.

Dr. H. E. Muller of Oakland, Cal., died on December 12 of edema of the glottis, complicating an attack of tonsillitis. Dr. Muller was born in Switzerland forty-seven years ago. He had been a resident of Oakland nearly thirty years, and for the past twenty-seven years had practised medicine there, having graduated from the medical department of the University of California.

Dr. W. P. Caffrey of Castle Gate, Utah, died suddenly of heart disease on December 3 at the age of thirty-three years. He was a graduate of the University of Michigan, and had been physician to the Utah Fuel Company for five years.

Dr. Jerome Smith of Hodgenville, Ky., died on December 10 at the age of seventy-four years. He was one of the oldest and best-known physicians of Larue county.

Dr. John F. Failing, for many years a practitioner of Grand Rapids, Mich., is dead in Los Angeles, Cal., after a long struggle with pulmonary tuberculosis. Dr. Failing was born in Wayne county, N. Y., on October 24, 1841. He began the study of medicine in Lyons, N. Y., but gave it up to enlist in the federal army in August, 1862, being appointed hospital steward of the One Hundred and Thirty-eighth New York Volunteer Infantry, afterward known as the Ninth New York Volunteer Heavy Artillery. In this capacity he served in the army until the end of the war. He then attended the medical department of the University of Michigan and was graduated from the University of Buffalo in 1868. From that year until 1895 he practiced medicine in Michigan, from 1882 to the time his health gave out, in Grand Rapids.

Dr. William J. McMurray of Nashville, Tenn., died on December 4 at the age of sixty-three years. He was graduated from the University of Nashville in 1869, after having served with distinction through the civil war. He was President of the Tennessee Board of Health and had held many other positions of prominence.

Dr. J. E. Thomson of Delhi, La., died of appendicitis on November 27 at the age of thirty-two years. He was a graduate of the Chicago College of Pharmacy and received his medical degree from Tulane University.

Dr. William S. Forbes of Philadelphia died suddenly of heart disease on December 17. Dr. Forbes was born February 10, 1831, at Falmouth, Stafford county, Va., and was graduated in arts from the University of Pennsylvania in 1850, and in medicine from Jefferson Medical College in 1852. He served with the British in the Crimean war. He had for years occupied the chair of anatomy in Jefferson Medical College. He was senior surgeon to the Episcopal Hospital.

## Obituary.

### NATHAN BOZEMAN, M.D.,

NEW YORK.

Dr. Nathan Bozeman, whose death occurred on December 16, following an attack of apoplexy, was the last of the pioneers in gynecological surgery in this country. Like his contemporaries, Sims, Metcalfe, and Thomas, he was from the South, having been born in Butler County, Ala., on March 25, 1825. He studied medicine at the University of Louisville, receiving his degree from that institution in 1848. He began the practice of his profession in Montgomery, Ala., in 1849, and for a time was associated there with J. Marion Sims. While there he established a reputation as a gynecologist, having devised a new operation for vesicovaginal fistula, and making a record of seven successful cases. He also operated with success in a case of vesicouterine fistula. After a visit to Europe, during which he demonstrated his method of treating fistulas in the female genitourinary tract, he settled in New Orleans in 1859.

During the civil war Dr. Bozeman served in the medical corps of the Confederate Army, and at the close of the war, in 1866, established himself in practice in New York City. He continued for many years in active gynecological practice, adding to his reputation as a successful operator and an ingenious deviser of new methods and new instruments, among the latter being a self-retaining vaginal speculum. He also invented an operating-chair for use when the knee-chest position was called for. Dr. Bozeman was a member of a number of medical societies, local and national, and for many years took an active and important part in scientific discussions.

## AMERICAN HOSPITAL ECONOMICS.

To the Editor of the Medical Record:

Sir:—One of the phases of the discussion upon Hospital Economics opened by Dr. Arpad G. Gerster in your columns on December 2, 1905, and continued by Dr. A. L. Benedict in your issue of December 16, 1905, concerns the desirability of centralizing hospital service by the appointment of a small visiting staff who shall undertake continuous duty. As a corollary to this proposition, it is maintained by the former writer that a more economical hospital administration would result. It is pointed out that in continental Europe, where this system obtains, a single medical officer often controls 250 beds, that he is in daily attendance throughout the year (with a reasonable holiday), and that he is required to devote much time to at least the economic side of general hospital administration. Were such a system to be instituted in those hospitals of the Boroughs of Manhattan and the Bronx which maintain a general medical service, that entire service, representing all the medical cases among the sick poor of a population of 2,000,000 would rest in the charge of a medical "trust" of only twenty-eight physicians. (For argument, the *medical* service only is herein considered.) The question, however, is a very much broader one than whether or not any particular hospital or group of hospitals is to be enabled to save a few thousand dollars per annum. Every large hospital is necessarily a great educational factor with influence reaching far beyond its own doors. The nurses, the internes, assistants, medical students, and the visitants themselves are all being trained, gathering experience which is to be for the ultimate benefit of the entire community. It is of far more importance that this training and experience should be liberal and should be shared in by as many practitioners and students as possible without confusion or detriment to the service, than it is that John Doe should have his leg bandaged with cheaper gauze, or take his medicine from a cheaper spoon. That due economy should be exercised in all departments of a hospital supported either by trust funds, contributions, or taxation, requires no argument, but such economy belongs in every instance to the superintendent's office, be he trained layman or medical expert, and while the medical staff should willingly cooperate with him, the suggestions for such economy and its accomplishment are his responsibility exclusively and should not be shirked. The physician who by virtue of his experience and scientific attainment is honored with the charge of a large hospital service, ought never to be expected, much less required to fritter away his time in determining whether it is cheaper to use resterilized bandages than buy new, or whether green medicine bottles are cheaper than white—the more so, were he responsible for 250 sick!

For the internes, students, and nurses it is a distinct privilege to have an occasional change of visitant, who introduces new methods or teaches them new theories. For the chronic case it is often an advantage to have another visitant examine it with fresh interest, and for the acute medical case, it matters little which of several visitants happen to treat it, all being presumably competent. (In one of the largest of the metropolitan hospitals the average stay of all medical patients in the wards is only eleven days.) For the visitant a rotation of service is an advantage, for may he not learn from his colleagues, and is he not less apt to fall into perfunctory methods of routine? I would go further, and say that for the hospital it may even be an advantage, in rotation of service to secure occasionally a visitant who has had experience part of the year in some kindred institution. I have personal knowledge of many important reforms which have been thus extended from one hospital to another.

This whole question is usually argued exclusively from the surgical standpoint. The surgeon requires much more time to train his staff and nurses in his own methods of antisepsis and operation. Moreover, having operated, he should be accorded time to follow his cases to their conclusion, and his successor in a too frequent rotation of service might find disadvantages such as in no wise affect his medical confrère. This difficulty has been met in certain American hospitals by allowing a "continuous" surgical service, but by having several such services conducted in parallel lines. If genuine reform in hospital economics is to be secured, it should be accomplished through cooperation of trustees and superintendents in comparing the experience with their own institutions with others as would be done in the hotel trade or any large business, and by adopting a uniform and intelligible system of accounts, not by lessening the number of their medical advisers or increasing the responsibilities already put upon them.

W. Gilman Thompson, M.D.

New York.

## THE TREATMENT OF PUERPERAL FEVER.

To the Editor of the Medical Record:

Sir:—Referring to your editorial on the discovery by Oliver Wendell Holmes of the true nature of puerperal fever, can you not do proportionate justice to the physician who first published the right treatment of this disease? In the *Chicago Medical Journal* for September, 1873, I published a paper entitled, "Puerperal Fever; Treatment by Intrauterine Disinfection." Reference was made to this twenty years later by Dr. J. M. Baldy (in the *Philadelphia Polyclinic*, May 25, 1895, p. 217) who, referring to puerperal septicemia, wrote: "At this time a free use of the intrauterine irrigator, as first suggested by Dr. O'Brien, of Scranton, will flush out these infected products and end the trouble." The title of my paper expressed the principle involved—*Intrauterine* disinfection, which sharply differentiated it from vaginal injections which are as old, I suppose, as Hippocrates. In the body of the brief paper I said, "The axiom I would give is to neutralize the septic matter by *intrauterine* injections of carbolic acid," meaning carbolic solution, of course. I reported a case in which I used a solution of 15 grains to the ounce, and said, "I believe the proposition is self-evident that if we think there is septic matter in the womb we ought to reach it directly with disinfectants." I mentioned the long, curved tube necessary, and referring to the fear of uterine colic, said. "This objection does not apply to the postpartum uterus, as it has been dilated and is tolerant of fluids and used to expelling them." I also referred to vaginal injections as a curious anomaly when the trouble was in the womb. Whether any one ever made the same clear suggestion before, I can only affirm now, as I did in the paper itself, that it has not come within my limited research. In the spirited controversy at the New York Academy of Medicine in 1883 between Gaillard Thomas and Fordyce Barker, the latter intimated that he had published something of the kind in 1874 (the year after my paper), but the stenographic reports of his clinical lectures at Bellevue in 1873 (Medical Record, pp. 305 and 329) show that in practice he went no farther than vaginal injections. Those reports told a tale of high temperature, aconite, veratrum viride, and quinine, turpentine stupes, and vaginal injections; then death and post-mortem examinations followed by eloquent theories of fever in which "Nosocomial Malaria" (whatever that was) figured largely. And this was a fair index of the treatment of puerperal fever at that time. Thomas, in a correspondence with me in 1883, intimated that intrauterine injections for puerperal fever may have been used before my time, but all the leads pointing to a time before my paper that I was able to follow up led to *vaginal* injections or—nowhere.

It would be scarcely believable now what dread physicians in the early seventies had of intrauterine injections; what the gynecologists knew about them had been derived from unpleasant experiences with the non-impregnated uterus, and I had the greatest difficulty in inducing my brother physicians to use them for puerperal fever. In the next five years after my paper, articles on puerperal fever multiplied in the journals and occasionally casual mention would occur of intrauterine injections, as in a paper by Dr. Rodman of Kentucky (Medical Record, Jan. 8, 1876, p. 18); but it was not until Thomas read his paper (Medical Record, Dec. 15, 1883, p. 646), that the profession awoke to the vast import of intrauterine disinfection. You may wonder why I did not make some claim for recognition at that time, and here is where you may connect me up with Holmes and Semmelweis, if not in honors at least in modesty. The New York Academy of Medicine held an adjourned meeting to discuss further the important topic, and finding that my paper had not been mentioned, I wrote Thomas for an invitation to attend the second meeting to mention my paper. He replied that "Physicians might attend but only members were permitted to speak." I did not call this little bluff, though Dr. Shrady kindly offered me the use of your columns, but having opened wonder's wide and startled eyes on the arena of medical controversy I, like Holmes, recoiled from the conflict and devoted any poetic genius I had to the peaceful field of treating "measles, mullygrubs, and mumps."

If you find that old Galen or Hippocretes published the modern treatment of puerperal fever I will cheerfully join you in honoring him, but if it chance that any bouquets are coming my way you may kindly hand me a spray of edelweis or forget-me-not now, so I may thank you, instead of scattering Carnegie medals on my tomb fifty years hence when I may not be in a position to respond.

One thing is sure—this treatment has, equally with prevention saved thousands of lives from a scourge that formerly slaughtered more mothers than did war and famine.

J. Emmet O'Brien, M.D.

Scranton, Pa.

## THE ETIOLOGY OF TABES.

To the Editor of the Medical Record:

Sir:—In your issue of November 4, page 748, Dr. Joseph Collins raised various objections to my presentation of the etiology of tabes, to which I would briefly reply. Dr. Collins speaks of experience, and quotes for Fournier 1,000 cases of syphilis, and for Erb the widest possible; for himself he quotes no experience in syphilis, but in some four hundred cases of tabes. If I would employ a competent man, by paying a premium for each tabetic found, I feel sure he would fail to find many more than four hundred tabetics with actual symptoms within the boundaries of Greater New York. The average duration of tabes may be estimated at about twelve years. How many tabetics could have existed during the last twelve years? Has Dr. Collins a monopoly on tabetics? It is so easy to quote large numbers, to prove them would lead to great difficulties. I, therefore, attach no importance to the four hundred cases of tabes or to any other number. Moreover, Dr. Collins's tabetic material is practically all public. What interest has a teacher of neurology in tabetics which he exhibits or sees in public service? What else can he do but expound accepted views? For this reason, Dr. Collins cannot otherwise but lean on recognized authorities with large numbers. As a matter of fact, however, very few tabetics, studied from the beginning to the end of the disease, with an occasional postmortem examination of the nervous system, are necessary to teach any earnest and independent worker what a routine inspection of large numbers will fail to perceive. Large numbers, even if actual, are, therefore, detrimental for progress. I have treated only twenty-seven tabetics and sixty-four luetics, but my first five cases of tabes were sufficient to compel me to reject the syphilis theory. I have seen many more tabetics and luetics, and could well my numbers, but it is not for me to do so. That much for experience. Dr. George Franklin Shiels, in your issue of November 25, page 869, expresses a similar opinion concerning large numbers and the relation of tabes to syphilis. I, myself, intended to say something about the exhausted ingenuity of neurologists and their liability to become victims of autosuggestion, Dr. Shiels's expression gives me, therefore, due satisfaction. I have received a few letters from readers of the Medical Record, each one of which contains words of encouragement, and they all inform me that their writers held my opinions for years, but lacked courage to come forward. I am therefore, and after all, not "original," but simply the exponent or the accoucheur of time, which was pregnant with sentiments against the syphilis theory, which I delivered.

Dr. Collins has great difficulty in only one case out of ten to establish pretabetic syphilis, but this difficulty is not serious, for he overcomes it after all. He states that he has examined many syphilitic and tabetic cadavers. It is true we have still many syphilitics, but nobody dies today from syphilis. Where did Dr. Collins get his many syphilitic cadavers? We have, comparatively, but few tabetics; they all die, if not cut off by some other disease, from the tabetic lesions. Very few die in public institutions.

I have examined only two tabetic cadavers, one with a decided history of syphilis and one absolutely without it; and only one syphilitic cadaver of a young man who committed suicide, because his physician had enlarged on the consequences of syphilis. As these examinations gave me what information I needed, I made no efforts for more.

Dr. Collins says my presentation of the etiology of tabes is so full of fallacies that it would take too much space to consider them all, but he singles out: "Syphilis, everywhere, presents itself as a blood disease," and asks wherein the reaction or constitution of the blood of a syphilitic differs from that of a nonsyphilitic, and what book on hematology describes the syphilitic blood. Dr. Collins should know that the condition which we recognize as syphilis is caused by the entrance of a virus in the blood, be it the *Spirochæta pallida* or anything else; and that, as the virus has a great power of diffusion, the lymphatic glands fail to arrest it completely, and it enters the circulation by many other channels, and starts a pathochemical process, which reduces both hemoglobin and red blood-cells, causing true primary anemia. The system immediately begins to resist the invasion by elimination of the poison, giving rise to cutaneous and mucous-membrane eruptions. If the system is not strong enough, or not assisted by art, elimination fails, syphilitic production and later degeneration follow, and the blood-making organs are finally affected, leading, in some cases, even to pernicious anemia or leukemia. This superficial sketch is sufficient to remind those who know that syphilis is a blood disease. There are quite a number of men who have written about syphilis and Dr. Collins can easily obtain all the literature on it without my assistance. He states that nobody has made the syphilis virus "per se" responsible for tabes. I did not say "per se"; however, if syphilis is the cause of tabes, nothing else but the original virus can be responsible, even if it has undergone transformation.

The histories of patients are important instructors, which teach us. The constitution of "us" embraces all those who are mentally free and capable to observe and to perceive conditions as they are, in contradistinction to those who are not, and who pick laurels from spurious trees planted by others. That Dr. Collins denies excessive coition as a possible factor of tabes is consequent to the position he takes, but the manner in which he denies it is not. Concerning coition, this grows excessive not by frequency, but by the detrimental effect on the individual. That sexual impulses descend from the brain toward the sexual organs is self-evident. When a person sees an attractive sexual opposite, when some agreeable odor streams from the opposite, when the opposite possesses some attractive quality, or is surrounded by alluring circumstances, then sight, smell, hearing, and touch report to the brain, and erotic impulses descend toward the sexual organs. When the reproductive organs congest with generative products, the sexual center in the lumbar cord receives the report first, and reports then to the center of circulation, which forces extra blood into the generative organs. So far the process is mechanical. From the moment the extra blood enters the genitals, sensation ascends to the brain, reflex impulses descend now toward the sexual apparatus, and the individual grows conscious of sexual irritation.

My presentation of the etiology of tabes is not, as it seems natural for Dr. Collins to suppose, an outcome of a desire for originality, but a consequence of personal experience and of a sense of duty which prompts me to call the attention of the profession to the established error, to induce independent observation and study. The chemical basis of life was recognized by Aristotle about 350 years A. D. and was in vogue for many centuries. About 1800 years later Paracelsus revived the teachings of Aristotle but gradually they were superseded by other views. Now, however, a new impetus has grown out of advanced knowledge of the workings in the laboratory of nature, which carries new laurels to the memory of Aristotle and Paracelsus and resurrects the principles of their teaching to stand forever. I said life is nothing but the result of chemical action. I add now, that all diseases, without a single exception, as also death, are consequences of pathochemical action, and that bacteria, whatever their names, are equally consequences of pathochemical action.

Dr. Collins and others hold syphilis aggressively responsible for tabes, and I do not expect them to admit trauma or any other factor as a cause, but that is of no consequence for progress, for everybody who has real experience with even only one case of tabes can make some independent observations and studies. I drew attention to some infectious diseases, after which, in some cases, tabetic symptoms appear, and held out the possibility of a predisposition, which, under certain conditions might develop true tabes.

Miss Ida E. had no syphilis, and that she contracted it from a man who died of general paresis is a myth. Dr. Collins should be very careful in making such assertions, the more so as the patient denied syphilis to me, and as her mother and brother state that she never had any symptoms referring to it; nor did her body give the slightest evidence of it.

Fedor von Raitz, M.D.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

GENERAL MEDICAL COUNCIL—SECOND FITZPATRICK LECTURE—CALCAREOUS FLUID IN PLEURA—PERIODIC RESPIRATION—TETANY WITH DILATED SIGMOID FLEXURE—SUNDAY FUND—INDIAN BLUE BOOK—DR. STEWART'S DEATH IN NIGERIA—DEATH OF SIR J. BURDON-SANDERSON.

London, December 1, 1905.

The winter session of the General Medical Council was opened on Tuesday with another address by the president. Many hoped that Dr. MacAlister would abandon this useless function, but he has followed the practice of his predecessor. It seems absurd to consume a day's time of a number of distinguished gentlemen in talking over the program and giving a vote of thanks to their president—gentlemen whose time must be too valuable to sacrifice for the five guineas a day honorarium. An application by Japan has been made for steps to be taken for Japanese physicians to be registered so as to enable them to practise in the Straits Settlement and other parts of the British Empire. The committees have, of course, produced their reports for the Council's decisions on the questions submitted to them. That on the instruction in practical midwifery is one of the most important. It is obvious that there are difficulties in regard to this subject which do not appear in reference

to clinical medicine and surgery. The usual returns on the army service were received and the thanks of the Council voted to the director-general. Communications from colonial governments respecting drugs were referred to the Pharmacopeia Committee. The question of dental degrees referred to counsel has resulted in the opinion that these documents must explicitly state that the recipient is fit to practise dentistry in order to make them registerable as qualifications. Universities conferring degrees in dental science will, no doubt, notice this and word their diplomas accordingly. A resolution was passed directing the registrar to accept for primary registration such degrees conferred after examination by the British universities. The new University of Sheffield has sent Dr. Cocking to represent it on the Council, but this is not to add to the expense, as the university has to remunerate him. This is not approved by many, but after all the new university has not yet a constituency of medical graduates and the Council's finances are in a very unsatisfactory state. On Wednesday the Council set itself seriously to its judicial duties. It is still sitting.

Dr. N. Moore devoted his second Fitzpatrick lecture to Dr. Edward Browne (1644-1708) and the Education of Physicians in London in the Seventeenth Century. Referring to his first lecture, which, as I reported, was on John Mirfield (1393), he summarized his attainments and studies and passed on to notice some of his successors down to Browne's time. First of these was Nicholas de Casa, a very learned man, who introduced a method of counting the pulse which, though felt and discussed long before, had not previously been counted. About the time of his death Thomas Linacre, the founder of the College of Physicians, was born. He and Clement, Wotton, Cains, Doyley, Gilbert, Harvey, Mayerne and Glisson were briefly noticed as representing the kind of knowledge with which the college began and to which it attained during its first century and a half. Edward Browne, son of the author of *Religio Medici*, was then more fully considered in relation to the education of his time and his opportunities. He was examined by the college when he had been studying for some ten years, and Dr. Moore naïvely remarked that there was then "no thorough examination except in this college." Some of us yet living could counter this by saying in their own younger days they had not met with what might fairly be termed "thorough."

At the Clinical Society Dr. Samuel West described a case sent to St. Bartholomew's Hospital as empyema in which, on exploratory puncture, a white fluid was removed which he compared to Devonshire cream as to appearance and consistency. It contained very little fat, no cells, but much lime phosphate. The patient remained pretty well for three weeks, and then died from an attack of bronchitis. His doctor had known that he had fluid in the chest for about twelve years. At the post mortem four pints of the fluid were found and in places the pleura was lined with a thick, mortarlike deposit one-half inch thick, and there were many calcareous plates, some adherent, but most of them detached. No sign of tubercle in any part of the body. The left lung was destroyed, leaving only some fibrous pigmented tissue around the bronchi.

Mr. Clutton said the material resembled that found in old tubercular abscesses, as psoas. In them it was often impossible to find certain evidence of tuberculosis, though that was undoubtedly the original process.

Dr. S. West also read a paper on periodic respiration. The first form—Cheyne-Stokes—consists in groups of respirations separated by long pauses, with gradual crescendo and diminuendo of the movements. The rate while it continued might reach 120. It may be met with in central nervous disease, cerebral or bulbar, when the patient is moribund, and is of no prognostic value. It is more frequent and characteristic in failure of the left ventricle and is then a fatal omen, even though there may be no other alarming symptoms.

The second form—grouped respirations—consists of two, three or four equally deep individual respirations of slow rate—eight to ten per minute. It is met with only in meningitis, especially posterior basic. If recovery takes place the symptom passes off and is of no importance for prognosis. Tracings were shown of the two forms.

Dr. A. Garrod referred to the physiological variety and said he had seen Cheyne-Stokes in a man of nearly ninety while sleeping. In heart disease the end might be delayed for months. Perhaps Dr. West had included uremic cases. Dr. French related a case of sarcoma of both ureters, no urine being passed for twelve days before death, in eight of which Cheyne-Stokes breaths was present and no other uremic symptoms. Dr. West replied that most cases in which Cheyne-Stokes breathing was present in kidney disease were due to cardiac failure, not to uremia.

Dr. Langmead reported a case of tetany associated with dilated sigmoid in a boy of six. There was abdominal distension and a hollow tumor over the left half. Five attacks had been noted, but the last was complicated with diphtheria, which proved fatal. At the post mortem the dilated viscus was seen to be the sigmoid flexure, which was very much enlarged. Two uric acid calculi were found in the right kidney. Only one case of tetany with sigmoid dilatation seems recorded. The dilatation is, no doubt, analagous to that of the stomach, and shows that this organ is not an essential factor in tetany. There seems no record of tetany associated with renal calculus, but three such were found in the post mortem record of the Children's Hospital in ten cases of fatal tetany, though calculi were found in only 0.57 per cent. of general autopsies at the hospital. Mr. Clutton said the case furnished another argument for operation in dilated sigmoid.

The Council of the Hospital Sunday Fund has agreed to include district nursing institutions within the scope of the fund to an extent not exceeding 5 per cent. The Council has further approved the committee's report as to hospitals having schools attached, and resolved to make n ogrant to those hospitals which fail to comply with the instructions founded on Sir Edward Fry's committee.

The Blue Book on Indian Sanitary Measures (1903-4) was issued yesterday. It contains chapters on the health of European and native troops, prisoners in jails, etc. On the health of the population there is much information, as well as on sanitary works and medical institutions.

Yesterday the friends of Dr. J. F. Stewart, of the Government staff in southern Nigeria, were officially informed of that officer's murder by natives. He had gone out on his bicycle and is supposed to have lost his way and to have been attacked by natives.

Sir J. S. Burdon-Sanderson, Bart., died on the 24th ult., at Oxford, in his seventy-seventh year. His death was not unexpected, for he had been in ill health for some time. He had received numerous honors and appointments for his services to science and medicine. He was M.A., M.D., D.Sc., of Trinity College, Dublin; LL.D., Edinburgh; D.C.L., Durham; F.R.S., London and Edinburgh. His latest office was Regius Professor of Medicine at Oxford University, which he received in 1805. He was educated at Edinburgh, became M.O.H. for Paddington and physician to the Middlesex and Krompton Hospitals. From 1874 to 1882 he was Jodrell Professor of Physiology in University College and in the last-named year went to Oxford as Wayneflete Professor of the same subject. Previously he had been superintendent of the Brown Institution (1871-8). Earlier still he had been employed by the Royal Commissioners to investigate the cattle plague of 1865-6, the epidemic in Germany of cerebrospinal meningitis, the health of workers in Cornish mines, etc. He was next a member of the Royal Commissions on Hospitals for infectious diseases, on tuberculous milk and meat, and on the London University. He was president of the British Association (1893). At the College of Physicians he was three times Croonian lecturer and received the Baly Medal in 1880. His reports to the Privy Council on public health and his contributions on physiology and pathology to the Royal and other societies are well known. In recognition of his scientific work he was created a baronet in 1899.

## OUR VIENNA LETTER.

(From Our Special Correspondent.)

THE ETIOLOGICAL TREATMENT OF SYPHILIS—THE UMBILICAL CORD IN INFANTS—THE BIOLOGY OF RADIATIONS—A CASE OF GALLSTONE PERFORATION.

VIENNA, November 20, 1905.

DR. RUDOLPH KRAUS has made interesting studies in the official Institute for Serotherapy in Vienna, on immunity and the etiological treatment of syphilis. Observations on monkeys have served to confirm the conclusions of Metchnikof and Roux that syphilis is transmissible to animals. A noteworthy observation is the fact that the initial lesion is transmissible, no matter whether it is pustular or in the form of a chancre, and each type preserves its own form on inoculation. The initial lesion produces, as many observations have shown, a cutaneous immunity, but specific precipitins are not formed. The foundation for the attempts at etiological treatment, and the allied studies relative to immunity in syphilis, is based on Pasteur's protective inoculation against hydrophobia. It appeared not unlikely that by means of active immunization with syphilitic virus the secondary manifestations, that is, the general infection, might be prevented just as the development of rabies is avoided in animals infected with that disease. By immunization with the virus of hydrophobia immune bodies are formed in the already infected organism, and in consideration of the long period of incubation existing between the appearance of the syphilitic chancre and the secondary lesions it seems possible to produce immunity in a similar way by the subcutaneous administration of syphilitic virus. The patients that were treated in this way all exhibited

what clinically were undoubted primary lesions. With the patients' consent they were treated for fourteen days with subcutaneous injections of an emulsion of excised triturated human chancres. Of thirteen patients treated in this way during the intermediary stage of syphilis eight developed the disease in the customary manner, five of them showing the usual lesions of secondary syphilis six to eight weeks after infection, while in three cases the secondary symptoms did not appear until three and a half months after the infection. In five cases, in spite of observation continued through several months, no evidence of a general infection could be discovered. Although no definite conclusions may be drawn from these results, they are, according to the views of prominent clinicians, of great interest, as the various measures that have so far been experimented with in this stage of syphilis, such as prophylactic mercurial treatment or excision of the chancre, have not prevented the appearance of the secondary lesions. Observations on monkeys intended, by means of active immunization, to prevent subsequent cutaneous infection were negative, the monkeys developing typical primary lesions. Similar results have been reported by Metchnikof, Roux, Neisser, and Baermann. These experiments lead to the conclusion that active subcutaneous immunization is not available to protect against subsequent cutaneous infection, but it is possible that by this means the general infection might be prevented. It is also certain that a cutaneous immunity is produced by cutaneous infection, for both in monkeys and in man one chancre prevents further cutaneous infection. Further experiments along these lines are in progress, and should they lead to successful results they would open the way not only to an etiological therapy, but also to an etiological prophylaxis. By subcutaneous active immunization a post-infectional protective inoculation could be carried out similar to that against hydrophobia, and by a cutaneous inoculation with an attenuated virus a preventative procedure similar to that with vaccine virus could be obtained.

In the City Gynecological Clinic of Budapest numerous observations have been made to determine the value of the pressure forceps of Bar in treating the umbilical cord in the newborn. This instrument consists of a clamp one and a half centimeters wide and half a centimeter thick made of spring steel and so constructed as to exert sufficient pressure on the umbilical cord to express the contents of the blood-vessels and Wharton's jelly, and to convert the stump into a parchmentlike membrane. The amniotic covering of the cord is not torn, however. The instrument can easily be pushed down to the root of the cord, and, of course, can be perfectly sterilized. Twenty-four hours later it is removed, but the stump is not resected. The clamp is applied as soon as the pulsation of the umbilical vessels has ceased; the infant is then bathed and the stump is surrounded with sterile gauze, and, together with the instrument, is covered over with a suitable dressing. After removing the clamp the stump is redressed in a similar way. This dressing is not changed until the fourth day, after which the gauze is changed daily until the stump drops off. In over three-quarters of the cases mummification of the stump followed, and in one-fifth of the cases it was cast off as early as the fourth day, usually without any reaction. In sixteen and three-tenths per cent. of the cases complete mummification of the stump did not follow, but although four hundred infants were treated with the clamp, no undesirable complications were observed in any instance.

Dr. Schlachta has studied the biology of radiations. He subjected hens' eggs to the action of radium and found that changes were produced in the shell, and also that the yolk acquired a pronounced odor and taste of trimethylamin, showing a decomposition of the lecithin. He then exposed lecithin to the rays and found that it was decomposed. Lecithin treated in this way was then injected under the skin of rabbits and it was found that necroses similar to those produced by the radium rays were caused. No very marked changes were produced in the lecithin by the radiations, but the ulcerative processes following injection were very severe. Czerlin assumed that the lecithin itself was not decomposed, but rather that it was rendered less stable. Exner injected cholin, which is a decomposition product of lecithin, and obtained results similar to those following protracted radium exposures. Schlachta began his work with the idea that the radium radiations were simply a form of oxidation, because they ozonize oxygen. Electrical discharges accompanied by the formation of ozone give rise to manifestations similar to those of radium rays, such as falling out of the hair and vascular degeneration. Ultraviolet light has a certain period of latency like radium, and also ozonizes oxygen. Schlachta injected into guinea pigs lecithin, together with peroxide of hydrogen, and also lecithin and eosin, and obtained a falling out of the hair in both instances. The question then arose whether oxygen must be present for the action of radium and Roentgen rays to be unfolded. If lecithin is exposed to the radium rays in a vacuum it remains unchanged and does not give rise to any reaction when injected into animals. Schlachta therefore concludes that the radiations are linked to the presence of oxygen in the tissues. It appears that numerous substances possess the power of radiation. Very small amounts of alkalies and acids, that is, fractions of a milligram, when injected subcutaneously, after twenty-four hours cause yellow discoloration of the skin, followed by falling out of the hair in seven days, and, in some cases, by excoriations, ulcers, or cutaneous necroses.

Dr. Eugen Polya operated on a case of diffuse peritonitis following gallstone perforation. The patient, who was a woman fifty years old, presented a pronounced picture of diffuse peritonitis. As the greatest tenderness was in the region of the cecum an inflammatory process of this region was suspected, but there was also slight jaundice with distinct resistance in the neighborhood of the right costal arch, so that perforation from a gallstone could not be excluded. The first incision was made in the right iliac region and at once a large quantity of mucopurulent bile escaped. Immediately a second incision was made and a perforation was discovered in the gall-bladder, which also contained two gallstones the size of hazelnuts. The patient made a good recovery and left the hospital in perfect health, except for a small sinus in the upper scar.

## Progress of Medical Science.

*Boston Medical and Surgical Journal, December* 14, 1905.

**A New (?) Anatomical Structure.**—Under this title G. D. Hough refers to a fold of peritoneum in right iliac fossa which is a guide to the apex of the cecum and to the base of the appendix: It begins at a rather indefinite place not far from the anterior superior iliac spine and runs transversely, right straight across the iliac fossa, to the cecum to which it is attached just at the base of the appendix. It is half an inch to an inch high and slants upward toward the liver like a fence blown half over by a heavy wind. It is on account of this slant, in all probability, that it is not a well-known landmark. The reason is obvious. Most surgeons, after opening the abdomen, use the index finger of the right hand for exploration and with this finger the fold cannot be easily felt unless (which seems to be rather unnatural) one begins above and passes the finger downward along the iliac fossa. If, however, one uses the left index finger for exploration and, with the palm of the hand turned toward the feet of the patient, sweeps along the floor of the iliac fossa, the first thing one strikes is this peritoneal fold. If it is followed up it leads at once to the apex of the cecum and base of the appendix; the finger naturally hooks under the longitudinal band, and the cecum can be pulled out. Hence under ordinary circumstances the incision need be only large enough to admit one finger.

**The Physician's Duty Toward Tuberculosis.**—A. T. Cabot discusses the duties of the profession with reference to tuberculosis. The first duty is to greatly diminish the amount of tubercular poison throughout the county. Hence bacilli should be destroyed as rapidly as they are thrown out of the body. To do this we must enforce respiration in all communities, must disinfect all premises which have harbored a tuberculous patient, should give instruction in sanitation and sanitary care to patients who cannot be separated from their home, should provide sanatoria liberally, should isolate actively infectious and seemingly incurable cases. Children with contagious forms of tuberculosis should be excluded from the schools. In prisons and reformatories tuberculous patients should be kept apart. The author suggests the county societies in the country regions as the bodies most likely to superintend the carrying into effect of the above-named measures.

*New York Medical Journal, December* 16, 1905.

**Ventral Suspension.**—S. Chandler enumerates the causes which lead to uterine displacement calling for suspension or fixation. The operator must be sure of his diagnosis and ready to perform any additional operation which may be called for at the time. Of the many operative procedures the author prefers that of suspending the uterus by suturing the fundus to the abdominal peritoneum, repairing injuries, and removing diseased parts when necessary. His objection to the Alexander operation is that it is correct only in theory and not always available as the ligaments may not be sufficiently strong to obtain a continued correction and he considers it open to the objection that it does not give the operator the chance to diagnosticate or correct the original cause, or the present cause, as the case may be. He further commends the practice (because of the freedom of action and the giving the uterus an antiverted state) of placing the sutures a little posterior of the central meridian line of the fundus uteri.

**Malformations of the Uterus, with Report of a Case of Bicornate Uterus.**—A. A. Kerr refers to various cases of uterine abnormalities already on record, explaining their mode of formation from the standpoint of embryology. He then reports the case of a young woman of twenty-three, who complained of right pelvic pain and profuse leucorrhea. Examination showed local tenderness, rudimentary uterine cervix, and an abnormal mass in the region of the right tube. Laparotomy revealed a distinct bicornate uterus, the right cornu being slightly larger than the left. The ovaries and Fallopian tubes were both normal. The appendix being found diseased, was removed, and the uterus curetted. The patient made an uneventful recovery and left the hospital in two weeks. The vaginal discharge, however, soon recurred, and an opening was found communicating with what seemed to be the right rudimentary cervix uteri. The opening was enlarged to the right of the left cervical opening, considerable pus found and the cavity packed. The discharge ceased and the patient was up and around in one week.

**The Pathology of Paretic Dementia.**—H. A. Wright dissents from the generally accepted view that insanity is due to abnormalities in the cerebral cortex and does not understand why paretic dementia should be classed as an organic insanity in the sense just referred to. He summarizes the changes noted in the morbid anatomy of the condition, but claims that the workers in the laboratory have failed to make proper deductions from their anatomical findings. The cause of symptoms is then summarized and the author claims that there are no mental symptoms manifested by these patients which are not observed in others suffering from some type of inorganic insanity such as mania, melancholia, primarily dementia, or paranoia. If paretic dementia implies cortical changes why do we not find them in the inorganic insanities? Again, asks the author, if these lesions in the brain, which, in character and extent, are quite similar and identical with what are found in those patients who have suffered from what is described as multiple disseminated sclerosis, cause very manifest mental disturbance in one patient early in the progress of the malady, how may we account for the fact that in disseminated sclerosis, with lesions well advanced, involving similar areas of cortical substance, that mental symptoms or abnormal mental states seldom or never become manifest during the progress of the case? The general contention of the author is that in paretic dementia the patient is suffering from two distinct maladies, one of the nervous system and the other of the mind, each dependent on different causes. The several lesions of the central nervous system in so called paretic dementia may be due to alcoholism, syphilis, or what not, and are solely responsible for the paralysis of muscles in the different parts of the body which are observed. The mental disturbance is induced by circumstances, such as are responsible for what has been designated as mania, melancholia, etc. He could therefore entirely discard the term paretic dementia, and substitute therefor, because much more appropriate and correct in its significance, though somewhat cumbersome, the term "concurrent multiple sclerosis and dementia."

*Medical News, December 16, 1905.*

**A New Procedure in Intestinal Anastomosis.**—The plan advised by B. L. Wright is as follows: The first step is to introduce three temporary or stay sutures, dividing the circumference of the bowel into three parts. The first suture is introduced at the mesenteric attachment, the other two at equidistant points from the first. They should be left long and their free ends secured. The second step is begun by the assistants now taking the first suture in one hand and the second in the other. By firmly drawing these in oppositite directions it will be found that the free edges of the gut naturally invert themselves and come into close approximation, forming a ridge, raised above the general surface of the bowel, through which the permanent suture can readily be passed. The third step is the passage of the needle bearing the suture through the ridge. Each third of the ridgelike elevation is sutured separately, so that when the operation is complete the entire circumference of the bowel has been sutured. The temporary or stay sutures can now be removed or can be tied and cut to give additional security.

**The Dissemination of Tuberculosis by Railway Travel.**—C. B. Dudley discusses this question from the standpoint of the chemist of one of our largest and best-managed railroad systems. His experiments lead him to believe that the dangers from infection due to railroad travel have been very greatly exaggerated. There is very little evidence that the time spent in the car is of any value as a factor in the acquisition of this malady. To acquire the disease prolonged exposure is necessary. Tuberculosis sputum is extremely difficult to dry and pulverize so that it is breathed in again. Dried sputum is more or less tenacious and gluelike. Consequently its reduction into a really fine powder which remains suspended in the air for some time is a difficult matter to bring about. Still further, sputum which has been artificially dried, then beaten and rubbed up into a dust from carpets on which it had fallen, readily falls to the ground. The viscous material in which the bacilli are imbedded is relatively heavy, even when dried, and in a fine state of division. Finally, one must not ignore the effect of light and air upon the vitality of this special germ. The structure of a railroad coach, long and narrow, and made up largely of windows, offers the best possible opportunity for the entrance of light and air. Statistics show that railroad employees suffer considerably less from tuberculosis than does the average of the community. From all these facts the author concludes that the influence of railway travel on the dissemination of the disease has been greatly overestimated. His experiments have led him to believe that the danger of infection from upholstery in cars and coaches is very much less than from naked surfaces, and that the crusade against hangings, carpets, and plush is not founded on careful experimental data.

**Centrifugal Urinary Analysis.**—This method is discussed in full by A. L. Benedict who presents the following conclusions: (1) Considerable centrifugal force should be employed to insure even and dense packing of precipitates, at least 2000 revolutions per minute are necessary. (2) The process should be continued until constant minimum is reached. (3) The inaccuracies of the centrifugal method depend to a considerable degree upon inaccurate graduation of tubes. (4) Fairly accurate estimates of chlorides may be made by counting each percentage in bulk precipitate as 0.02 per cent. of NaCl. (5) Fairly accurate sulphates may be made by counting earth percentage of bulk precipitate as 0.02 per cent. of $SO_3$. (6) Fairly accurate phosphates may be made by counting each percentage of bulk precipitate as equivalent to 0.02 of $P_2O_5$. If the precipitate reaches 10 per cent. or over, the reading should be controlled with a dilluted specimen. (7) The uric acid determination by centrifuge is much less liable to experimental blunders than the Hopkins and allied chemical methods but is either subject to fallacies of unknown cause, or it includes with uric acid other substances, probably basic purins. (8) All centrifugal tests are liable to vary widely from the corresponding chemical tests in individual cases.

**The Detection of Functional Disturbances of Digestion by the Examination of the Feces.**—J. D. Steele calls attention to our lack of knowledge in regard to intestinal as contrasted with gastric disturbances. He has found the examination of the feces to be most useful not in diagnosis but rather in following the digestion and absorption of the various foods and in determining the proper diet for patients suffering from gastrointestinal disease. It may be impossible to say just which digestive fluid is at fault but it is easy to say just which food stuff is not being properly handled and to restrict its ingestion. A "test-diet" is employed and may be expressed in equivalents as follows: 2¾ pints milk, 3 ounces well-dried toast, 2 eggs, 1½ ounces butter, ¼ pound tender rare steak, 6 ounces mashed boiled white potato and gruel made from 2½ ounces of ordinary oatmeal, ½ ounce sugar. This may be given somewhat as follows: Breakfast—2 eggs, 1-3 of the amount of toast and butter, 2 glasses milk, oatmeal and sugar. Dinner.—The steak and potatoes, 1-3 of the amount of toast and butter, 1½ glasses milk. Supper.—2 glasses milk. Remainder of toast and butter.—The method of examining the feces are described in full and must be read in the original paper. Not more than ten minutes are required, when the apparatus is once ready, for an ordinary examination. A plea is made for a more general employment of this method.

*American Medicine, December 16, 1905.*

**Cause, Course, Prevention, and Treatment of Beriberi.**—Hamilton Wright classifies beriberi into (1) acute pernicious beriberi; (2) acute beriberi; (3) subacute beriberi; and (4) beriberi residual paralysis, or the disease as it appears after the specific organism and its toxin have been eliminated and the engendered paralyses have failed to clear up. Acute pernicious beriberi is rapidly fatal as the result of the severe impact of the beriberic virus on the cardiac nervous system. Acute beriberi in its clinical aspect differs from the acute pernicious form only in degree. The gastroduodenal syndrome which ushers in the disease is as marked, and the consequential paralyses, sensory disturbances, and edema may be severe and widely distributed, but the terminations of the cardiac nervous system are never so deeply implicated. Death from cardiac failure is, therefore, a rare event in the early acute stage of the disease. The chief measure in the treatment of acute beriberi is rest in bed. The physician must insist on rest in bed until the pains in the calves subside and the heart sounds approach the normal. Calomel should be exhibited in small doses at short intervals. In the case of parturition or

wound beriberi, carbolic, or other antiseptic lotions, are called for. In the event of threatened cardiac failure, strophanthus is the best drug; for, undoubtedly, a factor in the circulatory disturbance of acute beriberi is a low peripheral pressure due to a poisoning of the nervi vasorum. Strychnine should not be used in the acute stage of the disease. The best results are obtained from absolute rest in bed and restriction of fluids. Rest in bed and the simple diuretics are also the best remedies for the edema. In the stage of residual paralysis, remedies which have proved effective in other forms of chronic neuronal degeneration are called for, such as gentle exercise, massage, electricity, and small doses of strychnine for arsenic. The cardiac condition should be closely watched.

**The Short Narcosis, the Short Incision, and the Short Stay in Bed After Ideal Operations.**—Bayard Holmes a strong advocate of short narcosis, short incision, and short stay in bed after ideal operations. He believes too much time is often spent by the patient on his back after operation, and too little by the surgeon at the bedside and in the laboratory before the operation. In order to make the stay of the patient short after surgical intervention, he should be studied in the hospital for days or even weeks before operation is undertaken. Dr. Holmes has found that patients can readily be kept anesthetized the necessary twenty minutes or half hour by the employment of gas, with only occasional resort to ether. In a few instances, on account of obesity, chloroform has been used to continue the anesthesia. The short incision is one of the dictates of good surgical judgment, as it inflicts the minimum amount of traumatism and gives adequate access to the field of operation. With the small incision, the complications which the protrusion of abdominal viscera add to the operation are unknown. Operators who have been accustomed to use incisions 4 inches to 6 inches long are surprised to find that they are able to accomplish the same results more rapidly, with less traumatism, and with fewer postoperative discomforts to the patient with an incision 2 inches long or 1½ inches long. The duration of the operation is curtailed, the intoxication and the discomforts of the anesthetic are lessened, the danger of hernia is minimized, the necessity of a long stay in bed is obviated, the chances of infection through the introduction of many stitches diminished.

**What Is a Poison?**—R. G. Eccles elucidates that (1) no substances are poisons *per se;* (2) that the idea that minute amounts of poisons are injurious is an error; (3) that different organisms respond differently to different poisons; and (4) that the quality of poisonousness is, for each particular organism, a function of dose. To know whether it is proper to consider any substance as a poison, it is necessary to know the animal or plant to which it is to be administered and the dose in which it is to be given. Under sufficient dilution, so that a large dose cannot be administered, neither strychnine, arsenic, nor other toxic body, can reasonably be considered poisons. Prussic acid, as present in fruit, is as harmless as water, and all so-called poisons, under sufficient dilutions, become absolutely innocuous. It has been experimentally shown that toxic substances, at certain definite dilutions, are not merely innocuous, but that they are positively beneficial. As protoplasm is indifferent to slight warmth, stimulated into greater health and vigor by increased warmth, but killed by excessive heat, so also it behaves to poisons in a somewhat similar matter.

*Journal of the American Medical Association, December 16, 1905.*

**The Tabetic Foot.**—S. I. Schwab and N. Allison have studied the tabetic gait and the factors in its causation, apart from the disturbances of the sensory nervous system, using as material for the study fifteen cases of tabes observed during a period of two years. Their conclusions, in substance, are as follows: The observations show clearly that the foot of a tabetic showing any degree of ataxia is a pronated foot. This pronation leads to muscular strain on the ankle, knee, hip, and spine. This, together with the hypotonia, tends to break down the long arch, thus producing a faulty mechanical instrument for walking. This pronated foot plays an important and hitherto unrecognized rôle in the production of the ataxic gait, and correction of this faulty mechanism tends to increase the power of the tabetic to walk normally. In conjunction with the Fraenkel exercise treatment, the correction of this faulty mechanism of the foot offers the most favorable treatment for the ataxic gait of tabes. The orthopedic appliance, a specially adapted shoe for this purpose, is described.

**Superior Accessory Thyroids.**—These structures are described by J. B. Murphy. It is probable that they often supplement or take on the function of the normal thyroid. They are found usually within a space, roughly represented by an inverted trapezoid, the larger base of which is a line running between the apices of the mastoid processes, the smaller base a line tangential to the arch of the aorta, and the sides represented by the sternomastoid muscles. They have been found outside of this area, in the pleura, bones, abdominal cavity, and elsewhere, but such tumors must be considered as metastatic. They may occur at any age, and are most common in females. In most cases there is no ostensible exciting cause, but in a few cases acute infection may be considered as such, and in several cases puberty was closely related to the development of these tumors. They are generally found at the base of the tongue, and vary in size from that of a cherry to that of an egg, or are even larger. The tumor is well encapsulated, not surrounded by an inflammatory area, and is bluish red in color, owing to the abundance of vessels. The consistency is soft, and it is sometimes difficult to decide whether one has to deal with a soft tumor or a cyst. The usually accepted theory of their origin is that they are remnants of the thyroglossal tract. While they may accompany normal thyroids, they have been found in several instances to be the only thyroid existing. Two personally observed cases are reported. The difficulties of diagnosis are noticed, and the lack of constitutional symptoms and often at first of any symptoms whatever. Generally, however, when the true nature of a tumor of the neck is not well established, an accessory thyroid should be thought of, and if a tumor is found at the base of the tongue, or between it and the hyoid in or near the middle line, if there is no adjacent inflammatory reaction, if there are no marked subjective symptoms, if it undergoes periodic changes in size and tension, if the patient be a woman, and especially if she complains of some disturbance of menstruation, the condition is highly suggestive. In the differential diagnosis, besides the specific differences between accessory thyroids and other growths, particular attention is called to the clinical course, the duration of the growth, and the presence or absence of the normal thyroid. Treatment is both medical and surgical, but the administration of drugs is usually unsatisfactory. Iodide of potassium may reduce the size of the tumor slightly, and Murphy suggests the use of thyroid tablets or the milk of tyhroidectomized goats. The presence of a normal thyroid is to be assured before surgical treatment is attempted. Extirpation is the only effective treatment, and the method of election is by the subhyoidal or submental route. The prognosis is good if the normal thyroid is present; the most unpleasant possibility is myxedema, which occurred in five of the cases tabulated. Recurrence of the tumor has been observed in six of the patients operated on.

**Albumosuria in Phthisis.**—J. F. McConnell says that in making a series of urinalyses for the purpose of computing the prognostic value of Ehrlich's reaction in the tuberculous, his attention was directed to the large proportion of the specimens giving a precipitate with the characteristics of an albumose. Finding little in the literature concerning the significance of this substance in the urine in tuberculosis, he has further studied the matter, and offers as a result a clinical deduction which he considers to be of importance as putting the empiric therapeutic theory of rest in this disease on a rational basis. He found that febrile cases giving a positive albumose reaction in the urine were not improved by exercise, but rather lost ground, while those giving no albumose reaction were injured by the rest treatment and decidedly benefited by regulated exercise. Details are given of the test employed for the detection of albumose in the urine, and illustrative cases are reported.

*The Lancet, December 2, 1905.*

**The Treatment of Tuberculosis by Tuberculin.**—The paper of W. Bueloch comprises a general consideration of this remedy with summarized reports of eleven cases. All of these were severe and had passed from the hands of physicians and surgeons and were regarded as incurable. They included lesions in various parts of the body. The case was markedly benefited, five apparently cured, one improved, in two no benefit whatever was observed, and two are still under treatment. The author thinks we have expected too much from the remedy. He notes that the most recent studies in immunity lead to the conclusion that the inclosure of the bacillus by a wall of poorly vascularized granulative tissue is a drawback as the antibacterial forces which we know to exist in the body humors are kept at bay, the parasite remaining locally, and being at long intervals discharged outward. In general the defense offered by the bacillus is so powerful that only a relatively small degree of immunity is developed by the host. This statement rests on a large body of evidence and it cannot be expected, even from a remedy like tuberculin, that a high degree of immunity can be attained in a short space of time or that the curative effects of the remedy are comparable to its prophylactic effects. The author does not deny that the remedy has remarkably curative powers. Recent ex-

periments show that protective substances of opsonic nature exist in normal serum and that the opsonic content of the serum can be increased by tuberculin injections. It is now manifest that the chief defensive mechanism against tubercle exists in the serum and not in the cells, as was believed, and the destruction of the bacilli by the cells must be preceded by the action of the serum.

**The Descendants of the Tuberculous and Hereditary Predisposition.**—G. Ogilvie notes that the question of a specific disposition to tuberculosis in the human species could be finally decided in a strictly scientific manner only by inoculating a large number of persons in the same way, with the same quantity and the same culture of the bacillus. This experiment certainly is not likely to be performed. But we have certain clinical facts which seem to prove conclusively an hereditary predisposition. Those cases of tuberculosis dying about the age of puberty usually show a small heart and a narrow aorta. Another interesting fact seems to prove or at least suggest a distinctly local predisposition, namely, that tuberculosis in the child almost invariably starts in the same lung which was first attacked in the parent. With regard to a general hereditary predisposition it has been said that a difference must be made between a specific disposition and a general constitutional weakness, and also between a truly hereditary disposition existing in both parent and offspring, and a congenital disposition not existing in one parent but produced in the infant by the parent's disease—*un phénomène para-tuberculeux*. These distinctions, which are certainly of much scientific interest, are, according to the author, of no great practical import.

**The Condition of Patients After the Removal of the Vermiform Appendix.**—L. Jones has investigated the after-history of 87 cases with reference to (1) pain, constipation, flatulence, etc., as referable to possible adhesions; (2) tenderness of the scar and (3) ventral hernia. The results are as follows: (1) In some of the cases in which there was definite suppuration around the appendix the viscus was removed during the patients' stay in the hospital, while in others the abscess cavity was merely drained, the appendix being left untouched. Considering these two classes apart, the first included 22 patients, and of these 12 could mention no defect in their present health, three suffered with slight occasional local pain, three had noticed some bulging of the scar, one was more constipated than formerly, and one was more flatulent. Two ascribed definite lesions to the operation: the first had become ruptured in both groins, an effect, he considered, of his abdominal scar; the second, whose scar had "reopened" after leaving the hospital, wrote pages describing various vague complaints and has probably developed a ventral hernia. Of these two the former has no proper ground of complaint. (2) The patients, upon whom operations had been performed during an acute attack but before obvious peritoneal infection had occurred, numbered 16, and in no case did any of these instance trouble sufficiently severe to incapacitate them in any way. Twelve were in perfect health; in one case the scar was slightly tender on pressure, in two others there was slight pain with some fullness in the scar, and in the fourth there was a definite hernia at the site of operation as large as a hen's egg. (3) Those patients operated upon during a subacute attack or in a quiescent period were 32 in number and furnished the following replies. Twenty expressed themselves as being better in every way and much benefited by the operation, nine could find some symptoms which they thought possibly due to the scar—for example, four had noticed slight occasional pain on exertion or on coughing, one suffered from constipation, one from "flatulent dyspepsia," another from tenderness in the scar, and three thought that the scar showed more prominently than before.

**An Unusual Cause of Sudden Death.**—B. Thornton reports the case of a vigorous man of twenty-eight, who ate a hearty breakfast, went to stool and was found dead in the closet a short time after. Autopsy revealed only slightly emphysematous lungs and a small amount of regurgitated food in the larynx and trachea, but not enough to prevent the entrance of air into the lungs. The author concludes that death resulted as follows: The man was straining to empty the bowels (which had not acted). There was a regurgitation of acrid, half-digested food into the larynx. This caused a spasm of the glottis. Being seated in a constrained position in a very small closet he was unable to recover his breath and the combination of these circumstances inhibited the action of the heart and caused it to stop.

*British Medical Journal, December 2, 1905.*

**A Report on Human and Bovine Tuberculosis.**—H. Kossel presents the following conclusions: By bacteriological investigation of tuberculous lesions in human beings, cattle and swine, two types of tubercle bacilli can be detected which may provisionally be called typus humanus and typus bovinus. The widely-spread tuberculosis of cattle is to be traced exclusively to infection with tubercle bacilli of the typus bovinus. Swine are susceptible in a high degree to the tubercle bacilli of the typus bovinus, in a lesser degree to those of the typus humanus. The tuberculosis of human beings chiefly arises from infection with tubercle bacilli of the typus humanus, which is transmissible from man to man. Tuberculous lesions in human beings can be produced by tubercle bacilli of the typus bovinus. Tubercle bacilli of the typus bovinus can be transmitted to human beings by food derived from tuberculous animals, especially by milk of cows affected with tuberculosis of the udder. The part played by infection from bovine sources in spreading tuberculosis in man is small in comparison to the danger threatening from a consumptive human being.

**Condition of the Skin in Pneumonia.**—Arthur H. Gregson has come to the conclusion that in lobar pneumonia the skin is dry, while in the lobular variety it is moist, at least in the folds of the axilla and groin. He believes that the drier the skin, the more likely is the temperature to end by crisis. He cites the history of two cases. One patient was a boy ten years old who after measles developed bronchopneumonia. His temperature rose to 104° F. The skin was hot and dry. The writer from this sign assured the family that the boy's illness would end suddenly, approximating the date. This proved to be the case, although the physical signs indicated bronchitis as well as pneumonia, and but for the state of the skin the latter would have been considered to be of the lobular type and would have been expected to end by lysis. Instead it ended by crisis. Another history is given. This patient's skin remained moist during the first days of illness. She slowly grew worse for ten weeks, during which time crepitations came and went in all parts of the lung. Death finally ensued.

**The Crystalline Lens in Health and in Cataract.**—William Job Collins declares that the prevalent teaching that the healthy lens becomes more solid as age advances, if this is to be held to mean that the older lens contains more solids in proportion and less water than the young, or that the lens becomes denser in the sense that its specific gravity is increased, is a doctrine not founded on fact and must be considered as fallacious. In so far as such an explanation is given as accounting for the progressive loss of accommodation during advancing years, culminating in presbyopia, such pathology must be discounted. The alleged enfeeblement of the ciliary muscle is no more equal to the task of explaining the progressive loss of accommodation. The writer continues, giving his own explanation of the remarkable correlation between the progressive growth of the lens through life, and the progressive loss of accommodative power from youth to age; as the lens grows into its capsule equatorially, every year witnesses some encroachment upon the intracapsular circumlental space, and as this potential cavity becomes occupied by the augmented lens in a passive state of refraction, less space and opportunity are given for that occasional active expansion which effects accommodation. The writer declares that the prevalent but erroneous teaching of the cornification and solidification of the crystalline lens as a natural senile change is responsible for the equally prevalent doctrine that the changes in the lens spoken of as senile cataract are merely exaggerated and intensified or accelerated senile changes. He believes that they are nothing of the kind. He has rarely found a cataract weighing as much as the ordinary healthy lens at forty years of age. In cataract also the percentage of solids in the lens is increased, whereas age alone gives no increase. He also finds in cataractous lenses certain chemical bodies in relative excess whose presence and amount favor the view that they have been occasioned by transformation of the albuminoid bodies contained in the normal lens—probably due to some failure of nutrition. Traumatic cataract from penetrating injury is due to swelling and solution of the lens substance under the influence of the aqueous humor. The writer then calls attention to the black cataract. As to the maturation of cataracts, those associated with myopia are apt to ripen slowly. Those beginning at the posterior pole or by striæ with anterior concavity stretching thence to the equator, are often slow in maturing. The writer does not think that methods of trituration of immature cataracts with the object of ripening them are very advisable. He believes that etiology is the best basis for classification and presents a scheme of classification accordingly.

*Berliner klinische Wochenschrift, November 27, 1905.*

**Simulation and Mental Disease.**—Siemerling says that the detection of pretended insanity has been greatly facilitated since it has come to be recognized that simulation and mental disease often occur together. On the other hand, it is unwise to go as far as do those authors who claim that pure simulation is never observed. The mere fact that a suspected individual confesses to simulation is not sufficient to permit the conclusion that the condition has actually been a pretended one, for the insane not infrequently make assertions to this effect. Individuals attempting to simulate insanity usually betray themselves through the exaggeration of their actions. It must be remembered, however, that in katatomia, the hysterical psychoses, and the excitable forms of imbecility, abrupt contrasts in demeanor and the grotesqueness of the clinical picture often convey an impression of artificiality. The forms of mental disease which have most often been simulated in the author's experience have been idiocy, mental depressive conditions of slight intensity, paranoia, and lapses of memory. If patient observation alone is not sufficient to unmask the deception, the author recommends hydriatic procedures and the application of the electric current.

**The Bacteriological Diagnosis of Weichselbaum's Meningococcus.**—Kalberlah, in discussing the difficulties attending the demonstration of the meningococcus in the cerebrospinal fluid obtained by lumbar puncture, concludes that in the first place it is necessary to allow the material to escape directly into tubes of Loeffler's blood serum. The tubes must be protected from cooling as much as possible while in transit to the incubator, secondly, the microscopical examination is to be made both on the fresh material and after twelve to fourteen hours' cultivation in the incubator.

**Sahli's Desmoid Reaction.**—Eichler first describes the method for testing gastric efficiency recently devised by Sahli. The fundamental principle involved which gives the reaction its name is the fact that raw connective tissue is digested only in the stomach and never in the intestine. Sahli gave his patients minute amounts of methylene blue or iodoform in little rubber bags tied with raw catgut. If, after swallowing such a bag, iodine or methylene blue could be detected in the urine within a period of 18 to 20 hours later, Sahli assumed that gastric digestion could not be deficient. Eichler first repeated Sahli's experiments in order to determine the correctness of the assumption that the catgut would be dissolved only in the stomach. He found that the presence of both pepsin and hydrochloric acid was necessary for disintegration of the material to take place. If the catgut was partially digested in this way and then subjected to the action of pancreatic juice, no further destruction occurred. The method was then practically tested on 30 patients exhibiting various forms of gastric disease, and the results in each case were in accord with those obtained on analysis of the stomach contents after an Ewald test breakfast. The author therefore concludes that the reaction, when positive, is a reliable indication of good gastric digestive power. In cases of hypermotility, however, the test may not be positive, even if normal amounts of gastric juice are secreted, because the pellet may be expelled from the stomach before time for digestion of the catgut has been allowed. If the reaction is negative, while the inference that the gastric powers are deficient will be a correct one, no definite information is given regarding the nature of the disease. Eichler therefore concludes that while the desmoid reaction will be found of value, it is not destined to supersede the Ewald test breakfast as a means of accurate diagnosis.

*Münchener medicinische Wochenschrift, November 28, 1905.*

**The Value of Bier's Congestion Treatment of Acute Inflammation.**—Danielsen has tested Bier's passive congestion treatment in 105 cases of different inflammatory processes, such as furuncles, carbuncles, cellulitis, panaritium, etc. In 101 of these a cure was effected more quickly than would probably have been the case if the customary methods had been followed. For a furuncle, the plan of treatment was as follows: The local congestion was effected by means of a dry cup provided with a rubber bulb. The degree of congestion is largely a matter of experience, but the patient's feelings afford a useful guide, as the treatment should not give rise to any pain. The cup is allowed to remain in position for three-quarters of an hour, and it was found advantageous in some cases to reduce the suction momentarily every two minutes or so. The treatment is repeated at intervals of twenty-four hours. If suppuration has already begun, the abscess is punctured under ethyl chloride anesthesia, and the cup is applied as before, whereupon a copious discharge of blood and pus, including the necrotic plug, usually follows. In treating cases of cellulitis, the congestion of the entire limb was secured by the application of a rubber bandage; considerable judgment is necessary in adjusting this, and several trials are necessary before the proper degree of tension is obtained. The bandage is allowed to remain in position for twenty to twenty-two hours, and is reapplied after an interval of two to four hours. In carrying out the treatment it is absolutely essential that the patient be kept under medical supervision, and the application of the congestion apparatus should never be entrusted to attendants or to the patient himself. The author considers Bier's treatment of acute inflammations and suppurations as the greatest recent achievement in surgery, and claims the following advantages for it: Painful, large incisions become unnecessary; the small punctures which are sometimes not avoidable may be painlessly performed under ethyl chloride anesthesia; painful packing of wounds need not be done; loss of function in joint or tendon affections is avoided; the length of time required to effect a cure is greatly shortened, and the formation of disfiguring scars is obviated.

**The Treatment of Tonsillar Inflammation by Means of Suction.**—Prym reports favorable results in the treatment of tonsillar angina by means of suction apparatus designed in conformity with the principles promulgated by Bier. Glass suction tubes are used, which are provided of such shape and dimensions as to adapt themselves to different-sized tonsils. The air is exhausted by means of a rubber bulb. The author has not found that their application is difficult, and when properly adjusted he states that the procedure is never irksome or painful to the patient. The effect of the treatment is a very prompt and notable improvement in the subjective condition, so that patients can usually take food after a single application, even if extreme dysphagia has existed previously. The duration of the inflammation is also appreciably shortened, though it is advisable to use the customary measures as adjuncts in addition to the suction treatment.

**The Technique of Pubiotomy.**—Reeb expresses himself as very much pleased with this operation, and reports four cases in which satisfactory deliveries were secured by its means. In each case a living child was obtained, and three of the mothers were out of bed on the twentieth day. In the fourth case, convalescence was prolonged owing to an injury to the bladder caused in passing the saw behind the pubic bone. The author attributes the accident in this one case to the fact that the finger was not used as a guide to direct the course of the instrument, and he advises that this precaution should never be omitted. The patient made a good recovery in spite of the complication, and when discharged her condition was as satisfactory as that of the other three. In a fifth case, in which it was doubtful whether delivery would be possible without operative enlargement of the pelvic outlet, the saw was placed in position but not used, as the birth was effected with the forceps alone. The author considers that the procedure is destined to occupy a prominent position in obstetrical surgery, and believes that by recourse to it the necessity for perforation of the living child and cesarean section will be greatly reduced. He recommends that the delivery be conducted by a special assistant who must not come in contact with the pubic wounds, and he also advises that the labor be terminated immediately after the bone has been sawed through. The lower incision is to be closed by suture, while the upper one is drained.

*Deutsche medizinische Wochenschrift, November 30, 1905.*

**Pseudotubercle Bacilli in the Diagnosis of Tuberculosis.**—Mezincescu says that as time goes on it is being realized with greater and greater conviction that the sources of error in the morphological diagnosis of tubercle bacilli are very numerous. The number of acid-fast bacilli that give the same staining reactions as the tubercle bacillus is constantly being increased. He describes a case in which smears made from an ulcerating tumor of the cheek revealed large numbers of bacilli which in their staining properties and morphology closely simulated true tubercle bacilli. On making sections of the growth, however, it was discovered that it was an epithelioma. Further investigation of the bacilli showed that they were completely decolorized by the action of absolute alcohol. The author concludes that they were smegma bacilli in this unusual situation. He also points out the fact that in smears of true smegma bacilli, certain organisms have been found which were not decolorized by absolute alcohol, and in all respects corresponded closely to the characteristics of the paratubercle bacilli.

**The Treatment of Tuberculous Arthritis.**—Garrè, in discussing this subject, emphasizes the undesirability of incising tuberculous abscesses. In case this is done, a secondary infection with pus organisms is almost sure to result, and should a subsequent radical operation be decided upon, it will have to be carried out in a thoroughly infected region. He has used iodoform injections with great satisfaction in such cases. The pus is aspirated through a

needle and a 10 per cent. emulsion of iodoform in oil is injected. The direct results of this treatment are satisfactory, and it does not jeopardize the success of later more radical measures, should they become necessary. In the treatment of sinuses, individualization is necessary. In some cases a cure can be effected by curettage or conservative treatment, others involve so much danger to their possessor and to his environment that early operation is indicated. A patient with a poorly-cared-for, suppurating, tuberculous process is as great a source of danger to others as a coughing, expectorating consumptive. In discussing the treatment of the different joints, Garrè says that conservative treatment has proved least satisfactory in the management of knee cases. Out of 185 cases, for which 177 resections and 8 sinovectomies were done, the disease was arrested in 94 per cent., although, of course, the functional result was not always very good. In speaking of tuberculous disease of the foot, he says that he restricts the iodoform treatment to recent cases without sinus formation in young patients who are in good condition, or to cases having only one joint involved and the tendon sheathes free in the absence of marked destruction of the bone. It is also serviceable in dealing with patients of advanced years, for whom otherwise amputation would come in question.

*French and Italian Journals.*

**Abdominal Hysterectomy for Infection Following Placental Retention of Two Months' Duration in a Fibroid Uterus.**—Druebert reports the case of a woman forty-one years old, who always menstruated regularly, until June, 1905. At this time the menses did not appear and the lower part of the abdomen at the same time became distended by a tumefaction which at first the patient thought to be pregnancy. In July pains developed and much blood was lost. During the entire month following the patient suffered from abundant and fetid lochia, followed by hemorrhages which necessitated her entrance into the hospital. Examination showed that the uterus had risen to the umbilicus, and had on its right border a fibroma as large as a child's head. A bloody and very fetid liquid flowed from the cervix. The patient denied all possibility of pregnancy. A rapid ablation of the uterus was made urgent by a new hemorrhage. After the operation the specimen showed interstitial fibroma and bits of placenta attached to the uterine mucosa. The patient was a widow which accounted for her silence concerning an abortion which had probably been induced by herself.—*Le Nord Médical*, November 15, 1905.

**Chronic Colitis: Indication for Surgical Treatment.**—V. Pauchet and G. Prieur believe that from a surgical point of view colitis may be divided into two groups, the muco-membranous form and the ulcerative form. Muco-membranous colitis is essentially characterized by three symptoms, constipation, abdominal pains, and expulsion of the muco-membranes. Chronic ulcerative colitis is due to simple ulcer, dysentery, or tuberculosis. Ulcerative colitis has the same symptoms as muco-membranous colitis, the points of difference being the discharge of pus and of the loss of blood. The surgeon ought to intervene in every case of severe colitis which does not yield to skillful medical treatment. In mucomembranous colitis surgical intervention is indicated by the following symptoms: acute and persistent pains, nervous troubles following the suffering, repeated hemorrhages, and progressive loss of strength. Operation in these cases is not serious and it often brings about recovery and almost always a distinct amelioration.—*Archives Provinciales de Chirurgie*, November, 1905.

**Toxic Amblyopia Due to Copper.**—Jean Galezowski reports this interesting case. The patient was a man fifty-seven years old; for seven years he had suffered from clouded vision. His pupils reacted slowly to light. When he was examined he showed all the signs of toxic amblyopia. The cause was discovered with some difficulty. He worked in the fields by day, but it was learned finally, that at night, in order to eke out his income he played sometimes for many hours on a musical instrument. The mouth-piece, originally silvered over, was made of copper. His two upper median incisors were covered at the border of the gums with a greenish substance. He had played upon this instrument since he was twelve years old. In this way he had absorbed a quantity of the copper. This may have occurred both through his lips and by means of his hands as well; for while holding the instrument, he perspired freely and then ate his food without washing his hands. He drank very little, neither did he smoke much. He seemed to be saturated with copper since his teeth and gums were covered with it and his hands impregnated with it. For some years he had suffered from violent gastric pains which were probably due to the copper intoxication. It must be admitted that copper may exert over the optic nerve the same influence as alcohol, tobacco, and lead.—*Recueil d'Ophthalmologie*, October, 1905.

**Two Cases of Dislocation of the Astragalus.**—C. Lepoutre declares that dislocation of the astragalus is of rare occurrence. There are two forms of this affection, dislocation by enucleation by which the bone is completely removed from its position; and dislocation by rotation. In the latter form the astragalus remains in its place but it is so twisted on its axes that its articular facets assume new and abnormal relations. The first case reported here was one of dislocation by enucleation. The patient was a mason and received his injury by a fall. After procuring a radiograph, operation was performed. External incision verified the diagnosis. Astragalectomy was the most simple proceeding; a counter opening was made, and the foot immobilized in a plaster cast. After the cast was finally removed the foot was found to be in good position, and complete recovery is looked for. The second case was one of dislocation by rotation. Operation was followed by excellent results. The diagnosis of this injury may be difficult. Various authorities differ as to the proper treatment. Some believe in bloodless reduction which is always difficult and often impossible. The difficulty of reduction depends upon the obstruction offered by neighboring tendons. —*Journal des Sciences Médicales de Lille*, November 11, 1905.

**Use of Antitetanic Serum, Preventive and Curative.**—M. Pergola has given injections of antitetanic serum in thirty cases, at the hospital of the University of Sienna, two of them having already developed tetanus, and the remainder being cases of wounds in which the treatment was preventive only. The wounds were such as were contaminated by earth, produced by firearms, and others such as are often infected by tetanus germs. In none of the preventive injections was any inconvenience experienced as a result of the injections. The dose varied between 10 and 40 c.c. No cases of tetanus developed after injection. Of the two cases that had already developed tetanic symptoms it may be said that the incubation had been long and they could not be called strictly acute cases. The tetanic symptoms lessened in proportion to the amount of serum injected. After reviewing carefully the literature of this subject the author adds that the mortality of tetanus seems to have diminished since the use of the serum was introduced, especially in protracted cases. The longer the period of incubation the better the prognosis . After the disease had developed the injections should be given at once and in large amounts, repeatedly. In dirty wounds preventive treatment is most important. The intracerebral application seems to have no advantage over the subcutaneous method of injection.—*La Riforma Medica*, October 7, 1905.

**Permanent Enlargement of the Pelvis by Hebotomy, with Two Cases.**—Ettore Truzzi, after recording two hebotomies done by him in the Hospital at Padua, with the best results to both mother and child, directs our attention to the great probability that a permanent increase in the diameters of the pelvis, both anteroposterior and transverse, will result from the operation, so that future deliveries may be carried on without operative interference. Such has been the result in cases reported by Van der Valde. By using no ligatures to connect the pelvic bones, and no fixation apparatus about the pelvis a slight separation of bones is maintained, which becomes filled by callus, leaving the pelvic basin somewhat enlarged. The author advises experimentation as to whether the introduction of a partly decalcified bone plate between the surfaces of the bones may not enable us to increase the permanent separation of the bones, and produce a greater enlargement of the pelvis. An increase in the transverse diameter is as important as an increase of the anteroposterior in delivery of vertex or face cases.—*Annali di Ostetricia e Ginecologia*, September, 1905.

**Agglutination Phenomena of Bacteria.**—Gino de' Rossi gives us the conclusions from his experiments on the agglutination powers of bacteria, thus: 1. Simple destruction of the cilia of bacteria retards, but does not prevent agglutination. 2. Agglutination of mobile bacteria is stopped or reduced by the action of heat. 3. Loss of agglutination power in mobile bacteria is independent of the suppression of mobility by the death of the bacteria, the temperature for sterilization favors phenomena of agglutination. 4. A moderate degree of heat and the destruction of the cilia both favor loss of agglutination. 5. These facts favor the theory of the protoplasmic nature of the cilia.—*Archivio per le Scienze Mediche*, Vol. XXIX, 1905.

---

**To Prevent the Vomiting of Tenicides.**—Apolant gives a capsule containing five grains each of menthol and sugar of milk a quarter of an hour before the proposed tenifuge is administered. He states that he has found this measure very valuable in preventing the nausea that so often interferes with the success of tapeworm cures. The dose of menthol is five times that noted in the U. S. Pharmacopeia. —*Deutsche medizinische Wochenschrift.*

# Book Reviews.

Amerikanische Streiflichter. Von Dr. Carl Beck, New York. Berlin: Leonhard Simion, 1905.

The articles which make up this little volume originally appeared in some of the German medical papers, and are mainly sketches of travels and observations on American life and customs. Dr. Beck, a German by birth, an American by adoption, has addressed these writings primarily to numerous friends and colleagues in his native land, to whom this country is most frequently pictured in a superficial or prejudiced manner, very often by travelers whose acquaintance of the land and its people is gained from a two weeks' sojourn, limited, perhaps, to Fifth avenue and Niagara Falls. Recent medical congresses and similar topics constitute the material for most of the articles, and the manner of their presentation will prove interesting, not only to those for whom they were written, but also to the American public. The interest which American physicians have always felt in German medical science has often been interpreted by the Germans to mean a lack of similar progress and opportunity in their own country, and it is only due to the recent visits to our shores of some of the great German medical lights that this misconception is being gradually dispelled and proper credit given for the advances which we have made. Then, again, the German graduate in medicine who settled in this country a few generations ago has often continued to be impressed by the extreme superiority of his medical attainments, and in his retrenchment has remained blissfully ignorant, in most instances, of the advances about him. Dr. Beck has not allied himself to the class referred to, but has noted and kept abreast of this American progress, and has taken every opportunity to condemn the narrow-minded spirit which characterizes certain of his German-American confrères. He is, moreover, well qualified by education and attainments and a long residence in this country to interpret correctly the various phases of American life to his countrymen, and, although not forgetful of his German birth, is ever ready to acknowledge the progress constantly made in the land of his adoption. This appreciation is met with throughout his book, and whatever criticism of our foibles is indulged in by the author is characterized by perfect good nature, and is, moreover, true.

The Practitioner's Visiting List for 1906. Philadelphia: and New York: Lea Brothers & Co.

This is the successor of the *Medical News* Visiting List, which was for many years one of the favorite physicians' diaries. In the text accompanying the blank pages of the visiting list we find among other information a scheme of dentition; tables of weights and measures and comparative scales; instructions for examining the urine; table of eruptive fevers; incompatibles, poisons, and antidotes; directions for effecting artificial respiration; extensive table of doses; an alphabetical table of diseases and their remedies, and directions for ligation of arteries. The blank pages are ruled in various ways to meet all the necessities of memoranda of practice.

The Physician's Visiting List for 1906. Philadelphia: P. Blakiston's Son & Co.

This standard visiting list is now in its fifty-fifth year of publication. In its arrangement and in the quality of its printed matter it is all that can be desired. Preceding the blank pages of the visiting list are dose tables, tables for converting apothecaries' weights and measures into the metric figures, of poisons and their antidotes, and of incompatibles; and following the visiting list proper are special memoranda pages, pages for addresses of patients, nurses, vaccinations, obstetric engagements, births, deaths, bills and accounts asked for, cash account, etc.

Die chirurgische Behandlung der Hämorrhoiden. Eine klinische Sammelstudie. Von Dr. Paul Schlacht. Zweite Auflage. Königsberg in Preussen: Gräfe & Unzer, 1904.

This little book has been developed from what was originally a dissertation, and has been extended to include a concise and terse description of the various methods employed in the treatment of hemorrhoids. The more recent surgical procedures are subjected to a critical analysis and the Whitehead operation is claimed by the author to be the most complete and satisfactory for the purpose.

Manual of Operative Surgery. By John F. Binnie, A.M., C.M., Prof of Surgery, Kansas State University, Fellow of the American Surgical Association, Member of the Société Internationale de Chirurgie. Second Edition, Revised and Enlarged. Philadelphia: P. Blakiston's Son and Co., 1905.

The second edition of this work appears in less than a year after the publication of the first, and in revising the book the author has made several additions based on the suggestions of various professional colleagues. Notice has also been taken of recent advances in cerebral localization, and short articles on the duodenum and tuberculous peritonitis have been appended. The book constitutes a handy reference manual to all those operative procedures which are not ordinarily described in the text-books on general surgery, and we can merely repeat here the favorable mention made of the book in a previous review.

Arbeiten aus dem Pathologischen Institut der Universität Helsingfors. Edited by Prof. Dr. E. A. Homen. Berlin: S. Karger, 1905.

The authorities of the pathological institute of this university have deemed it advisable to issue in regular journal form the results of the investigation and researches carried on in their laboratory, which have heretofore appeared in scattered publications of various countries. Although far removed from the well-known centers of European culture, this Finnish university has long been famous for its contributions to medical literature and its unhampered isolation allows it to draw its material, both clinical and pathological, from a large extent of thickly populated territory. The first number now at hand contains articles on the action of certain anaërobic bacteria and other toxins on peripheral nerves and spinal ganglia; studies on poliomyelitis; a contribution to the knowledge of syphilitic dactylitis; on the changes in the lungs produced by the aspergillus; on the action of certain hacteria and their toxins on the heart muscle; and a report on a series of unusual autopsies. These papers are all of a high standard, and some of them will probably be further reviewed in our columns.

A Treatise on Diagnostic Methods of Examination. By Prof. Dr. H. Sahli, of Bern. Edited, with additions, by Francis P. Kinnicutt, M.D., Professor of Clinical Medicine, Columbia University, N. Y., and Nath'l Bowditch Potter, M.D., Visiting Physician to the City Hospital and to the French Hospital; Consulting Physician to the Manhattan State Hospital, N. Y. Philadelphia and London: W. B. Saunders & Company, 1905.

Sahli's "Lehrbuch der klinischen Untersuchungs-Methoden" has long been known to readers of German medical literature, and it is a matter of congratulation that the work is now accessible to English readers as well. The book is a large one of over one thousand pages, and is fully illustrated, very many of the pictures, especially of the half-tones, representing the physical expression of nervous and other diseases, being from clinical material in Boston and New York hospitals. The author goes at his subject in a rather different way from most of the writers on diagnosis and diagnostic methods. He not only describes the various methods in detail, but he explains why they are used, and discusses the clinical phenomena which these procedures are designed to bring into relief. The American editors have added a few notes where the methods described differ from those in common use in England and America, and quite an extensive addition in the estimation of the blood pressure has been contributed by Theodore C. Janeway. These additions to the text and the illustrations have made the translation of even greater worth than the original.

Physical Diagnosis. By Richard C. Cabot, M.D., Instructor in Medicine in Harvard University. Third Edition, revised and enlarged. With five plates and two hundred and forty figures in the text. New York: William Wood & Co., 1905.

This new edition of Cabot's Diagnosis has been considerably extended and is nearly twice the size of the former editions. Besides the Physical Diagnosis of the Chest the book now includes the entire field of Diagnosis in Internal Medicine. The standpoint from which the volume is written is described by the author as follows: "To gain genuine familiarity with all the technical processes described in most books on physical diagnosis—such familiarity as makes one competent to use them with due regard for the sources and limits of error inherent in them—needs more than the lifetime of one man. But unless one has one's self used a technical process long enough to gain this sort of mastery over it, one cannot properly describe it, far less recommend it to others. Because of my lack of personal acquaintance with such methods as cystoscopy, ophthalmoscopy, and laryngoscopy, I have attempted no description of them, although I believe they should sooner or later be mastered by every internist. All that I have described I know by prolonged use." We have only to add that the book is eminently practical and trustworthy, scientific, and up to date; it is well and sufficiently illustrated, and there is a good index. The student will find this volume an uncommonly reliable guide, with nothing that he will afterwards have to unlearn; the practitioner will also profit by a perusal of its pages. Altogether this is the most useful and satisfactory work on Physical Diagnosis with which we are acquainted.

## NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

*Stated Meeting, Held November 23, 1905.*

DR. CHARLES F. ADAMS IN THE CHAIR.

**Specimens of Fibromyomatous Uteri.**—Dr. HERMANN J. BOLDT presented a series of twenty-five fibromyomatous uteri, two of which were removed by vaginal hysterectomy and twenty-three by abdominal hysterectomy. The tumors varied in weight from 410 to 4,700 grammes. In all instances the endometrium, when examined, showed some forms of inflammation, usually the glandular form of endometritis. Tuboovarian inflammation, reported as chronic salpingo-oophoritis, was found ten times. Only three times were the tubes reported as normal. Three times pyosalpinx was present. In not a single instance were the ovaries, when extirpated and examined, found to be normal, all being in a state of chronic inflammation. The blood-vessels were frequently thickened, in a condition of endarteritis. One tumor was found in a state of sarcomatous degeneration. Two were complicated with dermoid ovaries, one with a fibroid ovary. In one case the hysterectomy was done because the tumor caused an obstruction to delivery; was a fibroid of the cervix and it completely blocked the true pelvis. The mother made a good recovery, but the child died a few days after extraction. One case was operated upon at the end of the third or the beginning of the fourth month of pregnancy, because the large tumor forced the uterus into the true pelvis, and in this instance dislocation of the tumor into the abdominal cavity would have been a physical impossibility. The patient, although this was her first pregnancy, expressed a wish to have the uterus and tumor removed. The adnexa were retained. Dr. Boldt followed his customary after-treatment in abdominal operations in this case; that was, the patient was operated upon on October 12 and was out of bed within twenty-four hours; she remained up every day and walked about a little. During the night of the fifth day the woman had a severe attack of bleeding; the blood oozed through the opening of the stump of the cervix and was so profuse as to require a firm tamponade of the vagina. Dr. Boldt mentioned this, not because he had any reason to believe that the early getting out of bed had anything to do with it, but he thought it his duty to report everything unusual. The source of the bleeding was uncertain; it did not interrupt the recovery in any way, because the patient was about attending to her household duties two weeks after operation. This was a case in which Dr. Boldt thought that it would have been possible to save the uterus, but the operation would have been much more risky, and he thought that the patient acted wisely to request the organ to be removed. A full pathological report accompanied all the specimens. There was one fibromyomatous tumor with beginning colloid degeneration. Also one tumor in which tuberculous changes were shown—an unusual condition. Further, there was an intraligamentous fibroid which was interesting, because compression of the ureter on that side had given rise to a probable hydronephrosis. The general result of the pathological findings in this small series about corresponded with those in his former experience. He thought that if the specimens were looked at only with the naked eye it should be sufficiently convincing that it was erroneous to consider that fibromyomatous tumors were benign neoplasms.

**Specimens of Puerperal Uteri.**—Dr. Boldt presented these specimens which he had extirpated for septic infection. One of the uteri showed the injury which caused the septic peritonitis to have been due to perforation with a curette. He called attention to the non-report of the microorganisms occasionally in clear cases of puerperal sepsis, but was unable to explain why the pathologist had been unable to find streptococci in such seemingly clear cases. All the patients, with the exception of one, were in a desperate condition when they were first seen by him, and the one who was not in such serious condition became so within twenty-four hours. Four patients recovered and six died. He believed it to be very difficult for one to learn just when to operate, but he did not hesitate to state that if a patient had severe sepsis following abortion, especially a criminal abortion, and there was nothing within the uterus to account for the infection, and if the infection seemed to be coming from the uterus alone, and if the patient did not very soon show symptoms of improvement, it was better not to wait too long before deciding upon a radical operation; namely, to remove the offending organ, although he believed that it might occur that an operation might sometimes be unnecessarily done.

**Adenocarcinoma of Uterus, Ovaries, Omentum, and Liver, with Gallstones Encysted in the Base of the Liver.**—Dr. C. C. SICHEL reported the case of a woman, aged 40, married, who entered the hospital on October 3. Her family history was negative. Her menstrual history had been normal. She had had three children and no miscarriages. Her habits were good. About seven weeks before admission she began to vomit immediately after meals. There was no blood in the vomitus. There was some regurgitation. There was no pain after vomiting. The bowels were irregular. During the vomiting blood appeared at the umbilicus and there was continuous bleeding at this point, sometimes only in drops, at other times in a flow. The abdomen was distended. During these seven weeks she lost considerable in weight. Physical examination showed a temperature of 100.2°, pulse 90, and respirations 24. Heart and lungs were normal. The abdomen was distended, but not tense. There was a foul discharge from the umbilicus. The liver was normal. The extremities contained dilated veins. Palpation revealed a tumor on the left side, high up in the region about three inches below the locality of the spleen. Blood examination showed the reds to be normal and the whites to be decreased. The urinary analysis was normal. The patient was admitted to the hospital on October 3, and began to menstruate three days later; the flow was normal, lasting four or five days, moderate, and without pain. She had a rather high and rapid pulse. On October 12 an exploratory laparotomy was performed, the abdominal incision going through three to four and a half inches of fat. The abdominal muscles were very thin, about one-eighth of an inch thick. In the abdomen was an immense quantity of fluid. The omentum was adherent posterior to the liver, extending entirely across, adherent to the umbilicus, and the sloughing came from the omentum, which was infiltrated one-half an inch thick. The uterus was bound down by adhesions and was slightly enlarged. A fairly large cyst was found in the left ovary. There was a pyosalpinx on both sides with enlarged ovaries. The base of the liver was slightly nodular. The abdomen was closed. Subsequent to this exploratory operation the pulse became rapid and weak and twenty-four hours later the patient became much worse and died eleven days after operation. At autopsy the uterus was found to be very adherent, broad and large adhesions binding together the entire genitourinary tract. The liver was enlarged and nodular. The omentum was completely infiltrated with nodules, as were the abdominal glands. The other organs were comparatively normal. The microscopical examination revealed an adenocarcinoma of the omentum of very rapid growth. Innumerable epithelial cells were found arranged in their characteristic way, with some necrosis of these cells. The condition was undoubtedly secondary. In the base of the liver was found an encysted gallstone. The multiplication of the small bile ducts gave evidence of an acute inflammation and gave a typical picture of an adenocarcinoma. At the junction of the cervix with the body of the uterus the specimen showed adenocarcinoma. Section of the ovary showed secondary deposits. There was also a double pyosalpinx.

**Specimen Illustrating Panhysterocolpectomy.**—Dr. RALPH WALDO reported the case of a woman, 62 years old, who had

given birth to two children, the labors being normal, the woman remaining in bed but two or three days after her confinements. Her general health throughout life had been good until two years before she presented herself. After severe strain her "womb came out," and she then consulted her physician, who introduced pessaries, which relieved her only to a slight extent. She went from bad to worse and was confined to her bed, and she stated that while she experienced no special pain, there were disagreeable sensations in her body and back and the lower part of her abdomen and she was unable to get about. Examination revealed a procidentia, evidences of a small laceration of the cervix, and also an ulceration of the same. A panhysterocolpectomy was performed, consisting in taking out the entire uterus and vagina and closing the wound from above down, leaving a solid perineal body. The patient made an uninterrupted recovery and to-day was in splendid condition. The speaker here described his method of doing this operation. In these old women there was found procidentia, with cystocele, rectocele, etc., and he said he had not had as good results with other operations as with this one. This was his third case, and he had not yet had a failure.

Dr. Edwin B. Cragin, discussing Dr. Boldt's specimens of fibromyomata, said that in looking at the series of specimens presented one could not but be impressed with the rarity of malignancy resulting from these fibroids, although one must admit that, fibroid being so common, malignancy might be an associated condition. But as to a fibromatous myoma changing into malignant disease, he believed that all would admit at the present day that such a condition was exceedingly rare. He said that disease of the ovaries, when associated with fibromyomata, did not always indicate removal of the ovaries. Again it was astonishing what nature could do during the last months of pregnancy in the way of raising these tumors out of the pelvis and getting them out of the way just before the time for labor. He had seen cases where it seemed that a cesarean section would be the only way to deliver the woman, but nature arose to the occasion and pulled the tumor up out of the way and enabled the child to be delivered.

Dr. S. Marx said that for a long time he favored conservatism in cases of ovarian disease accompanying fibroid conditions of the uterus, but now he thought it was conservative to be more radical. In one instance where he left in the ovaries he had to reopen the abdomen and remove a cystic tumor. Another such similar case taught him a lesson, *i.e.* when ovaries were diseased and hysterectomy was done to remove fibroids, one should remove the ovaries as well. He believed that fibroids did very little harm in the way of causing dystocia from obstruction; most of them were harmless, because they were situated in the fundus. It was the subsequent degeneration and gangrene of the fibroids following labor that gave trouble and, for that reason, fibroids of the uterus which were large enough to be discovered, whether in the child-bearing period or not, should be removed.

Dr. Philander A. Harris of Paterson, discussing Dr. Waldo's specimen, described a procedure that he had used with satisfaction, operating from above and not per vaginam.

Dr. Hermann J. Boldt said that he had never seen simultaneously occurring carcinoma and myofibromata of the uterus. So far as malignant degeneration of these tumors was concerned he did not believe there was a well authenticated case on record. With regard to pregnancy when the patient was afflicted with fibromyomata, he voiced the sentiments expressed by Dr. Cragin; but in the specimen he presented delivery would have been impossible.

**The Treatment of Abortion.**—Dr. Hermann J. Boldt read this paper. He said that the induction of abortion should not be sanctioned in cases where there was dilatation with sufficient hypertrophy to compensate for the dilatation, nor was it indicated in psychical disturbances or in pulmonary diseases. It was indicated in pernicious hyperemesis and in some cases of chorea. If nephritis was present before conception, or during the first three or four months, he thought the induction of abortion was indicated. Due consideration should be given to all features connected with an individual case before an abortion was determined upon. The most favorable time was before the fourth month of gestation. The old method with bougies had proved itself the most reliable and almost invariably effective. If the bougie was not effective within twenty-four or forty-eight hours it could be supplanted with a tampon of a strip of iodoform gauze carried into the uterus, as much gauze being used as could be carried into the uterus without using force. He considered the treatment of abortion at four stages: First, in imminent abortion he advised absolute rest in bed and the internal administration of codeine, doses from .03 to .05 (gr. ½-¾) at intervals of fram three to four hours, until from three to six doses had been tdaken. From his experience he could not corroborate the claims made for viburnum prunifolium. Tampons, ergot, and icebags inthis stage should be avoided. In giving a prognosis in these cases one might be governed to some xtent by the amount of blood lost and by the character of the discharge. Patients who had a dirty, grumous, bloody discharge, although there had been no marked expulsive pains, had, in his experience, always aborted. He had formerly formerly been an advocate of active intervention, but experience had taught him that the expectant plan was better after it was evident that the progression could not be prevented. He had seen a comparatively large number of infections and accidents in the hands of those not experienced in gynecological technique, and, after observing a large number of patients in hospitals and private practice, he had gradually changed his views. Those patients did best in whom nature was allowed to take its course, and no intervention was practised unless there was a positive indication to intervene. When there were indications for emptying the uterus, such as elevation of temperature, decomposition of retained products of conception, or profuse bleeding, they should not be neglected. He had not noticed that the retention of the decidua in women who had previously enjoyed good health gave rise to any trouble during convalescence. Neither did such women seem more liable to endometritis or subsequent sterility. In emptying the uterus of conception products by artificial means it was preferable to use the finger rather than the curette whenever it was possible so to proceed. After all intrauterine interventions intrauterine irrigations were advisable. Unless the finger could readily be passed through the cervical canal and all parts of the uterine cavity be explored, the endeavor to accomplish the task with manual manipulations was inadvisable. However, much depended upon one's dexterity. If a sharp curette was used the endometrium might be destroyed to such an extent that subsequent atresia would result. Perforation in a non-infected uterus was not likely to result in harm if no further manipulating was done. A dull curette was useful only in those cases in which a large piece of the placenta was still in the uterus and was inaccessible to the finger. If a curette were used at all it should be a broad, sharp one, because it was less likely to perforate and covered a larger area. In a case of progressing abortion where there was bleeding and the cervical canal was closed, the ovum and its annex being in the uterus, the spontaneous expulsion might be aided by giving a hot antiseptic vaginal douche and lightly tamponing the vagina with iodoform gauze. The gauze acted as a hemostatic and caused contractions. The internal administration of an oxytocic might be resorted to. The upper part of the vagina was then firmly tamponed; this rarely failed to incite uterine contractions sufficient to expel the ovum. An almost certain sign that it had been expelled was the sudden cessation of expulsive pains. If this was effective nothing further need be done; not even a vaginal douche was necessary. In introducing an intrauterine tampon the strictest precautions in regard to antisepsis should be used. He used an abortion forceps, which was a slight modification of the Winter forceps, in the removal of the products

of conception where an instrument of this kind was necessary. If thought necessary, the interior of the uterus might be explored with the finger. The internal administration of ergot was advisable in such cases, two or three doses sufficing. In patients having progressing abortion with no bleeding and a dilated or contracted cervix nothing should be done except to administer oxytocics. If, after the expulsion of the ovum, there was a continuance of the bleeding some preparation of ergot should be administered. Should this not check the bleeding curetting was indicated with subsequent irrigation with one per cent. carbolic acid solution. A similar procedure was followed if the cervix was contracted under similar conditions. In cases of infection where it was necessary to empty the uterus as soon as possible he used a branched steel dilator like the one devised by Dr. A. Brothers. In some instances he used a heavy rubber one, or two inverted the one into the other, and then ballooned by attaching them to a bulb syringe. After cleaning out the uterus in these cases he irrigated with three or four liters of a one per cent. carbolic acid solution. He thought the intrauterine tamponade detrimental. He related a case of sepsis following criminal abortion in which a timely operation had saved the life of the patient, which illustrated the difficulties one experienced in deciding what was the proper course to pursue in cases of severe sepsis following abortion. Examination of the blood for bacteria, which had been hailed as a landmark to help decide when to operate, had been found wanting in most of the instances that had come under his observation. The silver preparation of Creté and the antistreptococcus serum had also been unsatisfactory. In a patient who had no decomposing elements in the uterus to account for the infection, or when there were reasons why they could not be satisfactorily removed, and if there was no exudate in the pelvis, so that the focus of infection was seemingly limited to the uterus, and such a patient was gradually becoming more ill from the infection, the offending organ should be removed ere it was too late.

Dr. Edwin B. Cragin said that it was not always easy to diagnose abortion. The patient might pass something from the uterus, had she aborted or not. Four years ago he operated upon a patient who stated that she had had a miscarriage while in Canada, and that the embryo was passed and was contained in a bottle. One month later, while in New York, she flowed and had some temperature. Supposing that her statements were correct, he examined her, expecting to find secundines in the uterus, but, instead, he found that she had an ectopic gestation. He believed that many cases of ectopic gestation were diagnosed as miscarriages, and the general practitioner should have his attention called to this fact. Any mass situated at the side of a pregnant uterus was a red flag of danger, and the general practitioner should be told always to examine, not only what comes from the patient, but also the sides of the uterus. In cases of threatened abortion rest in bed and the use of sedatives was the best that could be done. In cases of inevitable abortion the condition of the cervix was the guide for treatment. If a woman was bleeding, with the cervix undilated but dilatable, it was necessary to dilate that cervix, and here the gauze packing was the best method. If the products of gestation had been expelled and there was no elevation of temperature, all agreed that it was best to leave the patient alone, quiet, and clean. If products were not all expelled, rather than tamponading he thought it best to anesthetize the patient and make a careful exploration with the finger, to make sure the uterus was clean, and if not clean, to make it clean. He wished to indorse all that Dr. Boldt had said regarding the use of the finger as a curette; it was the best we had.

Dr. Von Ramdohr emphasized the importance of individualizing in these cases. If there was no elevation of temperature or extreme hemorrhage, he advocated the waiting treatment plus dilatation; the abortion then taking its natural course was preferable to any surgical treatment. He did not advocate the use of ergot until the uterus was empty.

Dr. Ralph Waldo wished to lay stress upon the importance of emptying the uterus after it had partially emptied itself. Of the patients that he had operated upon for pyosalpinx, in six out of every seven the condition followed induced abortion. Pieces had been left behind which had caused a septic endometritis and resulting pyosalpinx. Therefore it was very essential that the uterus should be completely emptied and kept in as clean a condition as possible.

Dr. S. Marx said the definition of abortion was an unfortunate one, some claiming it to mean the emptying of the uterus up to the period of viability, or the seventh month. He limited abortion to the condition up to the third month. The keynote to the situation was the condition of the cervix. He emphasized the importance of reconstructing the fetus outside the body, in order to be more sure of not leaving any part of it in the uterus. In order to soften the cervix gauze should be used; and whether then one removed the products of conception with the finger or with instruments was immaterial so long as the uterus was emptied.

Dr. John O. Polak of Brooklyn said that all agreed that the treatment of inevitable abortion was the controlling of hemorrhage and the avoidance of sepsis, the latter being diminished by emptying the uterus and preventing traumatism. He used the cervicovaginal tampon. In diagnosing the condition one should bear in mind the fact that conditions outside the uterus might cause hemorrhage; therefore, in case of hemorrhage and pain, one should make sure that the pelvis was clear and that tumor was absent, not only at the sides, but behind the organ.

Dr. Samuel W. Bandler said that in the hospital with which he was connected the uterine dilator and curette were almost never used. In cases of abortion the routine practice was to introduce iodoform gauze, particularly into the cervix, and to pack the vagina thoroughly and then to administer ergot. This method would dilate the cervix and without any injury. If examination was necessary the finger was used.

Dr. Charles G. Am Ende reported remarkable success in the septic cases with gauze impregnated with quinine and iodoform.

Dr. Charles A. Elsberg said that more abortions were induced by men who naturally were not good operators, and infection was more or less likely to follow. Therefore he did not believe conservative treatment in such cases was good. He assumed that every case of incomplete abortion was an induced one and treated it accordingly.

Dr. C. C. Sichel continued the discussion, which was closed by Dr. Boldt.

## MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, Held November 27, 1905.*

Dr. Floyd M. Crandall in the Chair.

**Address of the Retiring President.**—Dr. Henry S. Stearns said that his labors as president of the County Society had been pleasant ones. This Society was the largest local medical society in this part of the country and they could offer readers of papers the largest average audience of medical men of any medical society in Greater New York. The great work for the suppression of criminal practice had gone on during the past year even beyond what it had during any year previous, and more arrests of great offenders, but not so many of small ones, had occurred. There had been many convictions and new points of law brought up and established. The trustees had placed their shoulders to the wheel and helped the Executive Committee in continuing their work. Practically every cent they could grind from their careful Treasurer had gone towards the legal expenses. Dr. Stearns then introduced the incoming President.

**The President's Inaugural Address.**—Dr. Floyd M. Crandall delivered this address. He said that the society year upon which they were just entering would be a momentous one. During its course the Society would complete the first century of its corporate existence and enter upon a second. Starting in its infancy with 18 members, it now had 2,100. Amalgamation of the two societies would without doubt occur this year. That no legal difficulties might be raised, the State Society at its January meeting renewed its action looking towards consolidation. The annual meeting of the State Association approved amalgamation by a vote of 1,517 to 2. An order from the Supremee Court alone remained as the final step to complete the union. The functions of the new society, he said, might be divided into six general groups. Three of these (the scientific, social, and disciplinary) had to do with its own membership. Three (the hygienic, legislative, and legal) had to do with the public and the profession at large. The constitution provided five degrees of discipline, of which private admonition had been most frequently employed in the past and had been very helpful. The most important work in public hygiene at present was being done by the Milk Commission. It could not hope to lower the death rate so decidedly by any other means as by securing for the city clean, fresh, wholesome milk, and this was what the Commission was striving to do. The number of attacks made every year upon medical laws was astounding. As many as 397 bills, having a more or less direct medical bearing, had been introduced in a single session at Albany. In the three years from 1899 to 1901, 912 bills affecting medical interests were introduced. These attacks were renewed every winter, and for years the Society had kept a paid agent at Albany, who reported to the counsel every bill having the remotest medical bearing. Every man or woman exhibiting proper qualifications should be admitted to practice. The opposition to pseudomedicine was, and should be, educational, not professional. It was the educational question that was at the bottom of every one of these "isms," and they were the more aggressive as the educational barriers were raised higher. The medical profession approved the system which required the same general professional education for all its members. Every man or woman who entered upon the practice of the healing art should have an adequate education. Equal requirements were asked for all, and all who treated disease should go in through the same door. As medical men it was their duty to take the lead in securing proper medical laws and raising the standard of medicine. The raising of medical standard, and demanding more educational requirements, was not for their advantage but for the people who employ physicians, and, therefore, public-spirited men should take an interest when the standards of education and practice were threatened. He believed the Society should prepare and urge the placing on the statute books this coming winter the following: First, the illegal practice of medicine should be made a misdemeanor, which would carry with it a penalty of both fine and imprisonment for even a first conviction. It should be possible for the court to impose a fine of $500 and imprisonment up to one year. Second, a provision should be made in the medical law requiring all advertising medical concerns to post on their signs the names of the practitioners and in each office the name of the person so practising. Third, the law regarding the use of the title doctor should be made more explicit and the title should not be permitted to anyone who attempted to employ it in a commercial way, unless he was a legalized practitioner in this State. Last year almost $4,000 was spent in the legal work and much more was required to pursue the work that was before them. The awakened interest in patent medicines and the suppression of criminal medical practice was largely the result of their work. Their counsel, when he appeared in the courts, was aided by the fact that he represented more than 2,000 clients. The society needed contributions to pursue this legal work. So far as the speaker could at present see, the most important special features of their work for the coming year were (1) to make those changes in the constitution necessary to bring about an organization in harmony with the new State Society; (2) to obtain those changes in the medical laws necessary to make the legal work more effective; (3 )to devise some means to broaden the legal work and put it on a secure financial basis.

**The Future View-Point and Practice of Infant Feeding.**—Dr. Henry Dwight Chapin read this paper. He said that up to within a few years attempts to solve the problem of infant feeding had been directed towards making cow's milk like human milk. He reviewed the methods usually resorted to in the endeavor to attain this end. He said that percentage feeding had not come up to the expectations that were aroused. All the attempts to establish a scientific basis of infant feeding had resulted in some knowledge, much of which was only negative. He called attention to some of the difficulties that had arisen from different methods of analyses and different nomenclature, and said that chemists were in accord as regarded the composition of milk, although they differed as to the percentage of the different substances. Every food contained these elements in one form or another, and one might make a food from a sandwich and a glass of water that would contain all the elements in the proportion that they are found in milk, but this would not be milk and would not be suited to the stomach of the infant. Thus we might see that the chemist's help was limited in the preparation of infant food. We should study the subject from the infant's side. It would be as logical to analyze the placental blood of the mother and expect to understand from the result how valuable it was to the infant and what a peculiar function it had to perform as to expect to learn from an analysis of the secretions of her breasts what their functions were or how they were made use of by the infant. He said there had not been much attention paid as to how the secretions of the breast were acted upon by the infant. This was the fundamental point that would have to be established before there could be scientific feeding. During the normal nursing period a great change took place in the infant. At the weaning period it could subsist on table food. It was evident that a profound change had taken place in the digestive tract during the suckling period. The first fact that struck us was that aside from the colostrum secreted during the first week the breasts supplied the same kind of food up to the time the digestive organs were able to digest solid food. It would seem that as the infant's digestive secretions became stronger the milk would gradually be digested with less effort; but this was not the case. As soon as milk appeared in the breasts the rennet was secreted by the infant's stomach which acted upon the casein of milk, changing it into a delicate solid. Pepsin would not digest this solid. When a slight amount of hydrochloric acid was secreted it combined with a portion of this solid, which immediately became more solid. Pepsin would not digest this solid. As more acid was secreted a denser compound was formed which was readily attacked by pepsin. It was for this reason that maternal milk was suited to the infant from birth until weaning. This one food was so altered by the infant's digestive secretions before digestion commenced that the digestive apparatus should be fully occupied as it became stronger. As there were radical differences in the stomachs of different animals it was not surprising that their milks were radically different. There were other foods as nutritive as milk, but they were unsuitable because the infant's digestive apparatus was undeveloped. Milk was needed because it was an elastic food in its reaction with the infant's digestive secretions, being changed by them to suit the increasing strength of the digestive apparatus. Profound constitutional disturbances sometimes resulted from absence of food that supplied suitable work for the developing stomach. The art of successful infant feeding consisted in altering cow's milk so that it would bring about perfect nutrition and development in the infant. In practice it was best to use for dilution milk extra rich in fat and then to add some form of sugar. The

freshest milk, put up in bottles and kept cool, should be used. The cream had usually risen when such milk was delivered. Store cream was generally bacteria laden, consequently home cream was preferable. If all the cream in a quart of milk was mixed with enough skim milk to make twenty ounces, a mixture one and one-half times as rich in fat as the original milk would be obtained; all the cream and enough milk to make sixteen ounces when mixed would be twice as rich in fat, and all the cream and enough milk to make nine ounces would be three times as rich. This rule held good with any milk, as had been proven by a large number of assays extending over several years. The percentage of fat in the mixture would, of course, vary directly with the richness of the original milk. Here was an accurate method of getting a uniform feeding mixture if the same milk were used all the time. Fine percentages were obtained more often on paper than in the infant's bottle. A one-ounce dipper was most convenient in removing the cream from the bottle, and aided in securing accuracy. The first dipper should be filled with a teaspoon or the bottle would overflow. It was known to-day that the addition of alkalies did not make cow's milk like human milk, but that their effect was to prevent the stomach secretion acting on the milk and to throw the milk in a fluid state into the intestine for digestion there. Proper testing had shown that breast milk also required the addition of lime water in order to render it alkaline. There were gruel diluents which acted mechanically on the curds of the milk and exposed a large surface to the digestive secretions. Digestive enzymes acted by contact only, and it was essential that a large surface should be exposed to them, and for this reason the food should be broken up or porous. Another reason for preferring a gruel diluent was that all milk was in a form that was readily absorbable and which could supply energy required for carrying on the digestive process, which was considerable. When cow's milk was diluted this portion of the food was reduced. To supply its place a digested cereal gruel could be substituted. In making up food it was only necessary to remove the top nine ounces from a bottle of milk for infants under three months and dilute it with at least three parts of the digested gruel and add one part of sugar to twenty ounces of food. For older infants the top sixteen ounces might be diluted with from one to three parts of the gruel and, later, two parts of the top twenty ounces might be mixed with one part of gruel. By this method the fats and hydrocarbons were kept up to the infant's requirements for energy and the quantity of proteid increased as fast as the infant could digest it. The digested gruel not only acted as a diluent but also supplied additional proteid, thus adding to the nutritive value of the food. If the stomach secretion was too acid, as shown by vomiting or curdy stools, lime water or sodium bicarbonate should be added until a normal secretion appeared. Pasteurization might also be employed, for it reduced the tendency of the milk to form tough curds. Unsweetened condensed milk might also be diluted for infants that had difficulty in digesting cow's milk, but this food should not be employed too long. Additions that either profoundly altered the character of the milk or inhibited the action of the digestive secretions should be used cautiously and with a distinct knowledge of their effect. Whenever possible the cow's milk should be adapted to the infant's use mechanically and not by chemical manipulation.

**Stool Examination in Starch-Fed Children.**—Drs. Charles Gilmore Kerley and William C. Campbell presented this communication, which was read by Dr. Kerley. This work was undertaken with the view of learning something of the digestive capacity for starchy food in children under one year of age. The study comprised observations made on 30 children, 166 examinations having been made. In order to make the test a severe one, raw barley flour was used, which was cooked one and a half hours. In some barley water formed the diluent; in others it was given plain, as the only nutriment. The von Jaksch test was used. In 16 children the examinations were persistently negative to starch; of these, 11 were 6 months or older, 5 being under 6 months. Among those under 6 months, one was 19 days old, and took 142 grains of starch daily, the stool being negative to the two examinations made on two successive days. One was 5 months 26 days old, and was given 375 grains daily; five examinations were made, all being negative. One was 5½ months of age and for three days 450 grains were given, when it was thought wise to push the starch to test the digestive capacity; therefore 1,560 grains were given daily for two days and the stool failed to respond to the iodine test. One was 1 month 22 days old, the condition being thin, and he had diarrhea. Four hundred grains were given the first day, followed by a negative stool; 300 grains were given on four successive days, the stool remaining negative. One was 1 month 19 days old, and 185 grains were given for three days with negative stools. The starch was then increased to 300 grains for two days, the stools remaining negative. Five of these negative cases had moderate diarrhea, and one a severe diarrhea. He reported then three cases which were persistently positive. Among these, two had diarrhea and one was very young. The remaining 11 showed sometimes positive, sometimes negative, sometives red, at the differential examinations. All had diarrhea. Seven were negative in the majority of the examinations on the different days, and were recorded as having a negative tendency. In the testing with iodine of solutions of starch of different strengths, plain and dextrinized, it was found that a starch solution which was boiled, to which diastase was added, and which was then cooled, produced a pinkish-red color upon the addition of iodine, this being the reaction of dextrin to iodine. The first step in the digestion of starch was the formation of soluble starch, amylodextrin. In the second stage, the soluble starch was decomposed into maltose and a substance giving a red color with iodine, to which had been given the name of erythrodextrin. In the third stage, the erythrodextrin was further split up into dextrin, which gave no coloration with iodine and was called achroödextrin and a further quantity of maltose. In short, the digestion of starch consisted in breaking up by several more or less well-defined stages through a process of gradual hydrolysis of a very complex molecule into much simpler ones. Starch and water and the presence of a suitable ferment yielded maltose and the different dextrins. The dextrin reaction was present in 10 children, having been found in 18 examinations. They interpreted this reaction as meaning that dextrin was present in the stool, representing an incomplete starch digestion, due, perhaps, to the too rapid passage of the fecal contents, as was present in several diarrheal cases, or it was due to a deficiency in diastatic enzyme, not enough to produce a complete splitting up of the starch product.

Dr. D. L. Edsall of Philadelphia insisted upon a point made by Dr. Chapin, *i.e.* any system of infant feeding must be simple in order to be accurate in the end; accuracy must be striven for, but elaborate methods of preparing foods should not take the place of preparing them in a simpler manner; less accuracy was attained in this way than by accepting analyses that were approximate only. Two or three years ago, he said, he had published figures showing the analyses made up by nurses and mothers, and many of these figures convinced one that unless the doctor took all the complexity on himself little good would follow. Digestive disturbances *per se* constituted the most important part of the pathology in infancy. A few years ago enthusiasm followed the coming out of the stomach tube and an overwhelming importance was attached to gastric disease. At present broader-minded men taught that gastric disease was of comparatively mild importance and was more dependent upon general well-defined diseases elsewhere, and they pointed to the stomach as a supply tank which gave out material as required. In pediatrics there had been too much of a tendency to consider digestive disturbances as almost the whole thing; this was an error not only in the treatment of children but in the treatment of adults. He said he was more inclined to look upon these disturbances

in infants and young children as nutritional, and the essence of the whole thing lay in the fact that one could not separate the digestive tract from the tissues and their effects upon each other. The carbohydrate intake was much too low in many children. Excessive amounts of fats, of course, would produce digestive disturbances. He thought there was too strong a tendency to feed too small an amount of proteid to infants, and disturbances in infancy might be corrected by more attention to this fact. In many cases the digestive organs were upset because nutrition in general was upset. He referred to the studies of Prof. Chittenden, who showed that men could go for many months without disturbances of health on a general diet much lower than one was accustomed to recommend, and particularly upon a proteid intake that was not more than one-half or one-third the amount usually taken. Children would succumb more rapidly than adults when there was a reduction in the general diet, or a reduction in the proteid intake. He hoped other methods might be devised by which a child could be prevented from going into proteid starvation. In the observations made upon infants and early childhood, the ideal standard intake of proteid was unquestionably quite as high as that of mother's milk. The proteid of cow's milk was less readily assimilated than that of mother's milk. He asked how a child could digest readily and assimilate vegetable proteid as it could animal proteid. So far as adults were concerned the investigations upon this point showed that the vegetable proteid was as well assimilated as was the animal. In some infants it had been found that the absorption of vegetable proteid was quite as good as the absorption of milk proteid.

Dr. J. P. Crozer Griffith of Philadelphia said there were two factors which appeared to be difficult ones in infant feeding; one was the absolute inability to find an artificial food similar to the mother's milk, and the second one was to lack of studying the individuality of the baby. The infant should not be studied as a class but as an individual. In illustration he referred to twins who had flourished for months upon the same food. One of them was taken ill, with vomiting, etc., and the father became quite excited, sending to the laboratory a sample of the food for analysis, looking for streptococci, etc. The food in this instance was all right, but something went wrong with the child's digestion. The great tendency now in cases of digestive disturbances was to see if something was not wrong with the food; this he believed to be the wrong view-point. One should not forget the individuality of the baby, but should study the baby and see if anything had gone wrong with it. Therefore he believed it was wrong to assume that a child at a certain age should take a certain food; that was all right for the mass of babies, but not for the individual one. There were biological differences between the milk of all animals and just what these differences were was not exactly known. To be sure, one could substitute to a certain extent. He wished to emphasize the necessity of having proteid present; in some cases he had seen scurvy develop in babies who had a low proteid. He believed one should attempt to get a food as near like the mother's milk as possible; but one should always be ready to change that food for another when circumstances seemed to demand it. Every method of artificial feeding was bad, and he advised that one should not speak ill of another person's method and yet praise his own.

Dr. Henry Koplik said that they were taught that cow's milk for infants was an unnatural method of feeding and also that not enough stress had been laid upon the fact that intestinal digestion was particularly at fault when babies were fed with artificial foods, such as cow's milk. The infant should be more studied and not so much the charts and percentages. In feeding these infants one should only deal with proximate percentages.

Dr. Walter Lester Carr said that some years ago proprietary foods were given with a small percentage of proteid, while now the reverse seemed to be the custom.

Dr. Thomas S. Southworth said the only basis for artificial feeding of infants was that presented by Dr. Chapin. The general practitioner should better inform himself regarding the appearance of stools in babies. Too much cereal could be given as well as too much proteid and fat, and he believed too much latitude was allowed in the use of cereals.

Drs. Chapin and Kerley closed the discussion.

---

### Northern New York Medical Association.

At the annual meeting of this Association, held at Malone, October 24, 1905, Major Charles E. Woodruff, Surgeon U. S. A., read a paper on "The Neurasthenic States Caused by Excessive Light" (see page 1005).

Dr. J. H. Pryor of Saranac Lake, N. Y., opened the discussion and stated that the new facts recently presented showing the effects of light revealed a new field for investigation. In his opinion certain clinical facts and hints of therapeutic value could be explained on this theory. As a result of observation he had learned to doubt the recovery of a tuberculous patient if the individual had red hair and a lack of pigment associated with it. He had long doubted the alleged favorable result of continued sunshine in tuberculous patients who were of nervous habit or neurasthenic. They quite often developed nerve symptoms, particularly if they were of a distinctly blond type. These questions should be studied in the South and West, but it must be remembered that altitude and temperature were factors. At the present time the tendency to send consumptives to a warm sunny climate in the hope of securing an arrest was being more and more recognized as a mistake, and the benefits of cold and cloudy regions were growing more apparent. He held a strong belief that in the course of time patients with nervous manifestations would be sent more and more to cold and darker regions. Continuous sunshine produced symptoms and conditions which have been overlooked, and a cold climate certainly increased resistance and promoted nutrition more rapidly than a hot one, which caused languor and enervation. In endeavoring to determine the color of the eye only one method was known which would promise accuracy, namely, the Bertillon system of dividing the individuals into three classes dependent upon the amount of orange yellow in the iris. This had proved successful in identification, and the author of the paper was asked to consider the suggestion. Finally, study of the effects of light upon types of beings as elucidated by Dr. Woodruff might help to illumine many inexplicable clinical and pathological phenomena, which were now quite obscure. The line of investigation which he had started, if continued, might help very much in deciding what climatic conditions were necessary in a given case. Certainly the whole subject of climatology was in a transition stage to-day and many accepted theories would have to be revised in accordance with clinical facts. It was a pleasure to know that attention had been directed to the deleterious results of too much sunshine and that there were people and people, stomachs and stomachs, nervous systems and nervous systems, which had never conformed to theories and special scientific views. There was no ideal climate for all people and every attempt at differentiation would be a distinct gain, but it should be based upon clinical observation.

Dr. R. H. Hutchings, Superintendent of St. Lawrence State Hospital, Ogdensburg, N. Y., said that he had listened with great interest to Dr. Woodruff's paper and would like to supplement it by a statement of the complexion of the patients in St. Lawrence State Hospital. Our general knowledge of the influence of light upon the metabolism had had to be revised since Major Woodruff had pointed out in his book upon "Effects of Tropical Light Upon White Men," that light was not the good genius of health, that we had once believed it to be, and that the good effects which followed exposure to sunshine were really due to the fresh air obtained at the same time. The speaker was particularly interested in this paper, as it presented

many suggestive thoughts bearing upon the occurrence and prevalence of insanity among the various types of blondes and brunettes. He had recently examined carefully the patients in three of the buildings of the St. Lawrence State Hospital, who were largely native born. They were drawn from the rural counties of Northern New York. There was included in that district but one large city, Syracuse. In making this enumeration he had omitted all old persons in whom the color of hair and complexion in youth were doubtful, and had therefore been limited to an examination of 734 insane patients. Of this number, dividing them broadly into light and dark, he found that there were 349 light and 385 dark. Just what bearing these figures had upon the prevalence of insanity among the light and dark people could be understood only when we knew the proportion of each in the general population, but since in Northern New York there was a large admixture of the French-Canadian element, who were uniformly dark, these figures would appear to show that there was in the locality a preponderance of insanity among patients of light complexion. As to neurasthenia, it had been his experience that in Northern and Central New York the majority of neurasthenics were blonds. Thinking back over the cases of neurasthenia that stood out most clearly in his memory very few would be called dark and several were very light blonds.

## New Instruments.

### A VENEPUNCTURE TROCAR (STERN'S TROCAR).

By HEINRICH STERN, M.D.,

NEW YORK.

By venepuncture I understand the direct insertion of a needle or a trocar into a vein for therapeutic purposes. Venepuncture is destined to take the place of venesection in almost every instance. The advantages of venepuncture over venesection are: greater simplicity, greater safety, greater convenience for both patient and physician, greater cleanliness, more rapid accomplishment of the purpose, possibility of immediate intravenous saline infusion after abstraction, rapid healing of the small

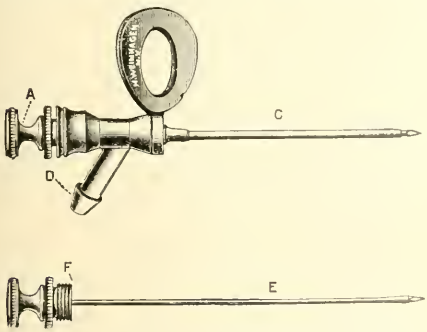

Fig. 1.—Stern's Trocar; A, trocar handle; B, thumb-rest; C, cannula; D, blood outlet or infusion inlet; E, perforator; F, packing box cap.

puncture wound. Some years ago, Strauss devised a needle for needling the veins. This needle is nothing else but an aspirating needle to the cannula, of which a small handle is attached vertically. The venepuncture instrument, described in the following, is constructed on the principle of the trocar which, when *in situ*, with withdrawn perforator, cannot injure the blood-vessel, as Strauss' needle is apt to do. Besides this, it exhibits various other advantages which will be readily appreciated when perusing the description.

The entire instrument is 7 cm. (3 inches) long. The cannula alone measures 4 cm. (1⅝ inches.) The cannula is made of sterling silver. The perforator, entering the cannula, is of steel heavily nickel-plated. The thumb-rest is in the shape of a ring, which may be detached. The outlet, which is to be connected with a rubber tube, is at the side of the thumb-rest when the latter is *in situ*, so as to interfere as little as possible with the operator. The perforator can be withdrawn far enough to permit

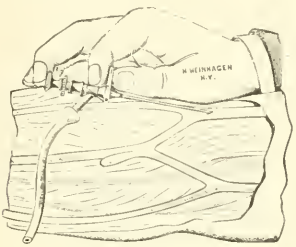

Fig. 2.—Illustrating mode of introduction of Stern's trocar into the cephalic vein.

passage of the blood through the outlet. This outlet serves also as the inlet for a saline infusion.

In an aseptic case together with the trocar are packed (1) a piece of narrow rubber tubing fitting into the outlet of the instrument, and (2) a connecting tube made of glass which is to be attached by its wide end to the tubing of the fountain syringe containing the solution to be infused, while the narrow end is made to fit into the narrow rubber tubing leading from the outlet.

*Mode of Employment.*—After the arm is corded as for venesection, a piece of rubber tubing being well adapted for the purpose, the handle or thumb-rest of the instrument is held between thumb and index finger, while the middle finger rests against the handle of the perforator to prevent the latter from sliding backward. The operator then thrusts the trocar directly into the most prominent vein of the forearm—the right one, if possible. (See Fig. 2.) The puncture is made so that the point of the trocar is toward the axilla, and although the needle points in the same direction as the blood current, the blood flows out readily when the perforator is withdrawn beyond the outlet. The piece of rubber tubing packed into the aseptic case should be attached to the outlet before the instrument is introduced into the vein. This rubber tubing should lead into a graduated vessel, so that the operator may ascertain the amount of blood withdrawn. Immediately after depletion, when the cannula is still in position, an infusion may be administered through the same

Fig. 3.—Glass connecting tube.

tubing and outlet. All that there is to do to accomplish this purpose is to connect the narrow tubing leading from the outlet with the tubing of the fountain syringe by means of the specially constructed glass connecting tube which accompanies the instrument, and to remove the rubber tubing used for cording.

*Notes.*—The chance of injuring nerves and arteries is reduced to a minimum by inserting the trocar into the cephalic vein, which is not situated in as close proximity to these structures as the

median basilic, which is the vein generally chosen for venesection.

The vein in either arm may be punctured; however, if the vein on the left arm is not more prominent, it will be found more convenient to needle the cephalic vein of the right arm.

The chance of admitting air into the vein when employing this trocar is entirely eliminated; a needle may possibly permit the passage of air, a trocar, constructed like the one here described, never.

Venepuncture and subsequent needling of the vein may be accomplished in about 95 per cent. of all cases in which depletion is to be performed. Only in cases when the arms are very fat or when, on account of edematous swellings, the course of the vein cannot be recognized, is it necessary to resort to venesection.

The rubber tubing used for cording should be drawn sufficiently tight to make the veins stand out prominently, but not so tight as to suppress the radial pulse. The instrument is manufactured by H. Wainhagen, of New York City.

**Supernumerary Thyroid at the Base of the Tongue.**—Dudley P. Allen, John M. Ingersoll, and A. I. Ludlow report this case, which is especially interesting on account of the rarity of benign tumors of the tongue. The patient, a girl, eighteen years old, was anemic. The personal and family history were negative. Three years before her entrance to the hospital an enlargement on the dorsum of the tongue had been observed during an examination for "chronic catarrh." The present examination revealed a hemispherical shaped tumor about four centimeters in diameter, covering the base of the tongue. The swelling projected backward till it touched the posterior pharyngeal wall. There was no glandular enlargement and no pain. The growth was removed under chloroform anesthesia. Since during the first part of the operation, no appreciable hemorrhage occurred, it was thought that the lateral attachments might be safely separated. This was begun on the left side by cutting through the mucous capsule. This incision, however, was followed by a flow of blood so copious as to threaten asphyxiation on the one hand and a fatal hemorrhage on the other. The remaining attachments were instantly divided and the cavity packed with gauze. The flow of blood not yet being controlled, ligature of the lingual artery on the left side was accomplished through an external incision. This maneuver, together with the pressure of gauze in the wound, controlled the hemorrhage. But the patient by this time was thoroughly exsanguinated and in collapse. Tracheotomy was performed later on account of embarrassed breathing, doubtless due to the large amount of gauze packing. Two days after the operation, the packing was removed, and from that time the patient's recovery was rapid. The writers append an interesting pathological report.—*Surgery, Gynecology, and Obstetrics.*

**Rheumatics in Relation to Climate.**—Leonard Williams includes in the term "rheumatics" chronic articular rheumatism, chronic articular gout, rheumatoid arthritis, myalgias, and neuralgias. The condition is invariably associated with cold and damp. A low temperature increases metabolism, and of itself tends rather to prevent than to favor the production of the arthritic state. But if there is also a high degree of humidity, the largest exit for the effete matters—the skin—is effectually shut. The climatic factors which are found in association with rheumatics are those which interfere primarily with the cutaneous functions; and such interference plays an active part in the production of the malady. As to the effect of sunlight, a normal exposure to the sun's rays must act as a direct stimulant to the skin, maintaining all its functions in full working order. In sum, climatic conditions which favor the disease are precisely those which most conspicuously interfere with cutaneous activity. The writer concludes that to avoid rheumatics, it is necessary to pay particular attention to the maintenance in full vigor, of all of the cutaneous functions; and that the damper and colder and more sunless the climate, the greater and more urgent is this necessity. The writer emphasizes the importance of the consideration of proper clothing. Instead of flannel and wool clothing, which is so generally advised, he insists upon the urgent necessity of substituting silk, linen, or cotton, any one of which is not wholly devoid of absorbent properties. He mentions the importance of the open window, and the value of the daily cold bath. He also suggests that Turkish baths, radiant heat baths, massage baths, and even the ordinary hot soap bath are not prescribed as often as they ought to be. Finally, he believes that the vast majority of people are overclothed.—*The Birmingham Medical Review.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended December 16, 1905:

### CHRONIC DISCHARGE IN ORGANIC AND FUNCTIONAL DISORDERS OF THE DEEP URETHRA; DIAGNOSIS AND THERAPY.

By JOHN M. THOMPSON, A.B., M.D.,

BOSTON, MASS.

Among the varied phenomena present in organic and functional disorders of the deep male urethra, chronic discharge is not only the most common, but also the most significant; and yet, despite this fact, it is the particular manifestation above all others that proves the most indomitable stumbling-block to the physician in point of therapy,—apparently, no doubt, through either an insufficient knowledge of, or a sheer indifference to, correct diagnosis.

The majority of practitioners realize the widespread prevalence of chronic processes in the deep urethra, but it would seem that only few properly appreciate their importance and serious consequences. For instance, it is rarely that the physician ventures to compare urethritis with syphilis, and yet statistics prove that the former is a far more destructive foe to humanity than the latter—not because the local process *per se* is of necessity more destructive than the constitutional, but because more dangerous results ensue from its chronic, deep-seated character.

When one contemplates for the moment the fact that the particular disorders which it is the purpose of this paper to consider are the principal agents concerned in rendering urethritis such a formidable destroyer of human life and barrier to human progress, one is assured that a knowledge of the differential diagnosis and treatment of these processes should commend itself to the attention of the reader even more forcibly than that of other more novel and, perhaps, more interesting lesions in the domain of genitourinary medicine. We shall first take a cursory glance at a few facts in the literature of our subject, and then shall endeavor to consider the cardinal points of diagnosis and of therapy proper. It is not deemed essential to enter into details, in view of the necessarily limited scope of this paper. The many accepted truths pertaining to the subject do not call for discussion; besides, the interest of the great majority of physicians centers in such information as enables them both to determine the correct nature of a process and to apply the proper agencies for its removal.

It is a conspicuous fact that failures are lamentably, and oftentimes inexcusably, common in the management of all chronic disorders of the male sexual organs, especially in the case of those we are about to take up, in which discharge is a prominent symptom. And, inasmuch as successful therapy is dependent upon correct differentiation, emphasis will be placed upon the diagnostic features of each process.

In the literature of the genitourinary tract, while it cannot be denied that sufficient attention and prominence have been given to chronic urethral disease, still, there is apparent cause for regret that such marked discrepancy of opinion prevails in regard to their classification, diagnosis, and treatment. For example, some of the textbooks include under the term spermatorrhea every species of seminal discharge, irrespective of cause. No less eminent authorities than Dr. S. D. Gross and S. W. Gross, his son, of Philadelphia, confounded the three affections—chronic prostatitis, prostatorrhea, and urethrorrhea—and the latter even went so far as to say that "prostatorrhea may exist with or without inflammation of the prostate, and is a catarrhal affection." It need hardly be said that true prostatorrhea is never a catarrhal inflammation. Overall, in his work "The Prostate Gland and Adnexa," one of the latest, tells us that "prostatorrhea is due to an inflamed condition of the gland as a result of gonorrhea." Belfield, in his chapter on "Diseases of the Prostate," contributed to Morrow's "System of Genito-Urinary Diseases, etc.," correctly remarks: "All modern works on genitourinary surgery devote a chapter to chronic prostatitis (often miscalled by one of its symptoms, prostatorrhea)." Strictly speaking, however, the latter is not a symptom of the former. Prostatorrhea has no connection whatever with chronic prostatitis (which generally follows a history of urethritis), and occurs in those who have had no venereal disease; furthermore, it represents a functional and not an inflammatory disorder. In an article on "Functional Disorders of the Male Sexual Organs," contributed by Morrow to the voluminous and exceptionally valuable system of genitourinary diseases which he has so ably edited, spermatorrhea is used as "a generic term to denote all abnormal or pathological losses of the seminal fluid." Without detracting in the least from the merit of this article, it seems misleading to the rank and file of medical readers to employ the term spermatorrhea, which, like prostatorrhea, is a true functional process from a pathological viewpoint.

The reader's attention has been called to this phase of the subject in order to enable him to avoid that endless confusion which is found to exist in nearly all of the works on genitourinary diseases by our latter-day recognized authorities. There is no doubt that correct diagnosis of the different chronic deep-seated urethral lesions is to some extent dependent upon a proper classification, quite as much as upon a thorough knowledge of the etiology and significance of the discharge associated with these conditions. And when the fact is considered that these different lesions simulate one another very closely at times in point of subjective phenomena, that

correct diagnosis finally turns upon the differentiation of persistent or intermittent discharge that is to all intents and purposes the same in one process as it is in another—under such circumstances it becomes obvious that proper classification of the chronic functional and organic processes peculiar to the deep urethral region is positively essential to their successful management.

Among the different factors that conspire to defeat the physician's efforts in the treatment of these cases should be mentioned the patient's indisposition to cooperate with his medical adviser, who, with Nature, is perforce obliged to assume entire responsibility. Then, too, the genitourinary specialist is unable oftentimes to utilize in his treatment the advantages that result from rest, isolation, hygienic and dietary precautions, temperance, and abstinence from customary pleasures and other indulgences —all potent agencies in the progress and outcome of disease processes. Surely, he is oftentimes also far from being master of his situation, and has occasion to see failure ahead—and that, too, in the very cases where he would be sure to succeed under favorable conditions.

The processes peculiar to the deep urethra that are characterized by persistent or periodic discharge from the meatus, or appearing in the urine, may be divided conveniently into two types, namely, *organic* and *functional*. In the former are classed chronic posterior urethritis, chronic prostatitis, chronic seminal vesiculitis, and chronic cystitis—processes that follow a history of simple or specific inflammation of the urethra due to the gonococcus, pus organisms, traumatic, and toxic sources. No matter how closely the discharge may resemble that in the functional disorders, it is to be remembered that *pus* is the distinguishing element. The functional disorders include urethrorrhea, prostatorrhea, spermatorrhea, and phosphaturia, all of which result from what may be termed abnormal physiological activity, due to sexual continence, excess, indiscretion, or persistent ungratified sexual desire. At times it is possible to find these functional disorders referable to derangements of the nervous system, from illness, neurasthenia, overwork, persistent worry, etc., in short, from whatever sources are productive of excessive wear and tear on the nervous system. The functional types are noninflammatory, and pus is not present in the discharge, whether it appears at the meatus or in the voided urine.

Let us sum up in a word under what conditions these processes occur clinically: (*a*) One of the organic lesions may exist alone or in combination with one or more of the others; (*b*) the same is true in the case of the functional conditions, though not to such an extent; (*c*) an organic affection alone, or with another, may exist in combination with a functional; (*d*) discharge may be constant or intermittent, and when apparently absent can be squeezed out with the thumb and forefinger passing vertically toward the meatus; (*e*) when a specimen of discharge is not obtainable at the meatus, the urine will always supply the necessary amount for examination.

Inasmuch as the majority of physicians are disposed to turn to the printed page (not having the advantage of visiting hospital and dispensary clinics) when in need of information, it is essential to guard against the mistake so common to our modern textbooks, namely, devoting too much space to accepted facts, as well as treating from entirely different and remote viewpoints diseases that closely simulate each other. We shall, therefore, consider each condition as briefly and as coherently as possible, and in such order as the reader will find convenient when studying the points of resemblance and difference.

I. *Chronic Posterior Urethritis*.—This is the first process listed under the head of organic, and is therefore of inflammatory origin, generally from an anterior inflammation with or without gonococci. The most frequent symptom is a mucopurulent discharge, which appears at the meatus, especially in the morning ("good morning drop"). Some patients do not detect it, except on squeezing. Micturition is frequent, difficult, and painful, with tenesmus varying according to the backward extension and nature of the process. Discomfort is felt at the vesical neck in uncomplicated cases, and rectal examination finds nothing abnormal. Upon irrigating the anterior urethra the first urine voided will be found turbid and shreddy, and the second will be clear; but in cases where the amount of secretion is too copious for the deep urethra to hold between the periods of micturition, the overflow will be caught in the bladder, when, of course, the second urine will be turbid and the pus shreds will appear in the last portion of the urine passed. This is a very important point to observe, as it is necessary to bear in mind that cystitis is not always present when the second urine is turbid.

To confirm diagnosis the microscope must be employed. In uncomplicated cases of chronic posterior urethritis there will be revealed pus in clumps and isolated gonococci or diplococci, columnar and pavement epithelium, collections of mucus, blood corpuscles, and shreds. Naturally, some of these elements may be absent, while it is not uncommon to find a few scattered spermatozoa, and possibly prostatic elements.

II. *Urethrorrhea (ex Libidine Sexuale)*.—Although a functional process, this is the one that closely simulates the above, and for this reason we shall consider its diagnosis in this connection. It is important to bear in mind that it is not dependent upon venereal disease, and frequently is not the result of coitus, but is caused by ungratified sexual excitement, perverse practices, excesses, coitus reservatus, and mechanical irritation.

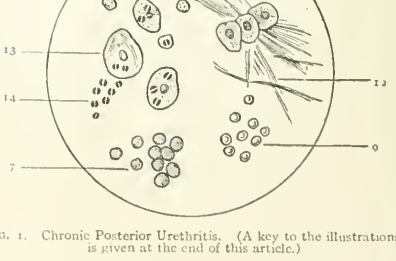

FIG. 1. Chronic Posterior Urethritis. (A key to the illustrations is given at the end of this article.)

The first symptom to be noticed is a thin, sticky, tenacious, and transparent discharge, without odor, at the meatus, especially in the morning. While it may stiffen the linen, it does not stain like the purulent discharge of urethritis. It may follow straining at stool and micturition, but only rarely. It causes no physical, but

oftentimes mental, effects from unnecessary brooding and fear, and produces no change in the sexual function.

Microscopic examination reveals a few flat or round urethral cells, mucous corpuscles, free mucus and shreds but no pus.

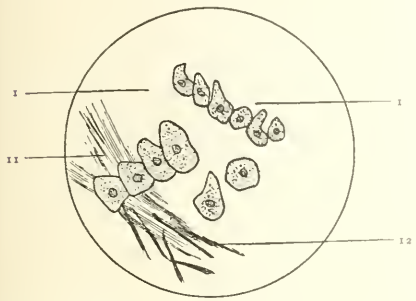

Fig. 2. Urethrorrhea. (A key to the illustrations is given at the end of this article.)

III. *Chronic Prostatitis.*—Commonly termed chronic prostatic urethritis, since the deep urethra and prostate are frequently found to be involved together, is perhaps the most serious disorder of a chronic type that is found in connection with the deep urethral region. But what is of far greater moment, it is the most stubborn and resistant to treatment, and consequently the process in which therapeutic failures are more likely to occur. Whenever the prostate is the seat of an inflammatory process, alone or accompanying chronic urethritis, the physician is likely to find some derangement of sexual function and disturbance of the nervous system. Then, again, in the early stages, patients may not complain of anything outside the urethral and prostatic regions.

In addition to the train of symptoms associated with chronic urethritis, there is pain on erection and at the time of ejaculation, owing to the obstruction that naturally occurs in the prostatic ducts. There is throbbing in the perineum and rectum, with a sense of fullness and weight. Pruritus ani and hemorrhoids may be present. Pollutions and reflex erections are common. Premature ejaculations tinged with blood are the rule, always causative of mental depression, lack of confidence, and aversion to female society, followed by neurasthenia, sexual debility, and fear of marriage.

Rectal examination with the index finger is imperative, and discloses more or less prostatic enlargement, tenderness, induration, and nodules. Irrigation of the anterior urethra back to the bulb should be carried out first; then, if the urine voided after this does not contain shreds, usually comma-shaped (Fuerbringer's), from the prostatic glands and their excretory ducts, the posterior urethra is involved. If these shreds are present in the second portion, particularly in the last few drops, they are evidence of prostatic disease.

The microscope, however, must be regarded as the final court of appeal, and should be employed in every case to supply confirmatory evidence. Chronic prostatitis will reveal pus, isolated and in groups, glandular, desquamative, tubular, or cylindrical epithelium, blood, caudate and round cells, in proportion to the stage of the process. Occasionally, dead and living spermatozoa appear, and prostatic elements. One must be careful not to confound this with prostatorrhea, which we shall now consider.

IV. *Prostatorrhea.*—This is a functional process, pure and simple, not dependent upon specific causes, and is found in those who are continent, if anything, more frequently than in those who present a history of urethritis. The discharge is thin, turbid, milky white, excreted at stool, and at the end of micturition. Subjective disturbance is referable to the perineum and rectum, in the form of a tickling, irritable sensation, although at times there may be smarting, burning, and tenesmus. As patients who have prostatorrhea are generally neurotic, depression of spirits, hypochondriasis, melancholia, or neurasthenia is likely to obtain.

In view of the fact that the subjective phenomena strongly suggest chronic prostatitis, the physician must needs rely upon objective signs in order to confirm the diagnosis. Unlike the urine of prostatitis, that of prostatorrhea is normal, and while rectal examination finds a normal prostate, one should bear in mind that massage forces out an accumulated material. The microscope will supply confirmatory evidence in the form of cylindrical cells, amyloid bodies (not constant), lecithin, and the pathognomonic Boettcher's crystals. A few scattered spermatozoa may be found, but it should not be inferred from these that the vesicles are involved.

Fig. 3. Chronic Prostatitis. (A key to the illustrations is given at the end of this article.)

V. *Chronic Seminal Vesiculitis.*—Notwithstanding the opinion of Fuller, experience appears to substantiate the views held by most authors, that vesiculitis *per se* is rarely met with. In view of the anatomical position of the vesicles and their physiological association with the prostate, the disease is found as an advanced process accompanying chronic prostatitis.

The subjective symptoms are pain and discomfort referable to the bladder, testicles, and end of the penis. At times patients complain of lumbar pain. Micturition may be urgent and frequent, or inhibited. The discharge from the vesicles is thick, gelatinous, glairy, and sticky, and is forced out frequently during defecation and micturition. There is nervous derangement and undue sexual ardor, followed, however, by marked impairment of the sexual function. The external genitals in time become cold, shrunken, and anemic.

The objective signs are more significant and valuable than the subjective. Rectal exploration finds the vesicles enlarged, indurated, and tender to touch, while the perivesicular tissues are likely to be relaxed. The microscope, how-

ever, furnishes conclusive proof of the existence of vesicular inflammation, and when in this thick, lumpy discharge are found an abundance of spermatozoa, dead and alive, it is safe to infer that the patient has vesiculitis. Of course, an accompanying prostatitis and urethritis will reveal their characteristics, which have been enumerated above.

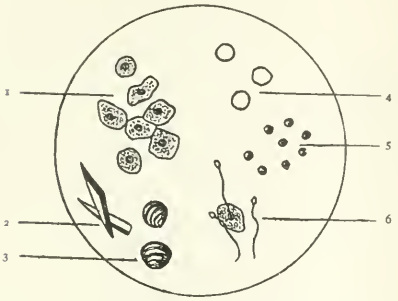

Fig. 4. Prostatorrhea. (A key to the illustrations is given at the end of this article.)

VI. *Spermatorrhea.*—Of all the processes associ- with the urogenital organs, this is no doubt the one least understood. Unfortunately the term is used to designate every species of seminal loss, irrespective of cause. True spermatorrhea, however, should be regarded as a functional disturbance resulting from insufficiency of the ejaculatory ducts. Inasmuch as it is due to a variety of causes, the symptomatology is at times varied. The chief factors are mechanical pressure, extension of posterior urethritis, prostatitis and vesiculitis, and disturbances of the nervous system.

The first symptom noticed is the discharge, which is sticky, and appears after stool and micturition. Patients complain of moisture and dripping, which may not be visible. There is pain in the head, burning of the eyes, and redness of the lids. They are apt to feel drowsy, depressed, and chilly frequently. As a rule these patients are seldom hypochondriacal, but they suffer with shortness of breath, wheeziness (*asthma sexuale*), palpitation, cardialgia, faintness, loss of memory, lack of confidence, and fear of their future health and welfare.

The diagnostic symptom under the microscope is the presence of spermatozoa. Of course, as this process is not inflammatory, it is easily differentiated from sexual vesiculitis by the absence of symptoms per rectum and in the urine.

As a matter of fact, spermatorrhea should be regarded in the light of a symptom and not of a malady. The writer is disposed to agree with Keyes, who terms it "a fetich created largely by Lallemand."

*Chronic Cystitis.*—This very common affection betrays itself at once in the majority of cases by its symptoms. Micturition is very frequent and painful, with extreme tenesmus, and in some cases blood accompanies the last few drops. Pain may extend in all directions from the vesical neck, causing distress in the bladder, scrotum, and rectum. The urine is cloudy and muddy in both glasses, with clumps in the last portion of the second; it is acid, except when alkaline fermentation goes on.

The microscope shows pus in abundance, mucous corpuscles, blood, large flat epithelium, and the other varieties peculiar to the deep urethral region. Gonococci and diplococci may appear also, with detritus and bacteria.

*Phosphaturia.*—While likely to occur during the progress of any of the above, this is more familiarly associated with cystitis, and for this reason can be considered in this connection more fittingly than elsewhere. It is the least important of the processes described, but one that should not be overlooked.

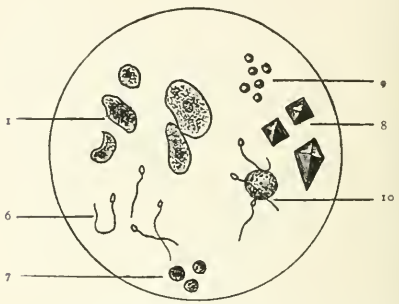

Fig. 5. Chronic Seminal Vesiculitis. (A key to the illustrations is given at the end of this article.)

Phosphaturia is simply an excessive elimination of phosphates, due to an inordinate or excessive wear and tear of nervous tissue. It is found in neurotic, neurasthenic, debilitated subjects. In phosphaturia the urine is alkaline, and for this reason murky and opaque, forming in a cloud-like mass upon standing. It is easily recognized by adding a few drops of acetic acid, which causes the cloudy mass to disappear.

Nothing further need be said, beyond warning the physician to be on the lookout for it, since it acts as an irritant to the mucous membrane and proves to be very depleting to the patient's vitality.

[A key to the illustrations will be found at the end of this paper.]

*Therapeutics.*—The first thing to determine when starting out to treat these cases is the nature of the process, that is, whether it is organic, functional, or a combination of both. Should the physician have to deal with a functional disturbance, it is obvious that results will depend upon an exact knowledge of the cause and the patient's assurance and determination to cooperate with the medical attendant. And since such a patient is likely to be of a neurotic type, more or less hypochondriacal, he will not be disposed to reveal his complete history. It is

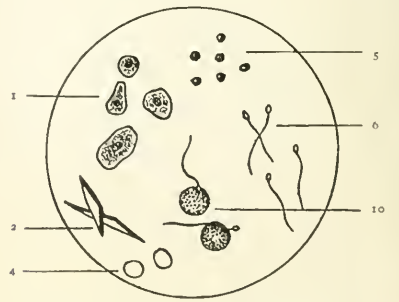

Fig. 6. Spermatorrhea. (A key to the illustrations is given at the end of this article.)

always prudent for the physician, therefore, at the start to gain his patient's confidence; and there is no more certain means to this end than that of sympathy and personal interest in his recovery. Under no circumstances should the physician hold his patient up as an object of ridicule, while, especially in the beginning, talks on morals and sexual perversion are decidedly out of place. Then, with the patient resolved to strive to the utmost to abandon all habits and practices causative of his trouble, and the practitioner earnest in his promise to cooperate, both will work together in harmony, and good results will follow in due course.

In all *functional* derangements of the sexual organs one will find mental and nervous disturbances and some local defects. The mental are generally due to unnecessary fear and brooding, aggravated, of course, by the unbalanced nervous system, over which the patient appears to have little control. Now, there is scarcely need for saying that the mental condition is not a necessary consequence of the disease; besides, it is not serious; in truth, the physician can, and should, inform his patient, with a satisfied conscience, of these facts; and also that this mental derangement is encouraged and increased by injudicious reading, unwholesome associations, and intemperate habits. In short, the sufferer from chronic functional disturbance of the sexual apparatus is responsible to himself for transgressing Nature's laws, and he holds firmly within his grasp the remedy for his own salvation.

The patient should abstain from all sexual and nervous excitants, and leave no stone unturned to restore his lost nervous force. Abstinence from tobacco, alcoholic drinks, worry, overwork, and extreme mental effort is imperative. A congenial occupation, regularity in his mode of life, with good habits in a wholesome environment, are all essential and productive of positive and beneficial results.

Medicinal agents hold a subordinate place in the therapy of all functional disorders. Some cases will require tonics, such as iron, strychnia, malt, and the animal extracts, while others will call for sedatives, like the bromides and valerianates, isolation, and rest. Exercise, diet, hydrotherapy, and electricity at times, also fill an urgent want.

When the physician is assured that his patient has conquered both the direct and contributing causes of the nervous derangement, the most efficient means of bringing about the cessation of discharge and of restoring normal physical, mental, and sexual well-being will be found in the skillful and judicious passage of cold steel sounds, alternating with gentle but thorough massage. Of course, the last maneuver will not be indicated in urethrorrhea and phosphaturia. In all cases there is likely to be present sluggishness of the bowels and fecal impaction in the rectum. Mild laxatives should be used in preference to drastic purgatives for the former, and cool enemata for the latter, in order to remove the impacted mass, to promote tone in the organs and muscles of the deep urethra, as well as to relieve congestion.

It is to be hoped that the physician will not allow himself to fall into that very common and unfortunate error made by followers of the older teachings, namely, that functional sexual disorders are the result of imaginary ills, and are not traceable to any well-defined psychical cause. For it is a fact that the influence of the mind is a formidable factor in all deviations from normal well-being; and if the laity were as cognizant as physicians of what constitutes the absolutely real ills in distinction from those in which the imagination is the chief determining factor, there is little doubt that many of us would be forced to seek sustenance "in pastures new and green." The practitioner knows full well that in the treatment of physical ills proper respect for and attention to the mental are oftentimes the essentials, if not the secrets, to success. As hinted at above, these cases require kindly interest and sympathetic appreciation; and, even if the medical adviser considers they do not need active medical treatment, he wrongs himself and his patients whenever he is blind to (and withholds) the necessary sound advice concerning the causes, nature, and consequences of their troubles.

In the treatment of the *organic* processes the personal equation does not call for anything like the important and serious attention so essential to the functional disorders. The former, except when associated with the latter, must be treated just as any inflammatory condition, although the destruction of the gonococci, or the diplococci, is as essential a factor in the therapy of chronic as it is in that of acute conditions.

As the plan of treatment necessary to pursue is practically the same for all the organic lesions enumerated above, the reader will find it an advantage to be familiar at the start with the following principal remedial mea ures indicated during the therapeutic management of each process:—

1. Gradual dilatation with steel sounds.
2. Copious irrigation with dilute solutions (pure astringent, pure antiseptic, or antiseptic and slightly astringent).
3. Topical applications with concentrated solutions (same as in 2).
4. Internal urinary antisepsis.
5. Meatotomy when the meatus is constricted, to permit proper dilatation.
6. Massage of prostate and seminal vesicles.
7. Administration of oleoresins for acute exacerbations and relapses.
8. Hydrotherapy, electricity, medicinal tonics, reconstructives, etc., p. r. n.

As the majority of patients seek the physician's advice during what appears to be a relapse or acute exacerbation, it will be expedient to administer a good reliable balsamic at the start, and the one to be preferred is oleum santalum, in ten minim capsules after meals and at bedtime. An efficient adjuvant to the oil and a necessary agent preliminary to the employment of those local measures, so indispensable in the treatment of all cases, is a reliable urinary antiseptic.

Under this treatment discharge and inflammation will be reduced to a minimum, while the urine will be rendered sufficiently clear and sterile. When this has been accomplished, resort may be had to local measures. Now, it is at this stage that the operation of meatotomy suggests itself in a large proportion of cases, and when marked constriction exists there is no procedure that is more certain to pave the way to success. It should be said, however, that, although a minor operation, meatotomy must be done in strict accordance with Otis's rule, under antiseptic precautions, and by no means regardless of the physiological necessity of a certain amount of narrowing at the anterior end of the urethra to ensure proper removal of the urine. Careless,

ness in the character and size of the incision will not only affect the propelling force, but will prove a constant eyesore to the patient in after-life.

In cases of chronic prostatitis and seminal vesiculitis it is better to apply massage before dilatation and irrigation, in order to remove the most formidable source of irritation to the urethra. But the physician should be well acquainted with this maneuver, and be able to discriminate between the prostatic lobes and seminal vesicles, before he can hope to confer the benefit which this remedial measure alone possesses.

As the technique of massage, or stripping, is no doubt familiar to the reader, it will be sufficient to recall only a few essential precautions. In the event of both the prostate and vesicles being involved, they should not be massaged at the same time, but preferably on alternate visits. The patient should call with a comfortably full bladder and empty rectum. He should void a small amount before and the remainder after the manipulation. It is advisable to caution him also to breathe naturally, so as to avoid straining, and to relax the deep urethra and surrounding tissues during the massage. The physician should manipulate with care, depending upon the cushion of the index finger, moved in the direction of the urethral end of the ejaculatory ducts, to remove the inflammatory product. It will be necessary to learn from experience how much massage to employ and how often. Usually from two to five minutes on each side every two to seven days will answer in the great majority of cases.

After massage gradual dilatation, followed by copious irrigations, will be in order; and when it is clearly understood that in the chronic processes the deeper structures are involved, that the follicles, glands, and crypts are impacted with mucopurulent and other material, it becomes obvious that dilatation must be carried to the maximum calibre of the urethra, in order to ensure not only the emptying of these traps, and the removal and absorption of all infiltrated morbid material, but also the restoration of normal circulation, on which *vis medicatrix naturæ* must needs depend in the work of repair.

The steel sound should be followed at each visit by copious irrigation through a soft flexible rubber catheter. Solutions of permanganate of potassium, 1 to 3000, and of nitrate of silver, 1 to 4000, have certainly stood the test of time, but the recently introduced silver derivatives possess the same virtues without the irritating effects of the permanganate and nitrate. These salts are practically non-irritating, and can be used in any strength. From a pint to a quart of solution, 1 to 3000 and stronger, acts as an efficient antiseptic, hastens the removal of all inflammatory products, and encourages repair of tissue. For topical applications in cases that have resisted other remedial measures, such as localized erosions and granulation areas, a few drops of a strong solution may be instilled through an Ultzmann-Keyes syringe, which is lubricated with glycerin, and passed behind the compressor muscle. This, while productive of tenesmus for a short time, proves very beneficial in some cases. The same solution may be used for applications through the endoscope.

A word should be said concerning the importance of urinary antisepsis, which is an essential factor to successful treatment in many of these cases. In these deep-seated chronic lesions of the posterior urethra the urine often acts as a source of irritation and infection. It has therefore been a custom to administer internally such remedies as would be eliminated by way of the kidneys and would sterilize the urine and convert it into an antiseptic fluid, thus supplementing local medication. For this purpose hexamethylen-tetramin has been largely employed of late. As is well known, this drug sets free formaldehyde in the urinary passages, and the urine thus becomes charged with one of our most potent antiseptics. In place of this preparation I have more recently resorted to the anhydromethylen citrate, which, judging from my experience, acts more efficiently and agreeably and can be continued for longer periods without causing irritation. It is very pleasant to take, and I have noticed in some instances that it promptly relieves painful micturition. Whether this be due to a special analgesic action, as has been noticed by others, I am not prepared to say. The ordinary dose is 15 grains, three or four times daily, taken in at least one-half glassful of water.

In suitable and properly selected cases, cold baths, douches, surf and still-water bathing prove very beneficial. Electricity, too, should be employed, if called for, while in some cases psychical treatment meets with ready acceptance and is productive of wholesome results. The personal equation should never be lost sight of, as the physician will be forced to depart from all routine measures in occasional instances.

A few typical cases are subjoined in order to illustrate the plan of treatment described above:

Case I. A single man, aged thirty, cook; habits and mode of life, temperate. Previous history negative up to June, 1902, when he sought the writer's advise for what he considered was an attack of gleet, following his first gonorrhea contracted in February, 1902, without complications. Physical examination revealed chronic anterior urethritis (and a patch of granulations in the urethra), but this process yielded to appropriate treatment so that he was entirely well on September 1. His next misfortune came on April 13, 1904, in the form of syphilis, for which he received the necessary aid, and in three months became apparently well, but continued treatment. On April 13, 1905, eventful as the first anniversary of the day he learned he was a victim of specific disease, while in the best of health, he noticed a thin, glairy discharge at the meatus; and finding it to be recurrent, applied for advise on May 3rd, when there was some burning and uneasiness in the rectum. He noticed, too, a decline in his sexual ardor, and was somewhat depressed. Sexual and alcoholic indulgence provoked no obvious change in his symptoms.

In view of his previous history he was at once put on oil of sandal wood, combined with a urinary antiseptic, and cautioned to observe the same suggestions as in his previous urethritis.

The fourth day found him much improved, so that the anterior urethra was irrigated and the rectum carefully explored. Both lobes of the prostate were found enlarged and indurated; the vesicles normal. Massage expressed nothing through the urethra, but the last urine contained fully a teaspoonful of secretion, which, when submitted to microscopic test, revealed the elements represented in Plate III. It was noticeable, too, how scanty these were in proportion to the abundance of expressed product.

Treatment with the urinary antiseptic was com-

bined with massage every third day, till June 3; then gradual dilatation with steel sounds, followed by protargol irrigations (1-5000) every other day up to June 17, when he was discharged at his own request, apparently cured. It should be said, however, that the patient was unemployed during the treatment, and took every precaution to hasten recovery.

Case II.—A short but physically strong man, aged 41, single; occupation, mechanical; habits, exemplary; surroundings, congenial. Previous history, negative up to three years ago, when he contracted gonorrhea that terminated in gleet for many months and disturbed the nervous system markedly, but not seriously. Fearful of another attack, and being congenitally neurotic, he resolved upon a life of continence, and continued association with a young lady for whom he appeared to have a Platonic regard. About two years ago he began to notice some sexual decline, and soon found that erections were at times productive of involuntary emissions. He became more nervous and frequently depressed, and any attempt at sexual gratification proved a failure and increased the depression, nervous irritability and indifference to all female society, including that of the one above mentioned. He sought medical aid of all kinds, even that of the advertising fake. His many repeated failures in obtaining relief, added to his inability to abandon his calls on the young lady, whose companionship for some time had proved more exacting than helpful, conspired to make him a pronounced neurasthenic at the time he came under the writer's care, in September, 1903.

The history of the case can be told in a word. Periodic discharge at the meatus of thick, starchy, gelatinous, glairy material, noticeably after straining at stool, or at the end of micturition; nervous system easily upset, with a disposition to brood, borrow trouble, and to magnify the dark side of life; the face had an anxious expression. He went to the Massachusetts General Hospital for expert opinion and advice. He was told he had heart disease, and later when he found his voice affected he was asked by a reputable practitioner whether he filled the position of towncrier or sold vegetables on the street? The fact is that he had palpitation, which oftentimes affects the sexual neurasthenic, and what, to those unfamiliar with the symptoms of spermatorrhea, seemed like partial aphonia, was nothing more or less than "asthma sexuale," symptomatic of which are shortness of breath and wheeziness. At times he noticed impairment of memory and lack of self-possession.

Under the microscope the discharged products contained the elements seen in figure 5.

Treatment was begun at once by placing the patient under a urinary antiseptic to render the urine sterile and bland. Massage was employed every five days for four months. Then the cold steel sound was used, at first regularly every week, then every two or three weeks, and allowed to remain in the urethra from five to twenty minutes. The result has been satisfactory in every way, especially of late, since he succeeded in isolating himself from the society of females and in abandoning all thoughts of and interest in them completely.

It will be observed in the above that the symptomatology of each organic disorder is coupled with that of the functional which closely resembles it. The writer has carried out this plan in order to help the reader in differential diagnosis, with which he must be unmistakably familiar before he can hope to be successful in his treatment.

The majority of physicians find themselves at sea in the management of these processes, and when they consult the literature of the subject for the desired help are confronted with such a crazy quilt of confusion that they are likely to give up in despair. The writer feels confident that in the above arrangement he has simplified the problem which has long been a veritable *pons asinorum* to the rank and file of medical men, and trusts that the reader may feel equally confident that as much has been done for the solution.

## EPILEPSY THE STRANGEST DISEASE IN HUMAN HISTORY.*

By WILLIAM P. SPRATLING, M.D.,

SONYEA, N. Y.

MEDICAL SUPERINTENDENT OF THE CRAIG COLONY FOR EPILEPTICS; PRESIDENT OF THE NATIONAL ASSOCIATION FOR THE STUDY OF EPILEPSY AND THE CARE AND TREATMENT OF EPILEPTICS; MEMBER NEW YORK ACADEMY OF MEDICINE; AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION; AMERICAN NEUROLOGICAL ASSOCIATION.

More than twenty-three centuries ago Hippocrates wrote an astonishingly accurate clinical description of the "sacred disease," as epilepsy was frequently called at that early day. So much obscurity and mystery, so much that was indefinite, intangible, and seemingly unsolvable, has surrounded this extraordinary malady for thousands of years that until recently we seemed to accept the general decree of its almost complete hopelessness so far as absolute cure was concerned, and did but little to offset this ancient conclusion.

In 1867, a distinguished German who had large sympathy for afflicted mankind began to demonstrate with four epileptics in a single cottage what could be done in a practical way for this class. Twenty years later the splendid example set by Pastor Von Bodelschwinde at the Bielefeld Colony in Germany, reached out across the Atlantic, and it is to our great credit that in imitation of it, State after State in the United States is creating colonies and special hospitals for as many as possible of the 150,000 epileptics resident in the northern half of the Western Hemisphere, 14,000 to 15,000 of whom are to be found in the great State of New York.

*The "Epilepsies" Instead of "Epilepsy."*—It is an indisputable sign of scientific progress that the time has forever gone by when we can speak simply of "epilepsy," and particularly when we can say "This man has epilepsy—give him some bromide."

We now make repeated and thorough physical, clinical, and microscopical examinations of cases of epilepsy to determine if possible the cause or causes of the disease before any treatment is applied; and we must now perforce speak of "the epilepsies" instead of "epilepsy," for the types and subdivisions of the disease are exceedingly numerous.

*The President's Address before the Fifth Annual Meeting of the National Association for the Study of Epilepsy, etc., held at the Academy of Medicine, New York City, November 29, 1905.

Fancy a surgeon applying a poultice to remove a splinter, or a lotion for the extraction of a piece of steel. So with epilepsy. The physician seeks to elimiate, to take away the cause, root and branch, even though it takes years to do it—for no case of epilepsy can be cured in less time than two or three years—and the symptoms complex that we too often regard as the disease will disappear.

*What Are the Causes of Epilepsy; Are they Always Discoverable?*—The causes of epilepsy are many and, unfortunately, they are not always discoverable; but they are discoverable in a far greater proportion than we often think, because the treatment of the disease to this time has so often been so absolutely, so unscientifically, so dogmatically empirical that the cause or causes have gone largely unstudied. We have dosed the epileptic without rhyme or reason, consequently we have too often failed to cure. We have literally saturated him body and mind with a single drug that in my judgment never yet cured a single case of the disease, and which in my fifteen years' experience in the treatment of some 2,500 cases, I have for the first time yet to prescribe for its relief to the point of feeling that through its use alone I could effect a cure.

The bromides have the power to palliate the severity of epileptic phenomena in selected cases, and even to arrest the attacks for long periods; but I do not believe they possess in themselves the inherent power to cure.

*What Is Epilepsy?*—Clinically, and from the more important viewpoint of treatment, we have learned much of epilepsy in the past twelve to fifteen years. But when we come—and I say this with the deepest sense of regret—when we come to the final analysis of our actual knowledge of the intricate biologic problems that lie inherent in the cells of the brain, and that under their own, or under associated, immediate, or remote stimuli are capable of inducing epileptic phenomena, I deplore the fact that we are still in semi-darkness.

But the light is breaking. More concise and widespread attention is being given to its etiology, and this attention is sure to bear fruit in time. As smallpox under Jenner's wonderful discovery lost much of its terrors, diphtheria under Behring's antitoxin was robbed of its high death rate, and yellow fever under our own confrères, Reed and others, seems destined to lose its demoralizing terrors, so will epilepsy yield up the long-kept secret of its cure.

I point to-day to the indisputable fact that the way is open, that the cause of neurology as represented in the need for a better knowledge of the etiology of epilepsy is pressing, and that the innermost problems of this fearful disease must sooner or later lie revealed to the patient, tireless, persistent efforts of a particular class of investigators we, in the United States, need to publicly encourage.

As a nation we are exceedingly wise and wonderful in many things; in other things we are almost without a vestige of wisdom. Witness the honors paid medical men and discoverers of great scientific truths in the countries of Europe; then turn the page and witness on the other side the complete lack of recognition by our own Government, State and Federal, of the great attainments of many American physicians, surgeons, philanthropists, and scientists, past and present. For this state of affairs we have ourselves most largely to blame. Let us rectify it if we can, and because it is right that we should do so, in time I am confident we can.

Epilepsy is the strangest disease in human history. It stands incomparably alone. It respects no race, no class, no age, no occupation. It afflicts the poverty-stricken wretch in the hut as it does the monarch on the throne. It may be in the infant at the moment of its birth, or it may be delayed until extreme old age, even ninety years or more.

Its attacks may come with lightning-like rapidity, striking its victim to the earth in the twinkling of an eye, or they may be preceded by warnings of days or weeks. It may destroy as quick as a flash the conscious life of the individual, leaving him absolutely undisturbed so far as his physical composure is concerned, or it may wholly destroy his physical composure and leave him in almost complete possession of his mental faculties.

Some forms of it may cause the victim to suffer many attacks daily from birth until senility, without any appreciable impairment of the faculties of the mind; other forms may destroy the mind in a few years.

That it is a disease of the brain no one of this age will probably deny. That it may have its origin in some cases in causes remote from the brain, cannot be denied. That its causes are multiform seems easy of proof. Some cases are unquestionably due to gross organic causes; others to organic causes the minute nature of which we have yet to determine, while others still are due to deep-seated errors in metabolism; to wavering, fluctuating factors that destroy or temporarily disintegrate or undo the biochemical relations of the organic elements of the body.

Its attacks may vary anywhere from two or three in a long life, or they may occur hundreds of times in a single day. They may occur only by night, or by day, or both; or again, they may never appear except when the patient sleeps, no matter whether it be night or day.

We have not yet reached a point where we can stand and declare a satisfactory prognosis of the many forms of this strange disease. So far we have based our knowledge of it upon symptomatology, but we are just now beginning to understand something of its etiology; not in the refined sense in which we must ultimately understand it before we can thoroughly know the disease, but in a more or less promising form.

The public care of epileptics in this country and abroad during the past 15 to 20 years, under the Colony System, has taught us one great truth, namely, that in the treatment of this disease we must never neglect to treat the individual first, for every malady is modified by individuality. To fail to do this is to confine our efforts to the treatment of a symptom, and not the treatment of a disease.

Had anyone stood in your presence 25 years ago and told you that to-day tuberculosis would be a curable disease in 25 to 30 per cent. of all cases, you would have received the statement with great incredulity—perhaps with positive disbelief. But to-day such a statement can be proved to the satisfaction of whoever is willing to believe. We have only to witness the splendid results attained in an open air, entire bodily, entire individual treatment of this disease, during the last fifteen to twenty years, to understand how true this statement is. The demonstration now in progress in this city wonderfully illuminates the splendid fight against the great white plague.

And I confidently make the prediction to-day that when we shall finally come fully to understand the necessity of treating the epileptic bodily and as an individual, as a preliminary step in the more specific treatment of his disease, and after we shall have pursued our laboratory methods to the point where we need to pursue them in order to get at a closer

knowledge of the true etiology of epilepsy in its various forms, we will cure epilepsy as often as insanity is cured to-day, that is, in from 25 to 30 per cent. of all cases. A great lesson we have yet to learn is that freedom from epilepsy is often a matter of right living.

It is most gratifying to this Association that several states in this country have taken up the question of making public provision for their dependent epileptics. But it is a sad commentary that there are no suitable institutions to be found in the United States to-day where epileptics with means—those who are not poor to the point of needing to become state charges—can go and be treated for their disease. The home treatment of epilepsy is too often unsatisfactory for the very good reason that the absolute control of the patient which is essential to success cannot there be obtained. I do not for a moment claim that the colony system, or any institutional system, is a sovereign remedy for the successful treatment of all cases of epilepsy. But I do claim that a colony system such as is being maintained, and particularly such as is being aimed at, at Sonyea, in the State of New York, has shown, and will further show, its capicity to bring about greater improvement in the mental and physical condition of the epileptic than any system heretofore devised.

The great work of this Association in the future should be to encourage other states in the United States to create colonies or institutions for the care and treatment of epileptics; in short, to carry out the objects set forth in its by-laws and which are as follows:

OBJECTS OF THE ASSOCIATION.

1. To promote the general welfare of sufferers from epilepsy.

2. To stimulate the study of the causes and the methods of cure of this disease.

3. To advocate the care of epileptics in institutions where they may (a) receive a common school education; (b) acquire trades; (c) be treated by the best medical skill for their malady.

4. To assist the various states in America in making proper provisions for epileptics.

There is still a vast uncultivated field for the workers of this body—a work destined to help a people already too long neglected.

---

## BACTERIA IN THE NORMAL ADULT INTESTINE, WITH SPECIAL REFERENCE TO THE ETIOLOGY OF ENTEROTOXISMUS.*

By HARRIS A. HOUGHTON, A.B., M.D.,
NEW YORK.

If the rôle of enteric intoxications in the etiology of nephric, hepatic, and arterial scleroses is to be appreciated—and, according to Metchnikoff, Bienstock, Rogers and others, there *is* a causal relationship—and if the surgeon is to have a working conception of when and where he can safely enter the intestinal tract, a study of its bacteriology is of prime importance. This study should include not only the relative and absolute bacterial content at different levels, the varieties usually present, and the normal volumetric fluctuations, but also a knowledge of the factors which diminish or exalt their virulence, promote or retard their propagation, and the chemical methods employed by the organism to detoxicate the products of their activity.

In forming such a mental picture, it will be seen that areas, here and there, fail to develop a clean-cut outline and clear detail. Instances can be cited. Assuming that a complete analysis of the crystallized protein molecule, showing the relations of the atomic groupings to each other and in graphic terms will soon be completed, it cannot be said that the lines of cleavage under different disintegrating influences always remain the same. Is it possible that atomic groupings of two or more protein molecules can be synthetized into new and saturated molecules? Can the chemistry of the test-tube be made to coincide with that of the duodenum? The physiological chemist must answer.

The bacteriologists are still unagreed as to the immutability of microbic species. When this point alone is determined finally, the whole subject of enteric putrefactions and fermentations will either be greatly simplified or further complicated. There is much to learn of the symbiotic influences which bacterial species exert upon each other; or, to speak of it in another way, there is much to learn of the significance of microbic associations, especially in those combinations in which the thermophilic and anaërobic organisms seem to play an important part. Vaughan and his pupils are now investigating the biochemical composition of the *Bacillus coli communis* and the environment necessary for the release of its cellular toxins. This line leads directly to the domain of natural and acquired immunity and all its peculiar problems.

From the viewpoint of the physiologist, more knowledge of the laws which govern the absorption of peptones and products of molecular disintegration and synthesis in the intestine is much needed. What factors accelerate or delay such absorption? With delay are the proteolytic enzymes capable of breaking down the protein molecule *in situ* into molecules smaller than those of peptone, and of a toxic nature? Under what circumstances may enteric poisons pass the barrier usually offered by the liver and become a greater menace to the whole organism? Are normal enteric bacteria essential to the maintenance of life in the higher organism, either in the preparation of foodstuffs for absorption or in preventing the aggression of more pathogenic bacteria? On the other hand, is their presence the determining factor in the invasion of certain enteric diseases, such as typhoid fever?

Such interrogations plainly show how limited is the present field of view, and how interdependent are medical sciences for progress. Much of the simpler and more fundamental work has been done and the evidence is ready for collaboration. The first point which naturally presents itself is a quantitative estimation of the bacterial content of the adult intestine at different levels and its variations in health. This is the subject to which I would direct your attention to-day. Paralleling this is one of equal or even greater importance, involving the study of the character of the intestinal flora, both facultative and obligatory forms, and how they are affected by diet. Julius Mannaberg[33] has reviewed the literature on this subject, and names nearly thirty species of bacteria and blastomycetes which have been found in the human intestine. Metchnikoff[38] has recently completed the work to date. Lembke[29] alone has cultivated forty-one and Matzuschita[36] forty-four varieties. While for the sake of reference, many have been classified as independent species, their right to such a position is very doubtful.

Before determining what may be considered normal when speaking of the bacterial content of the intestine, it will be wise to consider a question originally propounded by Pasteur[46] in

*Read before the Queens-Nassau Medical Society at Jamaica, Long Island, N. Y.

1885, and to which reference has been made. Basing his opinion on vegetable experimentation, Pasteur expressed himself as believing that bacteria were essential to animal life. He suggested the experiments carried out many years later by Schottelius [48-51] of hatching and rearing fowls in aseptic surroundings, feeding them sterile food, and allowing them to breathe sterile air. Chickens so treated lived only 17 days, and those which had lost weight during this régime quickly gained when allowed a normal germ-laden diet.

Prior to this, Nutall and Thierfelder[43-45] had tried similar experiments on guinea-pigs with signal success. The experimental animals developed as rapidly as control pigs from the same litter, reared normally. Confirmation of success was obtained on autopsy, when the intestines were found to have sterile lumens. The real value of such observations has been questioned, and with reason, for it is only with the greatest care and patience that they can be brought to a successful conclusion. Experimental animals live under very restricted surroundings, more onerous to fowls than to guinea-pigs. Both are in the main herbivorous, and as a broad principle it has been found that the intestinal tracts of herbivorous animals are often sterile, even at the height of digestion, while in carnivorous animals, a similar condition rarely, if ever, occurs. It may be possible that chickens do not thrive without bacteria any more than they would without gravel, and that the same rule does not hold for higher animals.

It seems as if the weight of evidence rested against Pasteur's assumption in the light of some observations made by Levin, the Scandinavian physiologist. Levin[30-31] stated that the feces of animals indigenous to that portion of the Arctic region in the neighborhood of Spitzbergen were usually sterile. Food and water bacteria of all kinds, and particularly the *Bacillus coli communis,* having fewer animal hosts, are prevented from ready propagation by the cold, and are therefore less ubiquitous. This was questioned by Cheauveau (quoted by Bienstock,[4] observations unpublished at that time), who joined the Princess Alice expedition to the Arctic regions with the Prince of Monaco in 1899. Levin replied by recording in detail 480 examinations made on the feces of 53 different kinds of animals, fish, and birds. It is perfectly reasonable to assume that if Arctic animals were dependent upon the establishment and maintenance of an intestinal flora, it would have been revealed in the feces. Aseptic intestinal tracts in the torrid and temperate zones are probably laboratory curiosities, and if by chance they do occur we may look for compensatory reactions on the part of the organism.

Bacteria not being essential, we are in a position to draw an arbitrary line of distinction between what may be considered normal and what abnormal when speaking of the occurrence of bacteria in the intestine. The following will undoubtedly help: *Any bacterial content from complete negation to saturation may be considered normal when the numbers, virulence, and microbic association fall short of overcoming adverse influences provided by nature for preventing the formation of substances detrimental to the welfare of the whole organism.* If bacteria do aid digestion, and form substances which are utilized by the animal organism, that may be considered normal. But if the environment becomes more favorable for the bacteria, and their numbers and virulence increase beyond the point indicated, that would be considered abnormal. This distinction accepted, it is obvious that the urine of perfectly healthy individuals should be practically free from ethereal sulphates, assuming, of course, that the formation of their bases is impossible in any other place than the enteric tract or in any other manner than the one under discussion.

This definition cannot be allowed to pass, however, without further explanation. It is quite probable that a state bordering on enterotoxismus or enteric intoxication is possible only by the constant ingestion of microorganisms with the food and a marked decrease in natural protective agencies. Take this fact in conjunction with another, that if we were to look for a perfectly normal man, we would hardly expect to find him in the adult New Yorker, who is in a continuous struggle against sclerosing organs, warped digestion, and sensitive prostate; whose bread is largely prepared in cellars; whose meat and milk are transported over miles of dusty railroads; whose food is subject to adulteration; and whose resisting powers are impaired by unnatural habits. But we should be obliged to turn back for a few centuries and seek out a primitive man from a primeval forest. Such an one ate his food as he killed it, drank water rarely contaminated, and moved from place to place with few associates as fancy dictated. He was untrammeled by the necessity of preserving his food in cold storage or of caring for his feces. So far as absence of microbic hosts allowed, conditions approached those which now exist in the Arctic regions. This primitive man could have ingested but few microorganisms or passed very little indican in his urine. If in the case of the latter-day urban, nature's protective agencies still protect, even with an enormous number of germs in the intestinal tract, their presence may still be considered normal.

Four methods have beeen utilized to determine the bacterial content of the intestine. The first of these is microscopical and cultural examination of the feces. Antony von Leeuwenhoek, F.R.S. (1632-1723),[52] that quaint Dutch character, who was a messenger to the town council of Delft, first described in the feces what he called animalculæ, afterwards named infusoria by Wrisberg. In his odd moments, von Leeuwenhoek made himself a microscope and subjected various animal and vegetable tissues to examination. He observed in saliva obtained from the mouth of a young lady who was "accustomed to keeping her teeth clean," animalculæ similar to those which he saw in feces, and said that they danced about "in a manner very pleasing to behold." Franz Simon[65] holds the credit of being the first to examine the feces chemically. No systematic bacteriological researches were made until the latter part of the seventies, when Szydlowski,[62] Nothnagel[42] and Bienstock (particularly the latter) began to attain the scientific accuracy which would be demanded to-day. But to Vincenz de Giaxa[16-17] of Naples belongs the honor of first showing that the enteric flora differs both quantitatively and qualitatively at different levels. During the past two and a half decades, the bacteria of both human and animal feces have been subjected to the most careful scrutiny, and at one American university it is the custom to require students to thus examine their own excreta for practice.

Some exceedingly interesting and even somewhat fanciful conclusions have resulted. For instance, Strasburger[58] declares that one-third of the fecal material after drying is bacterial remains. With the ingestion of easily absorbed food, one-half of the total nitrogen of the feces is of bacterial origin, and he places the total number of bacteria excreted daily by man at 128 billions. Klein's[23-24] estimates are lower, at eight billion eight hundred million. Woodward,* [66]

*Woodward's observations, recorded in 1878, are interesting in the light of present knowledge (the italics are

Nothnagel,[42] Uffelmann,[64] and Escherich,[12] while not venturing exact figures, say that the fecal bulk consists of bacteria. Others, such as Eberle,[11] Hellström,[21] Hehewerth,[20] and de Lange,[26] made counts by various methods, and were rewarded with varying results. Winterberg[65] introduced the use of the Thoma-Zeiss instrument for this purpose.

Many things must be considered in an effort to harmonize the work of these different investigators. In the first place Winterberg[65] and Hehewerth[20] have shown that on the same specimen, counts made with the Thoma-Zeiss and by cultural methods differ, the latter showing many less than the former. Strasburger's[58] method of approximating the number by weight has been criticised. When counts are made by cultural methods, only a very small percentage of the bacteria grow. This conclusion has been unanimously reached by Hellström,[21] v. Mieczkowski,[37] Eberle,[11] Sucksdorf,[61] Fürbringer,[14] Stern,[57] Gilbert and Dominici,[18] Salkowski,[47], Kumagawa,[27] Sherwald,[54] Hammerl,[19] and Kuisl.[26] The last two named blamed the culture media, but variations have failed to produce better results. There are certainly present in the feces some living species which are rarely grown. Two are known. Bienstock[3, 4] has lately shown that the *Bacillus putrificus* and a common inhabitant of the bowel is an exquisite anaërobe, and can be cultivated only when uncontaminated or when the symbiosis of aërobic organisms has been very carefully regulated. This organism doubtless causes the first break in the protein molecule, further disintegration being completed by members of the colon group. Another species not often cultured belongs to the thermophilic group of bacteria and they form a goodly percentage of the fecal flora. They are not culturable in temperatures ordinarily attained in the incubator. Their significance in intestinal putrefactions is not known. Klein[24] and Eberle[11] have shown that from 90 to 97 per cent. of all fecal bacteria are dead. The peculiar appearance of many under the microscope has been the subject of much comment. Their condition is such as would be designated by Grover Cleveland as one of "innocuous desuetude." In some the propagating power is materially reduced, while in others the cytoplasm has actually been dissolved out, leaving but the cell wall behind,with an appearance analagous to the "shadows" of red blood cells sometimes seen in the urine of nephritics. In other words, they have succumbed to the adverse conditions in their recent environment.

In judging of the numbers, varieties, and distribution of the germs of the intestine, what value can be placed upon the bacteriological examination of the feces? Very little, except stringent limitations be granted. Strasburger[59] has shown that the ingestion with the food of a large number of colon bacilli does not materially increase the bacterial content of the feces. Schütz[52] experimented with the vibrio of Metchnikoff, a species not usually met in the intestine and yet easily recognizable. After ingestion, it could not be recovered from the feces except in marked diarrhea. Escherich[13] has shown that qualitatively the bacteria of the feces may differ greatly from that of the duodenum, cecum, and colon. But following the conclusions of Escherich, Nencki,[39] and others, it may be said that a large number of a given species could not flourish for any length of time in the intestine without disclosure in the feces, although bacteriological examination of the feces will give no certain clue to either the numbers or distribution at different levels of the canal above.

Bacteriological investigations of the gastrointestinal tube of cadavers has given disappointing results. The notable lack of harmony again calls attention to the sources of error mentioned in connection with the examination of the feces, with other sources peculiar to the conditions. Examinations conducted immediately after death produce different results from those after the lapse of many hours, or when the sickness preceding death has been a wasting one. When the restraining influences of vitality are nullified, the *B. coli communis* immediately becomes a saprophyte, driving many bacteria from the field of activity. Cushing states for the late Dr. Livingood[8] that he found the duodenums of cadavers usually sterile when food was absent, but when food was present the results were so conflicting that the method of investigation was abandoned. Smith and Tennent[56] arrived at the same conclusion, but made particular note in one instance of a cyclist who had been killed, and they confirmed their observations on dogs. No details were given. Gessner[15] examined the intestines of 18 cadavers, death coming to many from accident, but he made no note of the stage of digestion, and did not examine by means of cover-slips. Dallemagne[9] reports the examination of 20 cadavers, but the work was mainly for qualitative purposes. Gilbert and Dominici[18] made counts of the bacteria found at different levels, and averaging observations made on animals with those of two cadavers, present the following figures: 50,000 per milligram in the stomach; 30,000 in the duodenum; 100,000 in the neighborhood of the ileocecal valve; from 25,000 to 30,000 in the colon, followed by a slight fall in the rectum. They estimate the whole number in the gastroenteric tract of the healthy adult at 411,000,000,000, which could be reduced to some extent on a milk diet.

In judging of the value of researches on animals, another difficulty presents itself in the discrepancy which exists between the habits and diets of animals and those of man. Cushing and Livingood[8] examined 27 dogs and 8 rabbits. They found that the duodenum, jejunum, and upper part of the ileum were nearly always sterile after a fast. The largest number of bacteria was found in the cecum. Ballner[1] examined six dogs. Dyar[10] has shown that the duodenums of rabbits are often sterile even at the height of digestion, and that the feces of goats and rabbits are often in a similar condition, partly accounted for by the character of the diet.

Reports of observations made on living human beings, either on the operating table or after the establishment of fistulæ, are of course more rare. It is obvious that in either case only one area can be examined at a time. Where patients have been subjected to preparations for an operation, the usual period of fasting has a marked tendency to reduce the bacterial content above the ileocecal valve. The causes which lead to operations are usually sufficient to disturb the normal bacterial balance. In the case of fistulæ it cannot be said that the conditions are entirely normal. Hewetson[22] made a large number of observations on the operating table, the patients in every case having fasted from five to eighteen hours. In cancer of the esophagus, the stomach was sterile in 50 per cent.; in gastric dilatation without ulceration, the stomach was sterile in 83 per cent., and the jejunum in 82 per cent.

mine: "My own observations have satisfied me that a large part of the substance of normal human feces is made up of these low *vegetable* forms, in numbers which must be estimated by hundreds of millions in the feces of each day. * * * They have recently acquired considerable interest on account of their supposed relation to the causation of diarrhea, as similar organisms have been supposed to act as the cause of dysentery, typhoid fever, cholera morbus, Asiatic cholera, and other diseases.

In gastric dilatation with ulceration, the stomach was sterile in 28 per cent. and the jejunum in 40 per cent. He made anaërobic cultures and found that the procedure disclosed no more species than did the ordinary methods. Cushing and Livingood[8] completed their observations on animals by 14 examinations on patients who came to the operating table or had fistulæ. They were able to vary the character of the flora of the small intestine or its quantity by variations in the bacterial content of the food. Klein[23] found the duodenum sterile when free from food. MacFadyen, Nencki, and Sieber[34] studied the celebrated case of Madaline Spycher in Kocher's clinic at Berne, a patient who had a fistula at the ileocecal valve. The flora varied with the food, and they were always able to make cultures. A similar case was presented by Chiechowski and Jakowski[7] with similar results. Tavel and Lanz[63] reported a case of resection of the pylorus for cancer, in which a sterile duodenum was found,

Notwithstanding some apparent contradictions, a rough harmony seems to underly these various observations, and we are able to form a very good conception of what may be expected in the healthy intestine. In the first place, there is a short neutral zone just above the ileocecal valve, where the findings are more or less constant. The bacteria are less in numbers here than in the cecal region below, and sometimes more and sometimes less than in the duodenum and stomach above. This is the point where the onward flow of intestinal contents becomes more steady and is less subject to the fluctuations following the ingestions of mealtime than any point above. From the stomach to this neutral zone, the bacterial content both absolute and relative is a varying quantity, depending on a number of factors. At all times the numbers are less than in the cecum or colon. The percentage at any one point will rise and fall in waves during the day, coincident with the rise and fall of the food content; the rise coming after meals as the chyme is passed along.

As the ileocecal valve is approached, and this neutral zone is passed, the stream becomes more constant, and we find the picture somewhat different. In the cecum there is an enormous rise in both the relative and absolute values, both to decline again in the colon. The feces move onward more slowly, and water is absorbed, leaving the microorganisms caught in the meshes of fecal matter, hindered to a large extent in activity or propagation by the physical conditions present.

It does not seem at all probable that a "terminal stage of absolute amicrobism" is ever achieved in the stomach and small intestine of the normal organism. The frequent ingestion of food and the swallowing of saliva tends to make such an event very unlikely. The separation of germs from the blood stream by the liver and consequent discharge into the duodenum with the bile (Buchner[6]) can be ignored under ordinary circumstances. But the stomach and the small intestine down as far as the neutral zone to which reference has been made can be made sterile in all probability. Marfan and Bernard[35] have shown that bacteria do not linger in the glandular ducts except in diseased conditions, and the fact that they do not has led Klein and Kohlbrügge[25] to undertake experimental work with a view to discovering on what factor such power of autosterilization depends. From the evidence at hand it can be stated with confidence that withholding of food for a few hours, care of the mouth, and antiseptic stomach lavage will produce the desired end.

The cecum may be said to act as a mechanical equalizer of bacterial content, and under normal circumstances there is very little fluctuation in either quantity or quality of bacteria between the valve and the rectum. This part of the gastroenteric tube responds very sluggishly to dietetic and medicinal treatment, but it seems to respond to a degree in time. We have no reason to suppose that it can be made sterile or that the mucosa of the colon has the power of autosterilization, which seems to be an attribute of the mucosa of the small intestine. Even the most rigorous régime of starvation, cathartics, and enemata fails to empty the cecum of its germ-laden contents, a fact which immediately suggests a point in the etiology of appendicitis.

This numerical estimation just given, taken in inverse ratio with the virulence and microbic association, when any given effect is produced, may be called the bacterial equilibrium of the intestine. When any or all are increased at the expense of the whole organism, that certainly is a deviation from the norm.

Now a word concerning the drug treatment of conditions arising from disturbed bacterial equilibrium. Numerous intestinal septics have been put on the market by enterprising manufacturers. Some are semi-proprietary, with longer chemical names than their importance warrants, and they are usually accompanied by more or less voluminous explanations as to their supposed mode of action. Every active practitioner constantly uses some intestinal antiseptic in an empirical way. Perhaps if his attention is drawn to the subject at all, he finds that some investigator has demonstrated beyond a shadow of a doubt that his own particular favorite is of no possible value. Shifting from one to another in response to such external stimuli, he comes finally to regard intestinal asepsis as an unattainable condition. For instance, Brotzu[5] has endeavored to show the value of various substances, such as salol, calomel, salicylates, and others, by the effect they produce with constant diet on the number of bacteria in the feces. His results could not make us enthusiastic users of any one drug. Stern has done the same for beta-naphthol and demonstrated that there is no decrease in the microorganisms of the feces following enormous doses. But it has been just concluded that judgment based on examination of the feces is more or less fallacious, so whatever is said must be taken with reservation.

Chemical examination of the feces with a view to determination of the amount of intestinal putrefaction has proven to be of some value when taken in relation to urinary examinations. But the procedure is disagreeable and not ordinarily available in clinical medicine.

If the subjective symptoms are to be a basis for our judgment, almost any drug will do, as the subjective symptoms of enterotoxismus are notoriously ephemeral and evanescent, now coming, now going, and now shifting, with apparently no reason. But if the value of any drug be judged by the effect that it has on the indican reaction of the urine, in general the judgment will be a good one. There is a certain percentage of cases where there may be an increase in the total ethereal sulphates without proportionate increase or with positive decrease in the excretion of indican. But an indican reaction once established, which decreases under treatment, shows the efficacy of the methods employed.

Manifestly it is impossible to continue the dosage of drugs over any protracted length of time, and the point quickly comes when the practitioner must turn his attention from endeavoring to kill the intestinal bacteria to treating the patient in such a way that appeal is made to the normal antagonism of the organ-

ism. Then, it must be remembered that enterotoxismus is the price which humanity pays for its artificial environment and urban congestion. In most cases it means some wrong habit of living somewhere. In others it seems as if it meant a marked diathesis, which can be overcome only with the greatest difficulty. Its successful treatment in the long run depends, as it does in a multitude of other ills, on teaching people how to live, proper balance in diet, exercise, and good habits—in other words, it consists in developing the organism to such an extent that no matter what the quantity or quality of germ-life ingested with the food, the forces employed by the organism to restrict their activity will always be in the ascendancy.

## OSTEOSCULPTURE; AN ORIGINAL METHOD FOR THE STUDY OF OSTEOLOGY.

BY H. C. GIFFORD, M.D.,

SYRACUSE, N. Y.

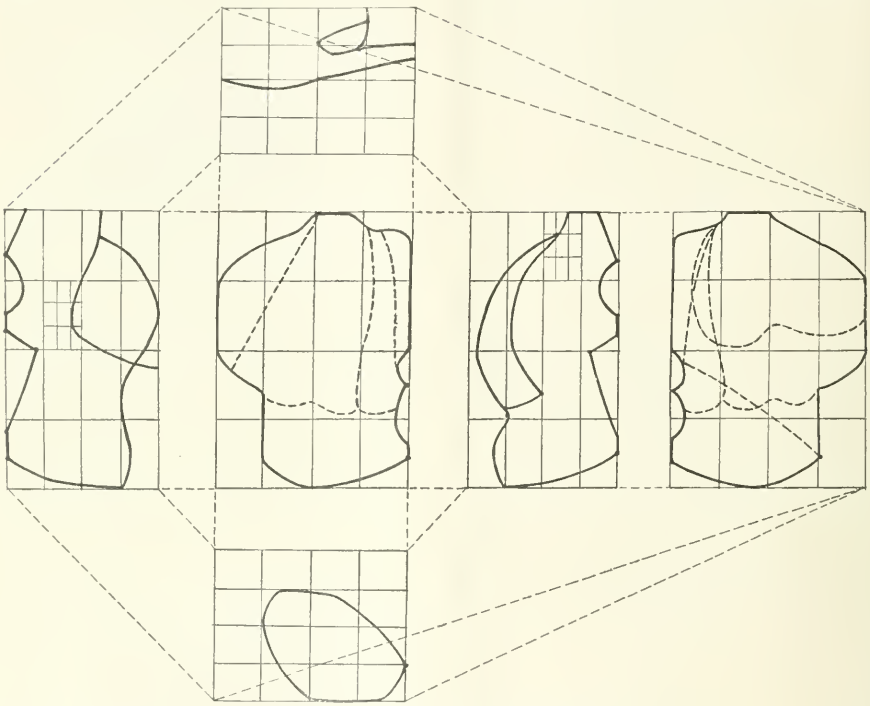
THAT anatomy is the basis of surgery, and osteology of anatomy, are two facts universally conceded. Reasoning from these two facts, together with the fact that prevailing methods for the study of osteology seem hardly adequate to the demands upon them, the idea was conceived that if one could sculpture from suitable material the various bone forms, he would necessarily gain thereby a far more practical knowledge of them than is possible by methods in present use.

For the past three years, and especially the past six months, experiments have been conducted with various materials and methods, until now a system

has been evolved which has proven so eminently satisfactory to the author that he ventures to bring it as a modest offering to the altar of his art.

The technique of the method is, briefly, as follows:

1. A rectangular solid is constructed (preferably of plaster of Paris), having its three maximum perpendicular dimensions equal respectively to the corresponding dimensions of any given solid (however irregular).



Working Drawing for a Model of the Astragalus.

2. Upon each appropriate face of the constructed solid the corresponding aspect of the bone is outlined. The various faces of any block mapped for cutting, the astragalus, for instance, may be shown in the form of a working drawing, as in the accompanying illustration. The interposed lines dividing such surface into fourths each way, are brought into use for the purpose of better localizing the outline for reproduction.

3. The extraneous portions are now cut away, according to the various outlines, leaving a rough, but accurate, approximation of the piece desired.

4. By a few more strokes the main features of surface topography are added, and we have a reproduction of any given model, sufficiently accurate for practical purposes, varying in fact much less widely than nature varies within normal limits on any given specimen.

5. The sculptured piece is now hardened by soaking in glue and drying. (Even yet the plaster is somewhat brittle, this being the most unfavorable feature of plaster of Paris for the work; and for long, slender bones, the fibula for instance, if less fragile specimens are desired, certain kinds of wood may be used to better advantage.)

6. When all the bones for a given part, a hand, for example, are sculptured, they are drilled and mounted in the usual way.

7. A further, and very valuable, practice consists in marking by appropriate methods the various muscle insertions upon each bone.

Although as yet a complete skeleton has not been made, the author has on exhibition several feet and upper extremities, and about six hundred models, sufficient to prove that the entire skeleton, so far as necessary, is amenable to delineation by this method.

By courtesy of Dr. G. M. Price, professor of anatomy in the Medical Department of Syracuse University, the method is soon to be tried on a class of students, to test its availability as a means of teaching undergraduates their osteology.

## DERMOID OVARIAN CYST SIMULATING FLOATING KIDNEY.*

By A. E. ISAACS, M.D.,

SURGEON BETH ISRAEL HOSPITAL.

Mary N., age 19, seamstress by occupation, was admitted to the hospital for an acute abdominal condition. There was nothing definite in her previous history except that she had been troubled with pains in the epigastric region and in the right side of the abdomen for about two years. Four days previously she had been suddenly taken ill with severe pain in the right side of the abdomen, and especially in the right kidney region. Vomiting continued for two days. There was considerable bladder irritation, with frequent micturition.

On her admission to the hospital the acuteness of the symptoms had subsided. Temperature was normal and pulse not frequent. On examination a tumor about the size and with the distinct shape of a kidney was found in the abdomen. It had a tendency to locate itself in the right kidney region, but

could be moved to any part of the abdomen or pelvis. It could be pushed up out of reach under the liver on the right side or under the ribs on the left, and could be gotten down into the pelvis for bimanual rectal examination. If let alone with the patient supine it would locate itself in the right kidney region. In consistency, shape, and size it resembled a kidney, its convex border and the hilus as well as the pedicle could be distinctly felt through the abdominal wall, though that the pedicle was attached to the convex border was not discerned at the time. Urinary examination, chemical and microscopical, was negative.

The absence of sufficient previous urinary history and the great mobility of the tumor caused me to diagnose ovarian cyst as most probable, with twisting of the pedicle as the cause of the acute condition.

Out of respect for the opinion of a few colleagues, among them some of our best diagnosticians, who thought it was a kidney, I made the incision along the outer border of the right rectus which would allow of removal of the cyst or be convenient for exploration of the kidney region should that organ be the one involved.

An Ovarian Dermoid Cyst Simulating Floating Kidney. From a Specimen presented at a meeting of the East Side Physicians' Association.

As may be seen by the specimen, it was a dermoid ovarian cyst with a pedicle about seven inches long which permitted the large range of motion. The pedicle was twisted on itself a few times, was attached to the convex border of the tumor, and its proximal end to the tissues covering the spine at about the promontory of the sacrum. This high attachment of the pedicle was probably due to a previous twist with local inflammation resulting in adhesions. The pedicle included the fallopian tube stretched over its whole length, the fimbriated extremity being adherent to the tumor.

**A Floating Eye-Hospital.**—The congregation of the North United Presbyterian Church in Philadelphia has decided to place a hospital boat on the Sobat River, a tributary of the Nile, 289 miles long, in the Egyptian Soudan, for the purpose of giving medical aid to natives along the shores of the river who suffer from trachoma. Dr. Hugh R. Magill will have charge of the boat. It is intended to make two trips a month from the mouth to the source of the Sobat. The boat will be named in honor of James A. Elliott, founder of the North Church, who died two years ago.

## THE ALKALINITY OF THE BLOOD IN FEBRILE TOXEMIA.

By FREDERICK W. D'EVELYN, M.D.,

SAN FRANCISCO.

Professor Loeb of the University of California, in one of his papers on the subject of Life, says that "the sodium ions of the blood are essential for the maintenance of life phenomena." This point had already been clinically urged by Sajous, when he stated that diminished alkalinity of the blood goes hand in hand with increased susceptibility to infection, and that in febrile diseases there is a direct ratio between a deficiency of sodium and death.

The following case presented in its course some features of interest, and the ultimate results I am confident were obtained largely through the recognition of the altered alkalinity of the blood, and its immediate clinical significance in its bearing upon the reserve forces, so essentially valuable in acute febrile disease, especially where pulmonary tissue is involved.

The case I refer to was one of right pneumonia in a substhenic male, 44 years of age, and about three-fourths of the lung being involved. It is not necessary to give all details; suffice it to state the pulse averaged 104, respirations 44, temperature (rectal) 104.2°; sputum was abundant, containing blood, fibrin, and mixed bacteria, Fränkel's diplococcus being in evidence. Alkaline drinks were given very liberally, and after first twenty-four hours a pint and a half of warm salt solution was given as a high enema every one and a half hours. The skin and kidney reactions were well sustained. The pulse was very variable, oftentimes deficient in tension, but no special stimulation was indicated.

On the fifth day the patient became more distressed, the respirations were more rapid and shallow, the pulse was intermittent, with reduced volume and tension, but with rate exaggerated; the face was jaundiced, the liver resistance and volume were increased; there was much venous pulsation in neck. The pulse suddenly dropped until its beats were far distant and feeble; the area of the right heart was increased and intruding upon the right pulmonary zone; the pulmonary heart sound became modified accordingly, while (and this was interesting) a rough murmur, presystolic in rhythm, was recognizable, with a superadded character which seemed to denote recent and progressive stenosis; the conclusion was that there was a fibrinous deposit in the right auricle extending into the adjacent ventricle. The radial pulse finally became so intermittent that it appeared at times as if it would never recover the beat. Mechanical respiration was initiated and sustained for a period of some five hours; while medication consisted of three minims of liquor ammonii portis and five minims of a 10 per cent. alcoholic solution of iodine mixed just at time of administration; a hot salt solution was given frequently as enema. No other stimulation or medication was employed. After six hours, the pulse in volume and rhythm became much improved, while at the end of twenty-four hours the heart murmur was only faintly in evidence. Abundant crepitant râles appeared over the anterior surface of the upper third of both lungs. The iodide-ammonia treatment was sustained, longer intervals intervening in the administration.

Some fifty hours from the initial alarming symptoms as above noted, the pulse suddenly became flabby, not broken, and the body was bathed in a profuse perspiration. No heart murmur could be detected; this "spell," which I did not consider as of the same character as the first, rapidly responded

to what was indicated—adrenalin and strychnine. Subsequent recovery took place by lysis; the lung cleared very nicely, the cardiac dullness became normal; jaundice and the hepatic conditions quite disappeared, and convalescence was complete. It is not illogical to conclude that, had the ordinary alcoholic and cardiac stimulants been used and the blood surcharged with toxic waste, the chances of overcoming the grave central condition would have been reduced to an unconditional surrender. Acute febrile diseases have always seemed to me to despoil nature early of many of her essential and defensive properties. This being so, it follows that the more nearly we can restore these, the better will be our clinical results. There is almost too much straining after the mysterious in modern clinical medicine, and our attention is apt to be engrossed by "microscopic evidence," while more grave factors are complicating a balance of reserve upon which the final prognosis must of necessity be dependent.

Clinically it is often better practice to work backward toward a starting point than to press forward to a fanciful goal. No disease demands this consideration more urgently than pneumonia, which still registers a death rate seriously uncomplimentary to advanced medicine.

---

**The Etiology of Noma.**—Charles Herrman from his work believes that although absolute certainty is impossible until pure, uncontaminated cultures and successful inoculations in animals can be obtained, nevertheless, the following conclusions may be presented with a fair degree of probability: The microorganism which the writer would call the spirochete of necrosis, corresponding to the streptothrix of Seiffert-Perthes, is the one which plays the most important part in the etiology of noma. This organism is identical with that found by Plaut, Bernheim, Vincent, and others in the ulceromembranous lesions of the mouth, and also with the spirillum sputigenum and spirochæta dentium of Miller, found normally in small numbers in the mouth. Though apparently two organisms, they are really different parts or different stages of development of the same organism. This microorganism is not a bacillus, but probably belongs to a family which serves as a connecting link between the bacteria and the lowest forms of animal life, the protozoa, namely, to the family of the spirochetes. This explains why it cannot be stained and grown on culture media by the usual methods. This organism is probably present in the atmosphere in the form of very resistent spores. By being deposited on food, water, etc., they may be introduced into the body with these. This organism is closely related to the bacillus necroseos found in the necrotic processes observed in some of the lower animals. In the human body, this organism requires unusual and exceptionally favorable conditions for its growth and development. On this account noma is very slightly contagious. In order that a gangrenous process should result, there must be a preceding physiological change in the tissue, which renders it possible for the organism to penetrate, live, and multiply in the apparently healthy portions. Ulcerative and gangrenous stomatitis represent different stages of the same process. The presence of diseased teeth undoubtedly plays an important part in the etiology of ulcerative and gangrenous stomatitis, partly by pressure and irritation, but primarily by producing a gingivitis, furnishing conditions favorable for the growth and development of the organism described; the space between tooth and gum serving as a storehouse for fresh supplies. In the infectious diseases of childhood, particular attention should be paid to the condition of the teeth. When diseased, they should be removed. The most rational treatment of noma is the application of the Paquelin cautery. It should be introduced so as to destroy not only the necrotic tissue, but also the finer filaments of the microorganisms which have penetrated into the underlying apparently healthy tissue. The term noma is here used to indicate a specific necrotic process. Similar processes may occur in any part of the body, providing always that certain physiological changes have taken place in the tissues, which render it possible for the microorganisms to penetrate, live, and multiply in the apparently healthy parts.—*Archives of Pediatrics.*

**Chronic Constipation in Children.**—Herman B. Sheffield declares that the causes of habitual constipation are very numerous. Faulty diet is responsible for a great many of these cases. Another cause, atony of the intestines, may be primary, congenital in nature, or secondary or acquired. In various chronic diseases associated with general debility and loss of flesh, the sluggishness of the bowels forms merely a symptom of the disease. In treating these cases, the causes instrumental in the production of this condition should first be arrested. Then the damage done during the continuance of the constipation should be removed. It is of great importance to train the child to have a movement regularly every day. An easy position for the child at the time of defecation should be studied. The child should be placed on a low seat so that it may assume a squatting posture. The aperture in the seat should not be too wide, for the gluteal group of muscles must be allowed to separate or relax. Correction of diet is very valuable for the prevention of this trouble but does not always remedy it. The addition of cream, buttermilk, honey, cooked or raw fruit, and vegetables to the regular "mixed diet" is invaluable as a corrective of constipation in older children. A glass of cold water on an empty stomach and before retiring is often very useful. Expert massage, oil enemas, and hydrotherapy, supplement one another in their beneficial effects. The galvanic or faradic current is sometimes used in very protracted cases. In certain cases drugs may be used besides the remedies just mentioned.—*Archives of Pediatrics.*

**A Preliminary Note on the Sterilization and Absorbability of Catgut.**—Charles B. Nancrede, F. R. Waldron, and C. F. Tenney state that the only material fitted for the majority of purposes is catgut. They find that sterilization by the Claudius method is entirely reliable. From experiments along this line they conclude: That tight winding of the gut markedly affects the gut physically and reduces the tensile strength; that strong solutions of iodine and potassium iodide do reduce somewhat the tensile strength of the gut; that more dilute solutions do not obviate this drawback except the most dilute examined which is probably not sufficiently germicidal; that alcoholic solutions preserve or increase the tensile strength except in dilutions which require the addition of potassium iodide to put the iodine in solution; that with a knot in the continuity of the gut, greater tension was almost invariably necessary to break the iodine gut than the wet, untreated gut; that the iodine gut is apparently somewhat more elastic than the wet, untreated gut; that the tensile strength of gut is lowered by the exposure to the Claudius solution, more so in case it has previously been exposed to formalin; that certain pieces of gut are absolutely worthless as ligature or suture material after exposure to the Claudius solution; that with a knot tied in continuity the relative loss of strength is much less; that in replacing unused gut in the Claudius solution, aseptic gut only must be replaced, as the iodine was present in the solution in less than one-eighth its original strength. The gut was kept in a glass-stoppered bottle, tightly closed. Finally, their experiments tend to show that the 1-4000 gut becomes absorbed in 15 days, the 1-5000 gut in about 20 days, the 1-6000 in 15 days, the 1-7000 in 12 days, while the 1-8000 gut becomes absorbed in the tissues in about 10 days.—*Journal of the Michigan State Medical Society.*

MEDICAL RECORD.

New York, December 30, 1905.

## THE ARMY MEDICAL BILL.

WITH the opening of the present Congress another effort has been made to secure justice for the Army Medical Department, and a bill for the reorganization of the latter has been sent in by Secretary Taft for legislative action. The need of such reorganization has been and is most apparent, and the arguments in its favor are well-known, numerous, and unanswerable. As Secretary Taft says in his memorandum accompanying the bill just introduced: "The proposed legislation involves no radical departure from existing methods, nor appreciable increase in cost, while its enactment into law will be highly beneficial to the efficiency of the medical corps of the Army." The urgent need of such reorganization was also strongly emphasized by President Roosevelt in his annual message to Congress.

It will be remembered that such reorganization has been urged by the army medical authorities at every Congressional session, save one, since 1898. It came nearer to being enacted into law at the last session than at any time before, being strongly endorsed then, as in the past, not only by the American Medical Association and the Army medical authorities, but also by the Army general staff and Secretaries Root and Taft, and was also made the subject of a special message to Congress by the President. In spite of all this, while the bill passed the Senate, it failed to receive action in the House. The Military Committee of the latter reported it favorably, but in such emasculated form as totally to fail of the purpose for which it was intended. During the sessions of previous years there was usually some pretext for letting the bill die in committee. Once it was actually discussed by the House, but failed of passage when a prominent member of the Military Committee opposed it, on the ground of economy, stating his opinion that the Army could secure the best medical talent in the country at a salary of one hundred dollars monthly!

In the past, however, the bill has failed not so much because it was opposed by any one as because no personal interests were brought to bear to secure its passage. Being a bill purely in the interest of the public service it offered the practical politicians no opportunities for the placing of political favorites or the paying of political obligations to their constituents. Had the plan of reorganization contemplated a recession from high professional ideals and opened up a way by which direct political appointments could be made from civil life to the medical corps, there can be no doubt but that such powerful political forces could have been aroused as long since to have secured its passage.

Not only is there lack of personal advantage for the politicians in pushing legislation for the government medical services, but the former are not held to their duty in this respect by political fear of a profession fully united for medical advancement. While numerically strong and representing the solid elements of the community, it is unfortunately true that the medical men of this country are usually content to keep out of politics and are not yet organized as an effective political force. Hence the humiliating spectacle of some hundred thousand of the best citizens of this country repeatedly appealing to Congress in behalf of needed professional improvements affecting the welfare of the State and receiving far less legislative consideration than is readily commanded by minor business interests of a personal character. The treatment accorded the army medical reorganization bill in Congress, and its vicissitudes, past and present, merely serve to illustrate the low political esteem in which the medical profession of the country is held at Washington.

The present bill is really non-partisan and purely humanitarian. It merely relates to the question as to whether the soldiers of the Army as now organized shall or shall not have enough doctors of the right kind to care for and safeguard them. It will be interesting to watch what attitude the present Congress will take in this matter. With its unqualified backing by the profession and from the White House and War Department, the bill should pass this year if it can ever be expected to do so. But even if it does pass without mutilation, the fact remains that a dignified and learned profession will have been for years in the position of having been denied adequate recognition on a matter concerning which there is none so competent as itself to pass upon, and which is one merely of public weal. The general public is being educated to a frame of mind where it is not safe to hold up public reforms merely because they do not carry with them opportunities for private advantage. Is it then too much to hope that in these days of independent politics the medical profession may be aroused and politically united for the advancement of non-partisan medical reforms?

If every physician in the country were to make of this a personal matter, and would write to the representative in Congress of his own district urging the passage of the bill, it would infallibly receive favorable attention in the House. Such an individual appeal would carry much greater weight than any formal resolution of the American Medical Association or even of the Association of Military Surgeons, for it would strike the personal note which is of necessity lacking in official resolutions.

The bill for the reorganization of the Army Medical Department should go through without delay, because it deserves to and because the public interests demand it.

## SOURCES OF ERROR IN TESTING GASTRIC EFFICIENCY.

THE credit for pioneer work in the modern science of functional gastric investigation undoubtedly belongs to v. Leube, who first suggested the use of the stomach tube as a diagnostic measure and also devised a plan of subjecting the gastric mucosa to

a definite thermic stimulus by the introduction of a certain amount of ice water ten minutes before the test lavage was performed. Jaworski first improved this plan by a somewhat different method of application, and then hit upon the idea of providing a digestive stimulant by the addition of cooked egg albumin to the plain water used. These more or less unsatisfactory gropings after a method suitable for routine use have never become popular, and it was not until Ewald and Boas, about twenty years ago, introduced the test breakfast that the analysis of the stomach contents became available as an every day measure. Riegel's test dinner of soup, meat, and potato, while superior in the one feature of affording the stomach a stimulus more nearly comparable to ordinary working conditions, has yet too many practical disadvantages—such, for example, as the difficulty in distinguishing between sarcolactic acid and that originating in local fermentation, and the impossibility of testing for occult hemorrhages, to mention only two of the number—to form a standard procedure for universal application. Sahli's butter-soup method, while promising theoretical advantages, has not yet passed through its probationary period, and until its reliability has been more firmly established cannot compete with the Ewald test breakfast in every-day practice.

That even the latter procedure is open to criticism in many counts has been recognized for a long time, and there has been a tendency in some quarters to discredit the method entirely on account of its more or less obvious shortcomings. Boas, in a contribution to the Ewald Festchrift (*Berliner klinische Wochenschrift,* October 30, 1905), considers the sources of error entering into such examinations and endeavors to show that frequently the unsatisfactory nature of the results obtained is due to improper carrying out of the various steps involved. In the first place, he says, Pawlow's observations on dogs have shown what slight variations in stimuli are sufficient to effect the mechanics of secretion, yet many authors, in their descriptions of the test breakfast, depart in important features from the original directions, and practitioners naturally are still more lax in their applications of it in practice. The test breakfast should consist of a roll weighing 35 gm. and 400 c.c. of either plain water or of tea unsweetened and without milk, which the patient is to take on an empty stomach, and which is to be withdrawn at the end of an hour. The directions given in different text-books offer all sorts of variants in the composition of the meal and in the time of its expression, while in practice it often happens that the patient takes it fasting, but not necessarily on an empty stomach. Boas urges that to avoid error it is always important to learn by a preliminary lavage whether the fasting stomach may not contain stagnating food remnants. Another error which is not without importance is that of having the breakfast taken not early in the morning, but at some later hour in the day which happens to be more convenient for physician or patient. Under such conditions satisfactory quantitative determinations are impossible. A source of error which does not seem to be susceptible of correction is the great variability in the composition of the gastric secretion which is observed in certain individuals, and which Hemmeter has called heterochylia. A physiological form of this affection exists in menstruating women, who have been found to exhibit the most abrupt fluctuations in their HCl secretion. A factor that may induce not inconsiderable elements of error is the presence in the stomach contents of abnormal constituents such as bile, blood, mucus, or saliva, and Boast states that, if these are present in quantity, quantitative determinations might as well be omitted and even qualitative results are of value only if positive. Deductions regarding the motor efficiency of the organ from the amounts of stomach contents obtained are also likely to be fallacious. A small residue usually indicates active motility, especially if a secondary lavage reveals no further food remnants, but a large amount of material obtained may be due mainly to active gastric reaction. A factor not mentioned by Boas, but to which other authors attach considerable importance, is the inhibition of secretion that almost invariably takes place in nervous individuals who are for the first time anticipating the ordeal of the stomach tube and so furnish a wholly atypical gastric secretion during the first one or more examinations, until the idea of the expression to follow has lost all its terrors.

This enumeration by no means exhausts all the objections that might be scored against the Ewald test breakfast. Boas does not refer to his own particular oatmeal test, presumably because it shows all the drawbacks of the other formula. It is therefore not surprising that an improved method for gaining an insight into the digestive capacity of the stomach should be a much-needed desideratum, and Sahli, in a recent communication (*Correspondenzblatt für Schweizer Aertzte,* No. 8, 1905), describes what appears to be a notable improvement. Taking advantage of the observation made by Ad. Schmidt, that raw connective tissue is digested only in the stomach, he ties off the neck of a tiny bag of rubber tissue containing a little methylen blue or iodoform with a strand of fine, raw catgut and has the patient swallow it after an ordinary meal. He then examines the urine at short intervals to detect the presence of either iodine or a blue coloration, which, if it occurs promptly, indicates that a good degree of gastric digestion must exist. This method has been tested in Ewald's clinic, and Eichler (*Berliner klinische Wochenschrift,* November 27, 1905) has reported on its comparative results obtained in thirty cases in which both the desmoid reaction of Sahli and the usual test breakfast were tried. The results are favorable to the new method and show that when the reaction in the urine appears within fifteen to twenty hours the stomach wall is secreting both pepsin and hydrochloric acid in sufficient quantities. The non-appearance of the reaction may, however, give rise to a fallacy, for in cases of good digestive power but marked hypermotility the little bag may be expelled from the stomach before time has been given for the digestion of the catgut to take place. In other respects also the test does not afford information regarding the details of the gastric processes, and Eichler concludes that although it is reliable and useful so far as it goes, it will not supplant the older procedure.

It would seem, therefore, that in spite of the manifest elements of difficulty and uncertainty which apparently are inseparable concomitants of the test meal, whether given as a breakfast or a dinner, this

is still to be regarded as the most efficacious means of investigating the functional capacity of the stomach. In order to give the information obtained by this means its due significance, however, greater care than has, perhaps, hitherto been regarded necessary must be taken to hedge about the entire maneuver from beginning to end, with every possible precaution and attention to detail. The Sahli desmoid reaction at present seems a very useful addition to the resources of the diagnostician, but it is likely that its widest field of utility will be found in dealing with those patients who either object to the introduction of the stomach tube through timidity, or in whom the operation is rendered inadvisable owing to the presence of some one of the well-known and not infrequent contraindications to esophageal instrumentation.

## THE AFTER-TREATMENT OF SURGICAL TUBERCULOSIS.

In patients who have been afflicted with tuberculosis of the bones and joints, the urogenital system, the peritoneum, the lymph nodes, or the skin, a so-called cure by operative or orthopedic means may be said to afford no guarantee whatever against a recurrence of the disease in the same or in a different locality at some future time, either more or less remote. In these cases of what is ordinarily termed surgical tuberculosis, it is essential to know whether apparently successful operative measures have been so in reality, and whether in addition there may not be some other unsuspected latent foci present. If some means were at hand for detecting this, appropriate treatment could be instituted at once, and the patient spared a later and perhaps more extensive recurrence.

In a suggestive article recently published, C. Kraemer (*Deutsche Zeitschrift für Chirurgie,* Vol. 79, Nos. 4-6) makes the claim that we possess such a means in tuberculin, and advocates its systematic employment for this purpose. The fact that a large number of patients remain in good health for the rest of their lives after appropriate operative or conservative treatment for one or more of the tuberculous lesions noted above, may be advanced as a possible objection to the universal application of tuberculin injections. Of this fortunate termination, however, we can never be assured in advance. The use of tuberculin may also appear superfluous in cases where the entire tuberculous focus has been eradicated at the time of operation, and another possible exception may include those instances in which, after the removal of the principal tuberculous process, subsidiary foci which have been left behind, undergo spontaneous resolution and cure. The latter has been known to take place in instances where the extirpation of a tuberculous kidney was followed by a complete subsidence of the process in the ureter and bladder. The element of uncertainty is very large, however, in all these cases, and the writer's contention that it would be better to be assured of a complete or incomplete cure by a test made immediately or some time after operation, seems reasonable and logical.

There are other aspects of this question to which Kraemer also calls attention. In the first place, individuals who harbor latent or hidden tuberculous foci are in a position readily to disseminate the infection to their surroundings, often unconsciously. In the second place, these patients are likely to produce offspring which, although not directly infected, are characterized by an hereditary weakness, if not actually a predisposition to contract the disease. Individuals in this class are therefore a menace to themselves, to those about them, and to posterity, and this is surely a sufficient warrant for an urgent warning against neglecting their incompletely cured ailment. If the result of a tuberculin injection made for the purpose of obtaining a diagnosis of the actual condition is positive, then early treatment will obviate the necessity for more radical measures at a future time, and will amply compensate for the slight inconvenience which attends these tests and the subsequent period of observation. Neither patient nor physician will then have to lament the omission of proper treatment during the time when a complete cure was still a possibility.

## AUTOINTOXICATION.

Autointoxication results from the absorption into the circulation of certain compounds of putrefactive changes in the intestinal canal. Brieger showed that disease may depend upon the presence in the system of substances capable of combining with the acids of the secretions to form salts which correspond with inorganic and organic bases. Selmi called these substances ptomains, chemical compounds basic in character, formed by the action of bacteria upon organic matter, in contradistinction to leucomains, which are classed as animal alkaloids, resulting from tissue metabolism in the body. Ptomains resemble vegetable alkaloids. Much has been written on the part played in digestion by the bacteria of construction and destruction, or the process of building up and breaking down, but space forbids a discussion of this here. We must assume that the processes are familiar to the reader and confine our remarks to autointoxication in its restricted sense.

First, then, by faulty elimination we may have normal excrementitious products retained in the body, for instance, in uremia from insufficient excretion by the renal cells; in the suppression of perspiration, whereby toxic products, which would otherwise be thrown off through the sudoriferous glands, are retained in the system; and a retention and absorption of the effete material that should be carried off through the bowels. Then we have incomplete chemical change, oxidation being incomplete, intermediary products being thrown into the absorbents instead of the less poisonous substances. An excessive formation or faulty elimination of uric acid is said to cause gout and a whole train of disturbances attributed to the condition called the uric-acid diathesis. The presence in the body of acetone in diabetes is another illustration of imperfect chemical change.

A deficient glandular secretion may result from incomplete chemical change. This occurs in that form of diabetes known as pancreatic, as well as in myxedema and Addison's disease. Excessive secretion of the thyroid gland is responsible for exophthalmic goiter. Albumins and peptones, as well as probably other compounds resulting from the digestive process through faulty absorption, may find their way

into the circulation instead of being reconverted into albumins, and so produce positive poisonous effects. Glycogen may in certain hepatic disorders find its way into the blood and urine, or certain foods such as the carbohydrates may be converted into glucose and produce, according to the degree of change, glycosuria or diabetes.

It is known that mental emotion may cause the milk of nursing mothers to become toxic, while the defective action of certain organs may lead to the formation of poisonous compounds. To undertake to outline a treatment for these conditions would tax the patience of the reader. Suffice it that the true cause of the disturbance should be sought for, and when found, combated according to modern ideas of intestinal therapeutics. To keep the bowels always freely open is the first requisite. Avoidance of such foods as are readily acted upon by the bacteria, such as milk, cheese, the carbohydrates, etc., should constitute a prime factor in treatment.

### Progress in the Care of Epileptics.

The fifth annual meeting of the National Association for the Study of Epilepsy and Its Treatment, held at the Academy of Medicine in this city on November 29, a special report of which is printed in another column, showed that satisfactory progress is being made in this country and abroad in the care of epileptics. Ohio, New York, Massachusetts, New Jersey, Pennsylvania, Texas, and Indiana have gone on record through legislative action as favoring State help for a class whose extraordinary malady shuts them out to a very large extent from home life, from educational institutions, from society, and from holding positions of trust and responsibility in the business world. In his address as president of the association, Dr. W. P. Spratling of the Craig Colony at Sonyea, N. Y., said that there are 150,000 persons in the United States who suffer from epilepsy, 14,000 of whom live in this State. Less than 1,100 of that number are at present under treatment in the Craig Colony, an institution that urgently needs to be made larger as soon as possible. Epilepsy is no longer regarded as an incurable disease. It can be cured in a considerable proportion of all cases if the disease is taken in time and treated properly for a period of two or three years. A unique feature of the New York meeting was a biographic reproduction of more than a score of epileptic convulsions of various types. These pictures were made at Sonyea last summer by Dr. W. G. Chase of Boston. To show such pictures in medical educational institutions in the future should be of great value. Many medical students go through college and enter practice without ever having witnessed a single epileptic convulsion; while many physicians never see certain phases of this strange disease. Through the use of the biograph, all this may be overcome and the student may now sit in the lecture hall and see an epileptic convulsion as accurately portrayed on the screen as though the actual fit was occurring before his eyes.

**A Dressing for Discharging Wounds.**—For wounds that are septic or have an offensive discharge Joseph Mullen advises dropping twenty drops of 40 per cent. solution of formaldehyde on the dressing three times a day. The effect on the wound is excellent, the dressing does not require such frequent renewal, and the odor of the discharges is eliminated.—*Medical Recorder.*

## News of the Week.

**New Health Board Building for Brooklyn.**—It is announced that the Department of Health intends to begin soon the erection of a new Board of Health building in Brooklyn. The building will be bounded by Flatbush avenue extension, Willoughby street, Fleet place and Fleet street, its dimensions being respectively 184 by 102 by 115 by 68 feet. This will give approximately 10,000 square feet, of which space one-half will be occupied by the offices. These are to be separate from the general building. There will also be a separate clinic and isolation ward. The Board of Aldermen has appropriated $295,000 for the purchase of the site, and bids for the contract for the building will be asked for within a few days.

**State of New Jersey Board of Medical Examiners.**—Dr. William H. Shipps has been elected acting secretary of the State Board of Medical Examiners of New Jersey, *vice* Dr. E. L. B. Godfrey, Secretary, who has been granted leave of absence until May, 1906. All communications should be addressed, during this period, to Dr. William H. Shipps, Bordentown, New Jersey.

**A Bureau of Exchange for Medical Literature.**—Dr. T. D. Crothers of Hartford, Conn., is anxious to secure the names and addresses of medical men who are interested in the literature relating to inebriety, alcoholism, drug-taking, drug neuroses, etc. One object is to obtain a list of names of physicians who would be pleased to receive reprints, papers, and abstracts of medical literature on this subject; also to establish a bureau by which the profession may be made acquainted with researches along these lines and thus be able to understand and advise concerning the rapidly increasing problems which center about the use of alcohol.

**The Medicolegal Society.**—At the annual meeting of this society, held December 21, the following officers were elected for 1906: *President*, Clark Bell, New York; *First Vice-President*, A. P. Grinnell, New York; *Second Vice-President*, Dr. J. Mount Bleyer, New York; *Secretary*, John R. Abarbanell, New York; *Corresponding Secretary*, Mortiz Ellinger, New York; *Assistant Secretary*, Dr. Anna W. Bloomer, New York; *Treasurer*, Theodore Baab, New York.

**Illegal Practice in Missouri.**—At the meeting of the Missouri State Board of Health which began its sessions in Kansas City on December 18 about fifteen practitioners from the northern part of the state were summoned to reply to charges of unprofessional conduct. The allegation was made that in certain districts where there are few saloons they had made a practice of providing all comers with prescriptions for alcoholic beverages and had even in some instances dispensed liquors themselves. The secretary of the board is quoted as having announced that about forty physicians would be prosecuted on these grounds.

**Louisiana Health Board.**—Gov. Blanchard has announced the membership of the new State Board of Health appointed to fill the vacancies left when all the members of the old board, including its president, Dr. Souchon, recently resigned. Dr. Clifford H. Irin of Bossier Parish is to be the president of the new administration.

**Varioloid at Governor's Island.**—Two military prisoners recently sent to Governor's Island for confinement in Castle Williams have developed varioloid or smallpox in mild form and are quarantined in tents near the post hospital.

All the other prisoners have been vaccinated as a precaution and the soldiers on the island, companies E, F, G, and H of the Eighth Infantry, will be revaccinated because they are about to depart for the Philippines.

**New Army Hospital.**—Plans for the new Army General Hospital, to be erected in Washington, D. C., have been accepted by Secretary Taft. A limit of $300,000 for the cost of the building was fixed by Congress, Majs. William C. Borden and W. D. McCall, of the medical department, and Major Thomas Slavens, of the quartermaster's department, compose the board that was appointed to consider plans.

**To Bar Consumptive Pupils.**—The School Management Committee of the Chicago Board of Education recently adopted without a dissenting vote a resolution calling for the appointment of a committee to draft a rule providing for the exclusion from the public schools of all victims of the disease. The committee was also empowered to prepare a plan for the medical examination of all "suspicious" pupils, with a view to determining whether or not they should be denied seats in the schoolroom.

**Yellow Fever in Havana.**—Early in the week over sixty cases of yellow fever with a score of deaths had been reported from Havana. President Palma has sent a message to Congress asking for a credit of $200,000 to fight yellow fever, as the present appropriation was exhausted December 24.

**Precautions Against Plague.**—Reports of the existence of bubonic plague in Hawaii have caused the authorities at San Francisco to require the quarantine officials at Honolulu to announce a new regulation under which all freight or express packages addressed to the United States must be fumigated before shipment.

**The Western Surgical and Gynecological Association.**—The fifteen annual meeting of this society was held at Kansas City, Mo., December 28 and 29.

**Fraternal Sanatorium.**—The board of directors of the National Fraternal Sanatorium has voted to accept the offer of 1,000 acres of land and a building, said to be worth $500,000 located at Las Vegas, N. M. The offer was made by the Sante Fé Railroad Company.

**Dr. William Seaman Bainbridge,** of New York City, has recently been appointed Consulting Surgeon to St. Andrew's Convalescent Hospital.

**Dr. Ernst Ziegler,** for many years one of Germany's foremost pathologists, died on November 30 at Freiburg, i. B., in his fifty-seventh year, after a painful illness.

**Kansas City's New Hospital.**—On December 18 the cornerstone was laid for the $350,000 hospital building in course of erection in Kansas City. The structure will be four stories high and when completed will have accommodations for over five hundred patients. It is believed that it will be finished within eighteen months.

**Meningitis at Newport.**—There have been eight cases of cerebrospinal meningitis among the apprentice seamen at the Newport Naval Training Station, and four of the patients have died.

**Southern Surgical and Gyneocological Association.**—At the meeting of this association held in Louisville on December 12 to 14, Baltimore was selected for the next convention. Officers were elected as follows: *President,* Dr. George P. Noble, Atlanta, Ga.; *First Vice-President,* Dr. Steward McGuire, Richmond, Va.; *Second Vice-President,* Dr. E. D. Martin, New Orleans; *Secretary,* Dr. W. D. Haggard, Nashville, Tenn.; *Treasurer,* Dr. C. M. Rosser, Dallas, Texas.

**Wyoming State Medical Association.**—At the annual business meeting of this society the following officers were elected: *President,* Dr. W. A. Wyman of Cheyenne; *First Vice-President,* Dr. Fred Horton of Newcastle; *Second Vice-President,* Dr. E. A. Croskery of Wheatland; *Treasurer,* Dr. Francis Hoff of Casper.

**Buchanan County (Mo.) Medical Society.**—At a recent meeting of this society the following officers were elected: *President,* Dr. O. B. Campbell; *Vice-Presidents,* Drs. C. G. Geiger and O. G. Gleaves; *Secretary,* Dr. Charles W. Fassett; *Treasurer,* Dr. J. B. Reynolds.

**Minnesota Valley Medical Association.**—The twenty-sixth annual meeting of the Minnesota Valley Medical Association was held in Mankato on December 5. At the business session the following officers were elected: *President,* Dr. M. Sullivan of Adrian; *First Vice-President,* Dr. G. R. Curran of Mankato; *Second Vice-President,* Dr. F. P. Strathern of St. Peter; *Secretary,* Dr. A. G. Liedloff of Mankato; *Treasurer,* Dr. G. F. Merritt of St. Peter.

**Seaboard Medical Association.**—The following officers were elected at the annual meeting of this society, held at Newport News, on December 7: *President,* Dr. John C. Rodman of Washington, N. C.; *Vice-Presidents,* Drs. B. R. Gary of Newport News; E. C. Hathaway of Bloxom, N. C.; J. W. Bowdoin of Accomac, Va.; W. D. Hassell of Grisom, N. C.; *Treasurer,* Dr. Israel Brown of Norfolk; *Secretary,* Dr. J. R. Bagby of Newport News.

**The Health Association of New Orleans.**—The governing committee of the New Orleans Health Association has resolved to present a resolution to Governor Blanchard, stating that it is the sense of the Association that the nomination for State Health Officer be made from the recommendations of the State Medical Society. It has also been proposed to erect a permanent isolation hospital to cost $100,000.

**Doctors and Druggists.**—Two hostile petitions are being circulated in Iowa for signatures, and will later be presented as bills before the legislature. One has been drawn up by the physicians, and asks that pharmacists be restrained from counter prescribing, while the other is sponsored by the pharmacists, and provides that physicians shall be prohibited from compounding prescriptions.

**Tuberculosis Exhibition.**—After removal first to Boston and then to Philadelphia, it is expected that the material of the New York tuberculosis exhibition will be displayed in the Municipal Museum of Chicago early in February.

**Dedication of Ottawa Tent Colony.**—A new structure of this colony, costing $15,000, and under the direction of the Illinois State Medical Society, was dedicated December 12. Nearly five hundred physicians and persons interested in the cure of tuberculosis were present from Chicago and other towns of the State. The principal address was delivered by Dr. Frank Billings of Chicago. Speeches were also made by Dr. J. W. Pettit and Dr. Geo. A. Zellar, Superintendent of the Hospital for Insane at Peoria. Dr. Harold N. Moyer presided.

**The Illinois Training School for Nurses** has just completed twenty-five years of existence as a corporate body. This institution was the first to adopt the three-year course, and also to affiliate with smaller schools in order that their graduates might attain the standard demanded for prospective State registration.

**Mercer County (O.) Medical Association.**—Officers of this association elected for the ensuing year are: *President,* Dr. D. H. Richardson; *Vice-President,* Dr. L. D. Brumm; *Secretary,* Dr. J. E. Hattery; *Treasurer,* Dr. W. C. Stubbs.

**Portland (Me.) Medical Club.**—At the twenty-eighth annual meeting of this association, held on December 7, the following officers were elected: *President,* Dr. J. H. Patterson; *First Vice-President,* Dr. C. R. Burr; *Second Vice-President,* Dr. Owen Smith; *Secretary and Treasurer,* Dr. G. H. Turner.

**Obituary Notes.**—Dr. George I. McLeod of Philadelphia died at Bryn Mawr on December 18 of pneumonia at the age of sixty-nine years. He was graduated from the Medical Department of the University of Pennsylvania in 1857. After graduation he became a resident physician in the Philadelphia Hospital and later he served in the medical corps connected with the troops from the State of Pennsylvania during the Civil War. He was Secretary of the State Committee on Lunacy, after having served for thirteen years as chairman of that body. He was for eighteen years a member of the State Board of Charities and for thirty-one years a member of the Twenty-seventh Sectional School Board.

Dr. Walter Williams Naylor died at Philadelphia on December 16 at the age of thirty-eight years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1889 and he became interne to Howard Hospital. He was police surgeon in the second district since 1897, and he was a member of the Philadelphia Medical Emergency Corps.

Dr. Elwood S. Gloninger died at Philadelphia on December 14 at the age of fifty years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1877. He was the first resident physician at Girard College, a position since abolished, and he was the son of David Stanley Gloninger, who established a hospital at Race and Crown streets in 1865 for the treatment of soldiers wounded in the Civil War.

Dr. Ezra H. Wilson, for many years connected with the Brooklyn Department of Health, died December 19 at his home in Williamsburg, in his forty-eighth year. He was a well-known bacteriologist, and was one of the first in this country to use formaldehyde as a disinfectant. In the old City of Brooklyn he manufactured all the antitoxin that was used by the Health Board, and he established stations for its distribution throughout the city. He was born in Port Jefferson, L. I., and was graduated from the College of Physicians and Surgeons in this city in 1882. He became connected with the Hoagland Laboratory as associate to Surgeon General Sternberg of the United States Army, and later succeeded him as director of that institution. Up to the time of his death he devoted his entire time to research work in bacteriology and hygiene.

Dr. De F. W. Chase of Boston died of nephritis on December 19 at the age of thirty-eight years. He was graduated from the Bowdoin College Medical School and later took post-graduate courses in New York City. He recently inherited $1,000,000 through the death of his stepmother in Swampcott. Her relatives contested the will, but the case never came to trial on account of the illness of Dr. Chase.

Dr. Wm. C. Armstrong died at Wayne, Pa., on December 20 at the age of forty-seven years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1880.

Dr. John M. Rand, one of the oldest physicians in Newark, N. J., died on December 18 after a few hours' illness. He was seventy-two years old, and had studied at Harvard and Dartmouth. In the Civil War he was Surgeon of the Twenty-fifth Army Corps.

Dr. Oliver A. Blumenthal of Syracuse died on December 21 at Saranac Lake of tuberculosis at the age of thirty-five years. He had made a specialty of the disease, but contracted it himself.

## Correspondence.

### WOMAN IN MEDICINE.

To the Editor of the Medical Record:

Sir:—I was interested in reading the article on "Medical Education," written by Dr. Castelli, and I wondered if his opinions were gained from observation, or were only adopted from the mouldy, worn-out theories of men who one hundred years ago were in a dreadful state of alarm because of the expected deterioration of women, body and soul, when, in addition to cross-stitch, they were to study some reading, writing, and arithmetic. The doctor says physicians in general are different now, because they derive all their knowledge from books; he immediately goes on to say that women are unfitted for the profession of medicine, because their knowledge of the world is all second-hand, the impression at first given being that the sexes were alike in this matter. He should have noticed that intelligent educated women are observant, and are, moreover, interested in what is going on around them, as well as what happens at a distance. Do the writings of such women as George Eliot and Mrs. Humphry Ward show that they had a limited knowledge of the world, such as the doctor intimates all women possess, or is the worldly knowledge of which he speaks to be obtained only by an actual participation in the delights and woes which lead to such questionable wisdom, and which is only mentioned behind closed doors, and in congenial society? Surely knowledge so gained is demoralizing to any sex, and instead of being a necessity to the equipment of a physician will be but a blot upon him. If such knowledge contributes to a physician's usefulness, it ought to be of still more value to a clergyman, so that he may know whereof he speaks.

The doctor says, if married, she is so "absorbed in maternal cares, all other considerations become of secondary importance." If this is true of the married woman physician, it cannot be said of the wealthy lady who delegates to paid dependents the care of her offspring, and this, too, without the excuse of having to earn her daily bread. But is it true? Is there not something in knowing how to systematize work and how to direct others? And why is the privilege of parenthood made so one-sided? Is it not as great a mistake for the male parent to be so absorbed in professional cares that he can give no thought to the care and nurture of his children, as for the female parent to lose sight of every other duty in the sole one of propagation?

The doctor goes on to say that sympathy in women is a product of her feminine weakness, and constitutes another objection to her in the profession. Whether the quality of sympathy is present or absent in the male sex, and if it is present, what it proceeds from is not made clear. Most people, I believe, would consider that sympathy, like mercy, would bless both giver and taker, and we notice that it is the sympathetic physician who, other things being equal, is always welcome at the bedside of the sick, and not the cold, unfeeling creature who has no care for any wounds and bruises but his own, and whose visit constitutes a daily dread to the patient. Occasionally the charge is made that women are rendered hard and unfeeling by the practice of medicine; evidently there are differences of opinion.

The statement that "woman's natural tendency is to lead a life of dedication to some one" is absurd. It is true that women, as a body, are more moral, more conscientious, and more affectionate than men; that we are more likely to find a daughter working hard to support a widowed mother, and educate the younger members of the family than we are to find a son performing those duties. But instances of this kind, though far from rare, would only prove the daughter's sense of duty and her family affection. For if an elder brother, or any other relative, could and would relieve her of the burden the offer would be thankfully accepted, and the "life of dedication" would be ended. The statement is made that immense numbers of

women are engaged in philanthropic work, and, again, that women only become philanthropists when they are married to a philanthropist, or through devotion to the ideas of a dead husband, or from disappointment. This sounds rather contradictory.

We have some philanthropists whose wives, as philanthropists, are seldom in the public eye. We rarely hear of Mrs. Nathan Straus, or Mrs. Andrew Carnegie, or Mrs. Rockefeller, except as the wives of their well-known husbands, and not as philanthropists. I shall mention the names of just a few women whose deeds of philanthropy are due—not to disappointment, not to sorrow for the dead, and not to love for any one living person, but to a Christ-like love and care for all fellow-creatures, especially the suffering and the needy: Baroness Burdett Coutts, Jane Addams, Elizabeth Fry, Helen Gould. Did Mrs. Coutts "dedicate her life" to her husband? and give up her philanthropic work as soon as the honeymoon was over! Not a bit of it. She simply made her husband her almoner, and continued her works of charity as before. This was one of the then unusual instances of a woman being free to do as she pleased with a large fortune. There are still but a comparatively small number of women so blessed and privileged, and one cannot give away what is not possessed.

As to "the immense numbers of women engaged in philanthropic work" giving it up as soon as they become wives and mothers, we find that the majority of women engaged in such work are married ladies, many of them with families, and that many of the single ladies receive a salary for their work who labor with them, and that, instead of the married ladies doing this work to please living or dead husbands, the gentlemen in question have rarely manifested an interest in, or displayed any sympathy with, their wives in this field of activity. Now as to this "man's philanthropy, with its thought of humanity at large, this philanthropy with its broad significance," which robs the widow and orphan, which has been the cause of untold suicides, and spread misery and sin over vast areas, so that millions may be given to educational institutes and hospitals, huge and lasting monuments to the donor's name and generosity; this is philanthropy, indeed, of a kind. Men of this class have been styled by one of our senators "unhung criminals," who grind the masses in the dust, and bestow alms on the children of the men they have robbed.

Another objection made to woman in medicine is that she is "systematically infirm" for seven days in the month; the doctor says he has noticed an inability for the performance of her duties, at these periods, in women medical students and women physicians whom he met in hospitals in the performance of daily tasks. Are women in the habit of speaking of their condition at this time to the men with whom they come in daily contact? If a student has burned the midnight oil and worked herself up to a state of nervous tension over some, to her, important matter, or a woman physician has been up all night with a critical case, and these women are not just as bright as usual next day, must the absence of the usual alertness be attributed to but one cause? Trying as the life of a physician is, it is not nearly so arduous as that of a trained nurse. The average duration of the working life of a trained nurse, after graduation, has been placed at ten years; she is sometimes required to remain on duty thirty-six and forty-eight hours at a stretch. She is often obliged to eat cold or lukewarm food, badly served and partaken of at irregular hours. She gets what sleep she can on some kind of lounge, too narrow and too short for her to lie upon. She must use tact with the patient and his relatives, who are apt to be severe critics. The care she bestows on her patient may mean his life, the lack of it his death. A physician who knows and trusts a nurse will often leave much to her discretion, so that she can use her judgment in case of emergency. All this means added strain. A few years of nursing often reduces women of splendid physique to physical and nervous wrecks. How is it we do not find any objections to nurses working in this way on the score of sex or posterity? Think of our thousands of trained nurses, compared to the few, comparatively, women physicians.

One is impelled to ask, "Why display such solicitude for women physicians, and evince such a callousness to the welfare of women who are such useful members of society as trained nurses?" Has this solicitude a financial basis? If trained nurses were paid $100 or $200 per week, instead of $25, would it not be straightway discovered that such a life was very injurious to the nurses as women, but that men were eminently fitted to perform the work called for in the discharge of the duties of the nursing profession? It should be borne in mind that economic conditions have forced women to enter the business and professional world—or to starve. Such conditions are none of her making, as the six millions of working women in the United States to-day can testify. Why should all avenues of work be closed to her, except the most insignificant and the most poorly paid, which are often as arduous as any?

This pseudo-protective care is nauseating to any lover of even-handed justice, who believes in calling a spade a spade, and not a silver trowel.

Maude Glasgow, M.D.
110 East Eighty-first Street, New York.

## OUR LONDON LETTER.

(From Our Special Correspondent.)

THE QUEEN AND THE LONDON HOSPITAL—JAPANESE ARMY MEDICAL SERVICE—AMALGAMATION OF SOCIETIES—DISCUSSION ON RHEUMATOID ARTHRITIS—MEDICAL COUNCIL—OBITUARY.

London, December 8, 1905.

The Queen takes a great interest in the London Hospital, of which Her Majesty is president. The governors' meeting on Wednesday resolved to recognize the interest of their Royal President by erecting a statue of Her Majesty in the grounds. This will be the first statue of the Queen on English soil. Of course, the funds of the hospital will not be used for this purpose. As soon as the idea was broached £1,300 was subscribed for it out of £1,500, which will cover the cost. The practical re-building of the hospital is nearly complete. About half a million has been spent in the last eight or ten years. It seems an extravagant price to have laid out on repairs amounting to a practical rebuilding.

The success of the Japanese Army Medical Service is being commented on our general press. Statistics have been issued lately showing that the Japanese have completely reversed the experience of former wars with respect to the mortality from disease and from wounds. Prevention of preventible disease has been the aim and an object lesson of splendid success the result. Between February, 1904, and May, 1905, the Japanese armies lost 52,946 men in battle and only 11,992 from disease. The same tale is told of the Japanese Navy, in which the total casualties were 3,682. Of these, 1,891 were killed and 1,791 wounded. Of the deaths, 1,445 were due to drowning in the ships sunk by mines. Of the 1,791 wounded, 117 died; 647 required hospital treatment, and, of these, 32 were among those that died. Here is a lesson for us and our War Office. And yet, on the authority of Lord Roberts, a force beyond 55,000 would have to take the field "without any trained medical establishment whatever." Surely the War Office should wake to its responsibilities.

Several of the societies have now considered, with more or less attention, the question of the proposed amalgamation. There seems to be a general concurrence with the view that union offers many advantages, but the difficulties are rather formidable. Most of these are financial, and some of them seem almost insuperable. Endowed or trust funds, reserves, costs of *Transactions*, varying amounts of subscriptions, how are all these to be arranged? Some seem to think that the amount of subscription is of no consequence, but others see that it must not be high. No one seems to have been struck by the fact that if all the societies amalgamated to-morrow, half a dozen practitioners could start another the day after.

Dr. A. E. Garrod opened a discussion at the Medical Society on Rheumatoid Arthritis. He said the clinical group of cases did not coincide in extent with the anatomical, and no single morbid entity corresponded to the rheumatoid arthritis of the text books. He sketched the systemic affection—probably infective—in which fusiform swelling of joints and thickening of their capsules were attended by conspicuous muscular atrophy and constitutional symptoms (anemia, pyrexia, rapid pulse, brown pigmentation). He emphasized the distinction between the active state and the sequelæ. The joints did not exhibit osteo-arthritic changes—at least in the active stage. Such changes were not specific, but were degenerative lesions and might be the sequelæ of any disease which damaged the joint structures. In some cases the joints became the seats of osteo-arthritic changes, but these cases were distinct from rheumatoid arthritis, which was rather a peri-arthritis. This and many other joint affections were only local manifestations of constitutional change—mostly of microbic origin. Absolute rest in the early stage, bath treatment and massage later were recommended. Gouty dietary was useless. Aspirin sometimes relieved pain. Guaiacol carbonate was reported to be useful.

Dr. Cave, of Bath, divided cases into infective and trophoneurotic. Possibly both groups were of toxic origin, as there were several infections; so, also, several portals. He referred specially to two: the biliary passages

and the alveolar sockets of the teeth. It was important to attend to the state of the mucous membranes, but diet was of minor importance. Iodide and guaiacum were valuable.

Dr. A. P. Luff thought it easy to sort out septic cases. He objected to the term chronic rheumatism being applied to rheumatoid arthritis, which was an infective disease from one of the mucous membranes, not necessarily symmetrical in early stages. Chronic rheumatism was really a fibrositis of joints with obvious cracking. Iodide and guaiacol carbonate were valuable, if pushed, especially together.

Dr. Buckley, of Buxton, regarded spondylitis deformans as a fibrositis distinct from rheumatoid arthritis. For the latter he advocated climatic measures and raw or underdone meat, with copious libations of hot water.

Dr. Harburn, of Buxton, thought most cases auto-toxemic, often of gastrointestinal origin. He supported or modified Salisbury diet, electricity, counter-irritation, arsenic and guaiacol.

Dr. B. Abrahams said it was remarkable how joints recovered in acute cases, as proved by radiographs, showing the lesion was really periarthritis. Guaiacol was useful in early stage, but not later. Sand baths helped later.

Dr. P. Weber said septic cases were more acute and more likely to relapse. Stills' affection in children and spondylitis deformans were both distinct.

Dr. Hale White, on the contrary, regarded Stills' affection in childhood as identical with rheumatic arthritis. He had found the bones quite healthy in a case examined in the early stage, so it was quite distinct from osteoarthritis.

Dr. Sandwith referred to cases of arthritis following dysentery and resulting in deformity and atrophy, just like rheumatoid arthritis. Egypt was a good climate.

Dr. Poynton had produced the lesions of rheumatoid arthritis experimentally and the organism was the same as that of rheumatic fever. He believed it could produce several different joint lesions. He did not feel sure that rheumatoid arthritis was a definite, distinct disease.

Dr. Garrod, in his reply, said he could not think all these cases were the product of a single microbe. The osteoarthritic changes represented residual lesions of different joint diseases.

The General Medical Council managed to complete its session within the week. The second and third days were occupied with judicial business, resulting in the expulsion of offending practitioners from the register, chiefly on charges of advertising, canvassing, or covering. In some cases the sentence was postponed until next session, to give the offenders an opportunity of coming up again with further explanations and proof of conduct in the interval.

A large part of the fourth day was occupied with similar work as to the Dentist's register. Seven persons on that register were brought up for forming a limited dental company, two of them having been previously convicted of infringements of the Dentists' Act and fined for that by the magistrate. The business of the company, consisting of these seven shareholders only, was carried on by objectionable circulars containing untrue statements and in connection with a so-called Benevolent Dental Society advertising on an extensive scale. It was proposed to pronounce judgment on the charge at once (on the report of the Dental Committee), but the Council was saved from so unjudicial a step by an amendment to hear the parties. The incident illustrates how unsuitable a body the council is for the discharge of judicial functions. After hearing some of the parties and solicitors, the council deliberated *in camera*, after which the president announced that two of the names would be removed from the register and the other persons would have to appear at the next session.

Several reports of committees on matters referred to them were received and ordered to be entered on the minutes, and in some cases the recommendations of the committees were adopted. The committee on teaching practical midwifery, mentioned in my last, was only able to send in an interim report, as replies from some teaching bodies were belated.

A long discussion took place on the report of the Education Committee, with reference to the curriculum, resulting in a resolution asking for a report as to (1) the desirability of transferring physics, biology, and chemistry to the preliminary stage and (2) the advisability of requiring a five-years' curriculum after such transfer.

The state of the Irish Poor Law service was brought before the council by Sir William Thomson, who asked for a committee and declared that the circumstances under which the medical officers worked were a grave danger to the public health. The president questioned whether the Council could undertake an inquiry of this sort unless brought before them by a responsible body outside. He suggested a postponement until next session, and in the meantime taking the opinion of the legal advisers as to whether the Council was empowered to appoint such a committee of inquiry. This suggestion became the finding of the Council.

At the ripe age of 83, on the 18th ult., died Dr. Henry I. Fotherby, consulting physician to the Metropolitan Hospital and ex-president of the Hunterian Society, of which he was also a trustee until about two years ago, when his health induced him to resign. His energy and zeal did much to promote this society's work. He also took an active part in the London Institution and served many years on the committee. He retired to his country home in 1888, where he enjoyed a peaceful old age, surrounded by many friends and continuing the interest he had always felt in all philanthropic, charitable, and Christian movements, and not at all abating that in the progress of his profession. He was M.D., Lond., and M.R.C.P.

On the 22d ult., died P. Robert Cresswell, J.P., C.B., V.D., senior surgeon of the Merthyr General Hospital and Hon. Colonel in the Welsh Volunteers. He qualified in 1859 and took the Fellowship of the Edinburgh College in 1873. He organized and sent to South Africa, in the late war, three companies of Welsh Volunteers, and will long be remembered as an earnest officer in the force which he entered as assistant surgeon in 1860.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

FAILURE OF EXPERIMENTS WITH COPPER SULPHATE—DISPOSAL OF MANILA SEWAGE—THE CHOLERA—PERSONAL NOTES.

MANILA, P. I., November, 3, 1905.

THE experiments which have been conducted for some time by the local health authorities, in the treatment of the city water supply with copper sulphate, with the view of rendering all the water safe against cholera germs, have shown that this method is a complete failure in actual practice, in Manila. The efficacy of copper sulphate placed in the local water supply was thoroughly tested at the Bureau of Government Laboratories. Solutions of copper sulphate varying from 1 to 2,000,000, to 1 to 150,000 were prepared. Cholera organisms which were introduced into these solutions were recovered in each instance in all strengths between 2,000,000 and 200,000. In the strength of 1 to 150,000, no growth could be detected after four hours, and in the strength of 1 to 100,000, no growth of cholera organisms was found in one and a half hours. From this it will be seen that even in strengths of 1 to 150,000, a period of at least four hours would be required in order to make the Manila water supply safe against the cholera vibrio.

Great hopes were entertained by the health authorities that the use of copper sulphate in the city reservoir would remove the grave menace which has hung over the city since the reappearance of cholera upon the Manila watershed, which occurred almost at the beginning of the outbreak. In view of the fact that the disease commenced during the rainy season, and which is not yet at an end, it is feared that the dejecta of cholera cases may be swept into the stream.

The military has been on constant guard, and so far, their efforts to prevent the infection of the water seem to have been effectual.

If copper sulphate could have been used successfully in the reservoir, it will be seen that the city of Manila could have viewed the presence of cholera upon the water-shed with more or less indifference, but in view of the fact that the strength of 1 to 150,000 would be required in order to render the water safe, it was not deemed advisable to permit the population to drink constantly a copper sulphate solution of this strength. While there may be no immediate danger from copper sulphate in such strength, still, an accumulative effect might be expected if the practice should be continued over a long period of time.

Another factor to be considered in using a disinfectant in such a wholesale manner is, that the greater portion of the human excreta in the city of Manila is disposed of in septic tanks, and it was seriously questioned whether copper sulphate in a strength sufficient to kill cholera organisms would not also destroy the saprophytic germs and thus stop the putrefactive action which they start in the septic tanks. If the latter should have been the case, a stench would no doubt have arisen which would have been well nigh unendurable.

In view of the conflicting results which have been obtained in various cities, it would seem that the efficacy of copper sulphate depends largely upon the composition of the water supply into which it is placed.

Cholera has been almost completely stamped out of the city of Manila. There are cases occurring every few days, but they usually can be traced to the infection being introduced from the provinces. In the provinces, the situation is not so reassuring as it might be. The disease is gradually spreading over a greater area, and the health authorities find themselves seriously handicapped in not having a sufficient number of experienced inspectors to send to the various towns in which it makes its appearance, to aid the local authorities in combating the disease.

Col. Joseph B. Girard, the Chief Surgeon of the Division of the Philippines, who went to the United States last Spring on account of his health, has returned to Manila, and resumed his former duties.

Col. Charles B. Byrne, who has been acting as Chief Surgeon of the Division of the Philippines, now becomes Chief Surgeon of the Department of Luzon.

Lieut. Col. Wm. B. Davis, who has been Chief Surgeon of the Department of the Visayas, has been directed to return to the United States on the November transport.

## THE TOYAMA MILITARY HOSPITAL AT TOKYO, JAPAN.

To the Editor of the Medical Record:

Sir: It is with a keen delight, and a glow of scientific pride in his profession, that an American physician observes Japanese medical advances as he travels through this interesting "Sunrise Kingdom" and looks about with more or less alert eyes through some of the great military hospitals of Japan. It was my fortune a few days ago to see the gigantic Toyama Military Hospital, located here in Tokyo. It has a capacity for 7,000 patients, and its four great sections are located in different parts of a beautiful park, the whole hospital grounds covering over 150,000 square meters. The chief surgeon was my guide. I have forgotten his Japanese name, but whatever it may be, his courtesy and kindly disposition to show the hospital in all its phases, whether good or bad, surely entitle him to a place in the front rank of this courteous Japanese nation. When a visitor, especially a medical man from a foreign land, desires to gain access to any of the Japanese Military Hospitals and look about through them, it is necessary to obtain an official permit from the Japanese Department of War. This is usually granted when the request comes from the Legation of the physician's country, in my case from Mr. Griscom, our Consul-General at Tokyo. Armed with this official permit, on presenting it to the sentry at the gateway of the Toyama Hospital an escort was sent with me to the reception room of the Administration Building, about one-quarter of a mile distant. My card was taken by a very much alive Japanese boy, who soon returned and with bows and smiles motioned me to be seated. Then came a wait, during which steaming hot tea was served, accompanied by Japanese cigarettes. In about fifteen minutes, steps from heavy boots, with the clanking of riding spurs sounded in the hallway. The chief surgeon appeared, and we started on our tour of hospital inspection. He spoke English fairly well.

All the buildings are of cedar and pine boards, neatly and securely nailed together. None of the fifty odd structures is more than one story high. There are two up-to-date operating rooms supplied with every modern facility. As I looked into one of these rooms the surgeons were just tying the last stitches of a thigh amputation case. The drainage tube was in, and the flaps appeared to be very neatly in apposition. In the other operating room I observed all the essentials of a first-class equipment and scrupulous cleanliness was everywhere apparent. A surgeon need touch nothing with his hands once he begins "scrubbing up." Foot levers open and close, turn on and turn off everything. The sterilizing process is as absolute as anything modern methods in Europe and America have devised, and the charcoal-heated sterilizers, made in Japan, which are used, are the simplest things imaginable. In another part of the grounds I observed the Japanese method of sterilizing bedding by steam. A great cylinder on wheels, four feet in diameter, and six feet long, is employed. It is readily moved about, and both of its ends may be closed and opened. A water arrangement is underneath, which connects with the cylinder space. Charcoal is the fuel. The cylinder is loaded with bedding, and steamed for one hour; the bedding then removed and allowed to dry. Common sense, efficiency, compactness, cheapness are predominating characteristics in the sterilizing procedures. The kitchen arrangements by which such a large number of patients are kept properly fed, must of necessity be on a very large and scientifically studied scale. The Toyama Hospital kitchens number two, and they meet their requirements. At least one dozen giant iron pots of nearly one cubic yard capacity have in them, in each of the kitchens, the various component parts of the Japanese ration which are cooking, or waiting to be placed in the ration cups and rice boxes which each soldier patient is entitled to receive. The rice boxes of wood are about the size of an American brick. The rice is thrown into boiling water for ten minutes, when it is deemed sufficiently cooked, and is rationed into the long rows of empty wooden rice boxes standing nearby. Vegetables constitute a part of the Japanese ration also, together with fish and some foods typically Japanese, the character of which I do not at present know. The food rations are hauled on hand trucks of bamboo to the patients at their bedsides in the different buildings. There is no general mess hall. Inquiry regarding the average length of confinement for each patient in the hospital, surgical and medical, suffering from all kinds of ailments, revealed the fact that forty days was the approximate term of invalidism.

The hospital is divided into four separate divisions. One is a receiving ward for the wounded and medical cases sent in from the field. Another is for the medical and surgical convalescents. Another for infectious diseases, and the last of the four sections is for those cases, both medical and surgical, sent from the receiving wards. As each of the four divisions has many separate buildings, the surgical and medical cases are kept isolated. For example, there are separate buildings in which are quartered the venereal cases, skin diseases, dysentery, beriberi, tuberculosis, and the different groups of surgical cases.

In looking through the venereal wards, inquiry elicited the fact that syphilis among the soldiers comprised about 10 per cent. of those diseased, chanchroidal bubo cases, etc., about 30 per cent., and gonorrhea the remainder. Though these figures are but approximate, I mention them because there seemed to be an idea prevalent on our Pacific Coast in the United States, when I was there last winter, that the Japanese is immune to syphilis—a very serious fallacy. The skin diseases seen comprised the usual variety of eczemas, some scabies, scurvy, and the less common lesions. Beriberi was very manifest, and several separate buildings in the infectious disease division were devoted to the care of this ailment. The pathological findings of this peculiarly Oriental disease, are as interesting as its specific cause is puzzling. According to the exhaustive studies of Dr. Kinnesuke Miura, Professor of Internal Medicine, University of Tokyo, there is usually found in beriberi a degeneration of the myeline substance, and later of the axis cylinder of the nerves; a marked myositis with accompanying cellular infiltration, and occasionally a degeneration of the posterior horns in the cord, but never any involvement of the motor cells in the anterior horn of the spinal cord.

In the surgical wards, many of the operative results were of the most gratifying nature, the plastic surgery being especially ingenious and effective. Many of the stumps of the amputation cases were ideal in every respect. A look into the laboratory revealed the fact that the Japanese recognize the great importance of this medical aid. Every essential facility was there to do efficient laboratory work, from excellent microscopes to the different culture media for bacteriological studies. Ii the art of massage, too, the Japanese at Toyama recognize a powerful factor in hastening convalescence. Many rooms are set aside for this distinct purpose, and at stated intervals each day the various patients assemble to receive their particular massage prescriptions, the basic principles of which closely resemble those of the Swedish massage system. When a patient has reached the stage of progress from massage enabling him to perform the required movements, he is sent to an improvised gymnasium on the grounds, where he is made to exercise his leg, thigh, foot, hand, fingers, arm, neck, or whatever part of the body his prescription calls for, the apparatus being out of doors and of the simplest but most practical nature. In fact common sense is one of the most predominating features that is revealed in the direction of this gigantic military hospital. It is common sense based on such scientific knowledge as Mr. George Kennan, the War Correspondent for the "Outlook" in the far East, was telling me about the other day. He observed the Japanese soldiers throughout the siege and final capture of Port Arthur use a small mosquito netting to cover their faces and necks, and a mosquito proof glove to cover their hands when they slept at night in the mosquito-infested districts. "Each soldier," said Mr. Kennan, "carried his own little net, and used it just as conscientiously as he avoided drinking any but boiled water."

In the matter of latrine sanitation, the Toyama Hospital has at the end, and comprising a part of each of its buildings, a room of two sections, one a bath room, about ten by ten feet in area, and a smaller room as a water closet. All fecal and urine excretions enter a large thick wooden bucket, about one foot in diameter, and two feet high. These are emptied each day, and their contents sold to farmers who use it as soil fertilizer. Toyama has no sewage system other than this. Its waste garbage is disposed of in the same manner. Sometimes cremation is employed. The hospital water supply comes from the Tokyo

water supply, which was installed several years ago. Though the hospital buildings, averaging nearly one hundred yards long by ten wide, are of unpainted pine boards, with tar paper roofs, they are kept scrupulously clean. All who enter must remove their shoes at the doorway entrance. The patients who are sufficiently strong, are permitted to roam about the beautiful grounds at will, where small groves, many flowers, picturesque fountains, well laid out walks, green grass, etc., all combine to make an ideal locality for convalescence. Though this last stage is one of great importance in every patient's illness, and though it appears to be ideally met and facilitated at Toyama, this state of efficiency simply expresses what exists in every other department of this great hospital's machinery. From the admission to the discharge of a patient, each department appears to work absolutely efficiently and in scientific harmony with all the others, just as the different departments of the Japanese army in the fields against the Russians have done, and with such signal success.

There are many vitally important medical lessons to be learned from the Japanese, and one of the best places in which to study them is the Japanese Military Hospital called Toyama, located at Tokyo.

DONALD G. MCCASKEY, M.D.,
FORMERLY OF MEDICAL CORPS, PHILIPPINE CONSTABULARY.

## THE PATRICK CASE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Albert T. Patrick, convicted of murder in the first degree, will, unless the Governor interferes, be electrocuted January 22, 1906. The Court of Appeals, by a narrow vote of four to three, has declined to grant him a new trial, and this certainly constitutes a reasonable doubt of his guilt.

I have investigated the records of the trial and am convinced that the proof of his participation in the crime, if there really was one at all, is based upon testimony of which our profession has no reason to be proud, so loose have been the methods adopted and the conclusions reached. The attempt to find minute or other disturbances in the organs of circulation and the lungs in a body where not only all the chambers of the heart, but the larger vessels and the capillaries, contained embalming fluid to a greater or less amount is one certainly not entitled to credit, and there is something very horrible about such testimony being used for purposes of conviction. One of the chief witnesses was a weak-minded person who, under suggestion, made several contradictory confessions as to his guilt and evidently testified through compulsion.

I write this letter to the MEDICAL RECORD, earnestly hoping that all who feel as I do will communicate with Governor Higgins at once in behalf of Albert T. Patrick, or send their names to me.

ALLAN MCLANE HAMILTON, M.D.
44 EAST 29TH STREET, NEW YORK.

# Progress of Medical Science.

*Boston Medical and Surgical Journal, December 21, 1905.*

**Some of the Advantages and Fallacies of Urinary Examination.**—E. C. Savidge believes that laboratory findings are often misunderstood and used as the basis for erroneous deductions. This is particularly the case with reference to urinalysis. The author notes the following pertinent facts with reference to the matter. (1) In almost all patients over forty who put the tension of concentration on their vasomotor system, faint traces of albumin can be found if the urine is examined often enough This is especially noticeable with those who have overdeveloped venous calibers, whereby the extra capacity of the veins keeps an undue share of the whole volume of blood in the veins of sewerage blood. (2) Certain forms of therapeutics can vary the specific gravity, the output of urea; can compass the solution of crystals which, like pepper in the eye, must irritate the delicate kidney substance and point to sure future trouble; can, in these relaxed venous cases, even remove albumin by enhancing the tonicty of the veins. (3) Having thus, by repeated laboratory use, seen the relation between arterial tension and the output of urea; between venous tonicity and albumin; between specific gravity and the appearance and disappearance of hemoglobin; the following conviction has grown upon the author, viz.: Varying these conditions will vary the laboratory findings. Also, the conditions may exist and be perfectly observable some time before the laboratory will give any finding.

*New York Medical Journal, December 23, 1905.*

**The Diagnosis of Acute Hemorrhagic Pancreatitis.**—After defining this condition, J. C. Wilson declares it probable in the highest degree that cholelithiasis is its chief predisposing influence. The direct diagnosis rests upon the sudden occurrence of intense pain in the upper abdomen with vomiting, possibly slight epigastric swelling and tenderness with obstinate constipation. A normal or subnormal temperature may be present and collapse comes on early. We must base our decision upon the onset of the foregoing symptoms in an adult who has suffered from chronic gastroduodenal catarrh or from attacks of biliary colic; the location of the pain and tenderness in the upper abdomen; the absence of the distinct, boardlike rigidity characteristic of early peritonitis and an early high leucocytosis. Conditions always to be thought of in doubtful cases are poisoning by food stuffs (meat and fish) and corrosive chemicals, hernial tumors, acute obstruction, and perforative peritonitis.

**Complexions of the Insane.**—An interesting series of observations has been made by C. E. Woodruff, who notes that data have been collected proving that the short rays of light were responsible for much nervous damage to our blonds who, from lack of pigmentation, were not sufficiently protected from light rays in the climate to which they have migrated. Not only are they more susceptible to neurasthenia than are brunets, but this nervous condition in America is most frequent in light or Southern climates, and least in the dark Northern and cloudy ones. It has been presumed that insanity also followed the same rule, for in every part of the world statistics show that the greatest number of cases occur in or near the lightest months—May, June, and July—a fact as true for India as for France or Germany. Statistics assembled by the author tend to bear out this general contention. In a general way it may be said that the well-pigmented Americans do not suffer from insanity as much as the less protected types, but exact comparisons are impossible until we study the normal population. The man with dark hair, brown eyes, and olive or brown skin, has a tremendous advantage in the struggle for existence in light countries, and can evidently stand mental and nervous strains which the blonds cannot endure, except in cloudy places. There is no doubt that damage is done by the short rays of light and by the ultra-violet if too intense, to living tissues, and it is of importance that observations should be recorded of the complexions of all the sick, particularly of those suffering from nervous affections.

*Medical News, December 23, 1905.*

**Wandering Gallstones.**—W. L. Estes reports two cases. He summarizes the symptomatology of the condition as follows: a tumor which usually presents all the manifestations of an abscess, though the exact character of the swelling may be masked by adherent coils of small intestines which may lie over it anteriorly; great pain, marked interference with the functions of the stomach and intestines; jaundice is usually present only in the earlier stages, and may be absent entirely. The general symptoms are those of septicemia. The general sequence of pathological changes is doubtless (1) development of the calculi in the gall-bladder; (2) after infection of the interior of the gall-bladder; (3) suppuration and ulceration of the lining of the gall-bladder; (4) coincident adhesions of the gall-bladder to the transverse colon, both omenta, and possibly to duodenum and mesocolon; (5) perforation of the gall-bladder by extension of the ulceration; adhesions strong enough to resist the pressure of the escaping contents of the gall-bladder; (6) encysting fibrous sac; (7) gradual working downward of the abscess and contents.

**Results of Cold Irrigations as Compared with Warm Irrigations in the Treatment of Gonorrheal Urethritis and Endometritis.**—These observations were made by E. C. Shattuck, whose reasons for trying the cold irrigations were, first, the care of chronic metritis in spite of all treatment did not make satisfactory improvement; second, it was desirable, if possible, to reduce the time of treatment; third, he had used cold intrauterine irrigations when hot water was not available, had seen no bad results, and knew that they were used to some extent by hydrotherapeutic authorities in similar cases. From the figures given it does not seem that the cold irrigations were of any special advantage in any way over the hot.

**Treatment of Lobar Pneumonia.**—A. Ko[illegible] describes the plan usually followed by modern physicians, nothing especially new being presented. He believes that drugs should be administered whenever possible by the hypodermic method. The patient's position in bed should be very carefully changed from time to time in order to equalize circulation in the lungs. This is especially important in the aged. External applications are useless though cold compresses may be of some value, but even these ought not to be changed too often. For high temperature, if it is disturbing the patient, small doses of the coal-tar antipyritics may be used with perfect safety, prefer-

ably combined with a small amount of caffein. Delirium calls for bromides and possibly the guarded dose of morphine. Too much water must not be given; carbonated beverages should be avoided. For cardiac stimulation alcohol is the best remedy; next in value comes strychnine. For a weakened right heart venesection may be indicated. In pulmonary edema wet cupping is of greatest service. Oxygen is indispensable at this point. Atropine, strychnine, and nitroglycerin may all be given in one hypodermic. To this we may add the fluid extract of digitalis. Tincture of musk is a valuable remedy deserving of more frequent use.

*American Medicine, December 23, 1905.*

**One Patient's Experience with Two General Physicians, One Neurologist, One Leading Physician, One Gastrologist, Two Ophthalmic Surgeons, One Diagnostician, and One Refractionist.**—George M. Gould reports a case in which the patient had suffered from profound symptoms seemingly of intestinal nature, but also from psychic symptoms, such as lapses of consciousness, at least closely simulating those of major epilepsy, morbid delusions etc. His disease was diagnosed by the leading specialists mentioned as indigestion, hysteria, neurasthenia, nervous breakdown, hyperchlorhydria, etc., but all the treatments ordered had no effect in lessening the symptoms. One ophthalmologist reported to the neurologist that nothing was wrong with the patient's eyes, and then tried glasses, which gave no relief. A leading consultant made the diagnosis of eyestrain as the fundamental cause of the trouble, and soon after the ametropia had been accurately corrected by the third oculist the patient was restored to health. The lessons suggested by the case are set forth by Dr. Gould.

**Diagnosis of Bright's Disease.**—L. B. Pilsbury states that for diagnosis of this disease it is unnecessary to make minute distinctions. Clinically there are the acute, subacute and chronic form, which often shade into each other almost imperceptibly. If an acute process is followed for months or years by a train of symptoms indicating constant disturbance of kidney function we may feel justified in making a clinical diagnosis of chronic kidney trouble, though we may be disappointed at autopsy in finding few anatomic changes. It is perfectly proper to treat such a patient for renal insufficiency. Clinically we need only decide whether the lesions are predominantly either acute or chronic, parenchymatous or interstitial. Strictly speaking, an acute nephritis must show an inflammatory exudate of serum, leucocytes, and erythrocytes between the tubules, but the degenerative changes are always present in the tubules and in the glomeruli. In chronic parenchymatous nephritis the secondary or fatty and conntracted kidney may be as small as that of a chronic intersitial nephritis, but it is distinguished from the latter by the fact that the stage of contraction was preceded by a stage of something else, and that the production of connective tissue was preceded and overshadowed by degenerative changes. In chronic interstitial nephritis the production of new connective tissue precedes or goes hand in hand with the degenerative changes in the tubules and the glomeruli.

**Control of Nasal Hemorrhage.**—Henry Jones Mulford describes a simple method for controlling nasal hemorrhage, citing cases and outlining the blood supply of the nose and pharynx. His method consists of the subcutaneous injection of adrenal extract into the arterial supply at the nearest accessible point to the bleeding area. The injection may be made directly into the artery supplying the part, or it may be thrown into the tissue closely adjacent to the artery. This certainly is simple, but the result is marvelous. The ingoing arterial current sweeps the solution directly into the leaking area, all the vessels of the part are constringed, and almost at once the hemorrhage ceases.

*Journal of the American Medical Association, December 23, 1905.*

**The Elimination of Chlorides In Nephritis.**—J. L. Miller referring first to Widal and Laval's observation as to the inability of certain nephritic patients to eliminate sodium chloride in a normal manner and to the confirmation of their findings by ohers, reports his own observations as to chloride elimination in patients suffering from various types of nephritis, uremia, and myocarditis, and also in normal individuals. The patients were kept on a fairly uniform diet, and when possible were weighed daily. The chlorides were estimated for a period of nine days, the first and last three of which they received only the chlorides contained in their food, while in the three middle days an additional ten grams daily was administered. The author's conclusions are summed up as follows: "In patients with moderately severe nephritis associated with edema, the ingestion of large amounts of sodium chloride is followed by a chloride retention. The patient gains in weight, the edema becomes more marked, the albumin increases and symptoms may develop resembling uremia. In patients with severe nephritis, and especially those with uremia, chloride retention is very marked, as scarcely any of the extra chlorides administered are eliminated. In individuals with apparently healthy kidneys, following the ingestion of sodium chloride, there is a chloride retention equal to that of mild nephritis. The individual gains in weight, but there is no visable edema, no albuminuria, and no uremic symptoms appear."

**Diethyloxyacetyl Urea**—F. M. Houghton has investigated this substance, one of a new group of chemical bodies belonging to the methane series and condensation products of urea and teh various oxyacetic acids. There being no short name for the ethyl compound of this group, he offers the name given above as the most desirable one indicating its chemical structure. It is a clear, transparent, oily liquid, sp. gr. 1107, with a peculiar characteristic etherial odor and taste. It is soluble in about twenty parts of water, and is soluble in most of the organic solvents, e. g., alcohol, ether, chloroform, etc. The sodium salt forms flaky, very soluble crystals, having a mild etherial taste. Its chemical structure warrants the belief that the depressing ethyl group, 40 per cent., and stimulating nitrogen, 9.6 per cent., are in the right proportion to produce a safe and efficient hypnotic. Experiments on cold-blooded and warm-blooded animals show that diethyloxyacetyl urea is a relatively non-toxic chemical compound. the estimated fatal dose for man being nearly two ounces. It produces prompt hypnotic action with any of the usual methods of administration in warm-blooded and in cold-blooded animals, and complete anesthesia is produced by large doses and is followed by complete recovery. The pulse rate, blood pressure, cardiac action and respiration are influenced little, if at all, by reasonable doses. While laboratory results indicate that it will be of practical value, clinical experiments are still needed to demonstrate its desirability as a hypnotic for human beings.

**Inversion of the Uterus.**—L. V. Friedman describes the types of uterine inversion and suggests the use of the term "initial" instead of "partial" for the cases in which the fundus has not passed the internal os, reserving the latter term for those cases in which the os has been passed but the uterine cavity is not yet obliterated. He thinks the condition is probably much more frequent than is indicated by the oft-published statistics of Denham and v. Braun, and that the mortality is higher than Winckel's figure of 22 per cent. in 54 cases. The prognosis of acute cases will probably always be grave, in spite of the ease of immediate reposition; shock or sudden overwhelming hemorrhages are possibilities to be feared. A certain number of cases are probably unrecognized and these may affect the mortality statistics. A diagnosis is often very difficult, and in no other condition is an error more dangerous to the patient. Inversion may occur after labor without pain, hemorrhage or pronounced shock, and the favorable time for replacing may have elapsed before the attendant is aware of the complication. While in acute inversion immediate reposition is usually advisable, Friedmann, in case of severe shock, provided thh hemorrhage can be controlled, would defer manipulation. Leaving an adherent placenta until after reposition has, he says, many objections; its removal is then more difficult and it adds to the bulk to be replaced. He describes the use of taxis and also the vaginal (Spinelli's) operation and the abdominal methods of reposition. The objections to the vaginal method (complete anterior colpohysterotomy with replacement of the uterus after incision) are the danger of infection, the risk of injury to the tubes and ligaments and even to the bowels, the resulting adhesions and the possibility of the rupture of a uterine scar in a later pregnancy. He believes that with the progress of surgery, the method of abdominal section and intra-abdominal dilatation of the cervical ring will yet give better results than the vaginal operation, though at present the statisics are not nearly so favorable. He gives the details of the operation and reports two patients thus operated on successfully by himself shortly after delivery, attempts at taxis having failed. If this operation can be perfected so as to insure invariable mechanical success, he believes that it will be an ideal procedure for reposition of the inverted uterus without injuring its peritoneal investment. It also permits inspection of the tubes, which in some cases may require resection.

**Gonorrheal Inflammations.**—S. M. Burnett remarks that while gonorrheal iritis has long been recognized by ophthalmologists, it is a singular fact that it is almost entirely ignored in the treatises on genitourinary diseases, with the exception of two American text-books. Opinions differ as to its frequency, some authors holding it to be extremely rare, while others consider it rather common. It secms from his own experience, to be rare in Washington, even in a class, the negroes, in which gonorrhea is most rife. It may appear under various forms; the so-called spongy iritis, usually one of the rarest types, is met here, he thinks, with greater comparative frequency

than the other forms. Another distinctive feature is its tendency to recur during the same or subsequent attacks of gonorrhea. Like gonorrheal rheumatism, it almost invariably appears in the declining stages of the disease, and one or both eyes may be affected. The importance of an early correct diagnosis for proper treatment is obvious, as a delay of a few days or even a few hours may mark the line between the preservation of good vision and partial or complete blindness. An illustrative case is reported. Burnett also gives the account of a case of conjunctivitis occurring in connection with gonorrhea, which he considers an instance of the rare indigenous infection by gonorrheal toxins, as careful examination of the purulent discharge revealed only pure mucopus. This case suggests to him the importance of bacteriological examination in every case of purulent conjunctivitis occurring in gonorrheic patients. If no gonococci are found the prognosis is materially modified as compared with cases in which they are present. No author, so far as he has observed, has mentioned the pronounced mucopurulent type of conjunctivitis from endogenous gonorrheal toxin infection seen in the case here described.

*The Lancet, December 9, 1905.*

**Irritation of the Kidney Caused by Hexamethyleneamina.**—A case is reported by T. W. Parry of renal irritation from the remedy named, familiarly known as urotropin. His patient was a man with enlarged prostate and chronic cystitis, who took the drug in five-grain doses t. i. d., the dose being given after a couple of days, every four hours. Irrigation was practised in the usual manner. Marked improvement resulted, and in a week the amount of urotropin taken was cut down one-half, but in two days increased to the original amount, as the patient retrograded. The urine, which had formerly had but a trace of albumin, showed an increased amount of this substance. Bladder irritability came on and it became evident that the remedy was being decomposed into (among other constituents) formaldehyde and that the irritating symptoms were referable thereto. Discontinuance of the urotropin led to a subsidence of all annoying symptoms. This result appears to show that urotropin, if given for a sufficient time, may not only cause persistent vesical irritability even with an acid, normal-smelling, non-sedimentary urine, but in certain circumstances it may produce a nephritic irritation of a decidedly detrimental character. The chemistry of urotropin is discussed at some length.

**Clay-Colored Stools without Jaundice, but with Copious Bilious Vomiting.**—The patient of W. Gordon was a middle-aged man who complained of intense pain in the upper part of the abdomen, copious vomiting of green bile, and passage of clay-colored stools. At times the latter were of a pale-cream color. Basng his views on similar cases previously reported, the author made a diagnosis of cancer of the pancreas. The peculiar color of the stools may have been due to a slight admixture with unaltered bilirubin. It is considered that under normal conditions the coloring matter of the feces is the result of the mutual reaction of the bile and pancreatic juice under the influences met with in the intestinal tract.

**Are the Problems of Cancer Insoluble?**—This question is discussed by E. F. Bashford, who declares that the investigation of cancer suffers from a too great readiness to hold dogmatic opinions on a subject of which we know so little. Reference is made to older hypothetical explanations of the nature and growth of the malady, and an outline is given of the organized agencies for the prosecution of the work at the present day. We now know that all races of mankind, and, in fact, all vertebrate animals, suffer from cancer, and that the histological lesions are alike in both men and animals, having also in both the same relative high-age incidence. There are certain limitations to transmission. Habitat, food and conditions of life play little if any direct part in causing a disease showing constant and unique factors in organisms so divergent. The results of certain lines of inquiry show that civilized man's responsibility for the occurrence of cancer in native races and domesticated animals is in all probability limited to providing them with an opportunity for reaching the "cancer ages." We now know that cancer possesses powers of growth after the death of the original host unparalleled by either organisms or tissues in the vertebrate kingdom. The artificial propagation of the disease tells us nothing directly as to its origin. It only indicates that the distinctive characters of any single malignant new growth, once acquired, are probably permanent, for under artificial propagation different carcinomata of one organ (the mamma) retain their individual characteristics. They are not convertible into one another nor do they merge into a common type. Artificial propagation gives the opportunity of studying many of the properties of malignant new growths in detail with a thoroughness unattainable in the case of sporadic tumors. It has already proved the inadequacy of the standards by which an anthropocentric pathology has attempted to measure the proliferation and to probe the nature of cancer. The true measure of that proliferation has not yet been arrived at. Its study suggests what appears at first sight to be a series of new problems, but may really be restatements of old ones—viz., Why is the amount of the growth of cancer relatively greater than that of any vertebrate organism? Are growth and cell division always progressive? Is cancer subject to a process of natural decay, or if not, how is its energy of growth and assimilation maintained? To all these questions it should be possible to obtain a definite answer with the means at our disposal, and once they have been answered the original problem, so long the object of futile direct attack, will present itself in another form more approachable than the old problem, "What is the cause of cancer?" has proved to be.

*British Medical Journal, December 9, 1905.*

**The Treatment of Typhoid Fever.**—William Ewart believes that the two essential aims in the treatment of typhoid fever are to feed the patient and to starve the disease. He explains the empty bowel treatment, which he considers worthy of a thorough trial. As to the question of stimulants, he declares that they are not often necessary, and in the majority of cases should not be given. As it is hopeless to disinfect the feces, the only course left is to suppress them. The writer speaks first of agents employed in the local treatment. Although neither paraffin nor charcoal is capable of arresting the growth of Eberth's bacillus in the bowel, nevertheless both are used in these cases with benefit. The writer has used the maximum daily dose of two teaspoonfuls of liquid paraffin every four hours for adults. This quantity might easily be increased. This substance in sufficient doses is a non-irritating mechanical laxative. Frequency in the repetition of the doses is indicated both for the sake of lubrication and for cleansing. He quotes various authorities as to the value of vegetable charcoal. Secheyron advocates its use as a general household antidote, his opinion being that although it is not a germicide, nevertheless it absorbs the toxins; this agrees with Bouchard's observation that sleep is restored to bad cases of typhoid fever by the administration of charcoal. A systematic inspection of the feces together with a daily examination of the abdomen will show if the powder is doing its office without any tendency to accumulation and concretion. An important part of the treatment is the frequent or daily administration of from one to two grammes of castor oil every morning if the bowels should fail to act at least once daily. Under empty bowel conditions paraffin and charcoal are brought into direct contact with the diseased surfaces. The writer has for some years entirely substituted whey for milk. Sometimes even whey has to be diluted, but usually complete absorption of the small amount of albumin which it contains occurs in the upper bowel except during the apeptic stage of typhoid prostration. The dietary of typhoid fever patients must contain the mineral salts and the organic acids and essences contained in fruits and vegetables. Common salt is a help to digestion and to metabolism. It should be given in the whey in the proportion of ten to fifteen grains to the half-pint in addition to sugar. Phosphates may be given in syrup as a medical food, but a vegetable diet is the natural source for their derivation and for that of other mineral and organic salts. The watery extracts, duly strained, of vegetables and fruit, especially when freed by boiling from any excess of coagulable albumen, may be given. The juice of various fruits and a daily cup or two of vegetable soup or broth lightly flavored with fresh beef or bacon and carefully clarified are excellent. Fruit jellies may also be given. The nitrogenous supply is represented by peptonized whey, and, if desirable, by artificial peptones. However, white of egg diffused in the whey before peptonizing is a more simple form. Sugars and dextrines are all absorbable without residue. Clarified honey and maltine come under this class. Oil is the least likely among the fats to yield any residue, but cream is more acceptable. It is substantially true that no organized remnant and no chemical precipitate can be left in the jejunum by the foods enumerated. It is the physician's duty to suit the proportion of each to the stage under treatment, remembering that it is a mistake to attempt much feeding during the first few days.

**Peritoneal Tolerance.**—W. Horton Date reports this case. The patient was a laborer, seventy-two years old, a farm hand. He first felt discomfort in his right iliac region four or five years ago. There were never any acute abdominal attacks, but just a feeling of distention. Constipation was habitual, and aperients were necessary. Two years ago, a swelling appeared above the right groin. Considerable pain developed in it. The swelling was tense, irreducible, dull on percussion and about the size of a hen's egg. At operation the lump was found to be an abscess. After being opened, a finger could be passed downward and backward toward the right sacroiliac joint. The abscess was drained. In two

weeks but a small sinus remained. Examination revealed the presence of a foreign body in this opening which was finally removed under an anesthetic. It was found to be an almost perfect rabbit's rib. Recovery was uneventful. The writer adds that it was remarkable that this rib should have traveled from the intestine without producing any acute symptoms. It had rested in the patient's abdomen for four or five years.

**Shock.**—John D. Malcolm states that shock, sleep, extreme lowering of the surrounding temperature associated with bodily exhaustion, death from old age, and death from certain complicated febrile conditions, have the following common features: the functions of the central nervous system are partly in abeyance, so that unconsciousness ensues, the powers of sensation and motion are lost, while the temperature tends to fall. Profuse loss of blood may lead to a condition very difficult to differentiate from that of shock. The writer believes that in shock, the condition of the unconscious, inert body approximates somewhat to that of a cold-blooded animal, so that its temperature is influenced by that of its surroundings, which, as a rule, is lower than the normal body heat. As to the changes in the vessels, the writer believes that whatever be the condition of the large arteries, the arterioles of the splanchnic area are not relaxed, and therefore the vessels of this area are not paralyzed as a consequence of shock. Perhaps in all states of unconsciousness which are not accompanied by any discoverable lesion, there seem to be two disturbing conditions tending to bring about a loss of brain power, nerve exhaustion and brain anemia, due, except in sleep, to the intense contraction of the arteries. The writer contends that the blood pressure is lowered where the vessels are contracted. A relaxation of the vessel from exhaustion of the vasomotor centers cannot occur until the arteries have been intensely contracted. Exhaustion follows extreme effort. The writer does not believe that there is any evidence of the existence of a paralysis of the vessels from exhaustion of the vasomotor centers. He calls attention to the fact that when a patient is in an extreme state of shock, the administration of vaso-dilators such as nitroglycerine and alcohol, causes the small vessels to relax, a greater volume of blood circulates through them and improvement in the pulse follows. He thinks that this would be an impossible effect of these drugs, if it is assumed that the pulse is already absent from over-dilatation. The complete or partial anuria observed in shock also indicates that the arterioles are constricted. As to treatment, the wrier adds, all the usual methods seem to be in harmony with his views. If it were true that the vessels became relaxed in the state of shock, the application of warmth and the administration of stimulants and other vaso-dilators would be harmful, at least theoretically. He thinks that the suggestion naturally following, that we should revolutionize our views on these methods of treatment, is one of the strongest arguments against the theory that the condition of shock is due to a relaxation of the vascular system.

*Berliner klinische Wochenschrift, December* 4, 1905.

**Gigli's Hebotomy.**—Dührssen says that the induction of abortion, the classical cesarean section, and perforation of the living child have been rendered almost entirely unnecessary by Gigli's operation of lateral pubic section, while symphysectomy will become totally obsolete. Hebotomy has now been performed on 115 recorded cases, and though death resulted in six of the cases the unfortunate outcome cannot, the author believes, in any instance be ascribed to the operation. He summarizes his views regarding the indications for hebotomy as follows: The operation is adapted for cases in which the true conjugate measures from six and a half to nine centimeters, and is to be performed in primaræ if after full dilation of the cervix and in the presence of good pains the head does not descend into the pelvis, or if with an incompletely dilated cervix and a movable head there is danger either for the mother or the child. In the latter case, Dürhssen's cervical or lateral perineal incisions, vaginal cesarean section, or the use of the metreurynter may also be required. In multiparæ, hebotomy is to be carried out in all cases in which former children have been stillborn in consequence of pelvic contractions, if necessary inducing labor by the preliminary use of the metreurynter. If living children have already been obtained as well as stillbirths, it may be advisable to place the saw in position but not to complete section of the bone until it is found to be unavoidable as Döderlein has advised. The author prefers to make the operation truly a subcutaneous one by carrying the saw behind the pubic bone by means of a special trocar under guidance of a finger in the vagina. Performed in this way he considers that already existing infection is not a contraindication, while troublesome hemorrhage is less likely to be encountered than if the more open technique advised by some authors is employed. He believes that the operation is one that can be safely performed by the practitioner, and does not think that a separate assistant must perform the delivery as Reeb has suggested. The greatest stress must be laid on the necessity for having the soft parts sufficiently dilated or dilatable to render obstruction to delivery from this source unlikely, and he advises that in order to avoid any possibility of vaginal laceration opposite the gap in the pelvic ring the outlet be freely incised on the same side as that on which the pubiotomy is performed.

**Experimental Observations on the Effect of Tea on Gastric Secretion.**—Sasaki has made a series of experimental observations on dogs having a Pawlow fistula, The experiments were conducted as follows: The animal was given 300 c.c. of tea through the esophageal fistula, this was allowed to remain in the stomach fifteen minutes, and any residue was then drained off through the gastric opening. The interior of the stomach was wiped dry with sponges and the resulting secretion collected at intervals of five minutes and tested. The results showed that the preliminary treatment with tea caused a distinct inhibition of gastric secretion. The gastric juice obtained under these conditions had a lower acidity and was secreted in smaller amounts than was the case in control experiments in which the same amount of plain water was given instead of tea. The author considers, however, that the local effect of the beverage may in man be somewhat neutralized by the stimulation to the appetite afforded by its flavor and aroma. He also suggests that the use of tea as a routine constituent of the usual test breakfast given for the purpose of obtaining specimens of stomach contents in cases of gastric disease may not be altogether rational in view of the apparently not unimportant local action of the infusion.

*Münchener medizinische Wochenschrift, December* 5, 1905.

**The Treatment of Wounds and Wound Dressings.**—Graser says that the fate of a wound is usually determined at the close of the operation. The progress that has been made in this field of late years depends more on the recognition of important sources of error than on the invention of new procedures. He regards as the greatest step in advance made during the last decade the recognition of the fact that it is not possible to free the hands from germs by any means of sterilization if they have been recently thoroughly contaminated with infected material. It is therefore of the greatest importance for the surgeon to avoid contact with surgically dirty substances and in case such pollution occurs immediate and repeated cleansing must be regarded as a sacred duty. The author warmly recommends the use of rubber gloves both as a means of avoiding soiling of clean hands in dealing with infectious cases, and for the protection of the wound in performing clean operations. He uses a cap while operating, but wears a veil only when suffering from nasal catarrh. For the ligation of vessels he employs iodine catgut of the thinnest possible sizes. His most radical innovation, however, is concerned with the actual dressing of the wound. All wounds which can be completely closed by suture and from which no oozing of blood or exudate is to be expected may, according to the author, be freely exposed to the air without risk of infection. He carries this principle so far as to leave clean laparotomy or hernia wounds entirely unprotected, save for a thin veil consisting of one or more layers of gauze, the edges of which are fastened to the skin by collodion or plaster. Free access of air is allowed to the wound in order that dessication of the secretions may occur as promptly as possible and thus form an impenetrable barrier to infection of the cut surfaces The author also applies the same principle in the treatment of amputation stumps and arthrectomy wounds If drainage is necessary in these cases it is secured by the insertion of a small glass drain through a special buttonhole in the skin a short distance from the incision proper. A suitable protective framework is adjusted to prevent injury to the stump and the adjacent joint is immobilized to a plaster dressing. The author has applied this principle of wound treatment to 500 laparotomies, 130 amputations, 52 osteotomies, and 70 resections of joints. Another suggestion made is that in cases in which the operation must be followed by the application of an extensive plaster-of-Paris dressing, this be to a large extent applied beforehand, as in this way the dressing at the close of the operation is much simplified.

**Operations in the House of the Patient.**—Landenburger reports the results obtained in eighty-eight major operations performed in the houses of patients often belonging to the poorest classes. Most of these were laparotomies, and all of the others were procedures such as suture of the patella or other joint operations which require the highest degree of aseptic technique. Seven deaths are recorded; one of acute pancreatitis, several others were cases of general peritonitis, and one following the extirpation of a large carcinomatous goiter in a man of seventy, who died of collapse twelve hours later. The

author advocates the performance of such operations outside of hospitals on the ground that the results justify the proceeding practically, while theoretically the same degree of asepsis is obtainable and it is even probable that there are fewer dangerous germs to be found about the average dwelling than are present in a busy hospital. Another advantage lies in the greater education of the general practitioner who, by his participation in such operations, gains a better insight into the pathology and necessity for prompt action in abdominal conditions than is possible in any other way. The author sterilizes all of his own sutures and dressing materials himself at home; the instruments and rubber gloves are boiled at the patient's house. He uses as operating table any substitute that may be found on the premises; the anesthesia is carried out according to Witzel's drop method, and in this form may safely be entrusted if necessary, to an unskilled assistant. The author is his own instrument-passer, and works with only one trained assistant. Although the preparation of the sterile goods entails more work for the operator, he secures the certainty of their proper sterilization and is not obliged to depend on the conscientiousness of nurses or attendants.

*Deutsche medizinische Wochenschrift, December 7, 1905.*

**The Hand as an Obstetrical and Surgical Instrument.**—Ahlfeld, under this title, endeavors to bring forward fresh evidence in favor of the thesis he has long maintained, to the effect that his hot-water alcohol method of hand disinfection is the most serviceable for routine use in obstetrics. He asserts that under favorable conditions it is possible to achieve absolute asepsis of the hand and to maintain it sufficiently long, and under conditions corresponding to those present in operative work. An experiment to demonstrate this claim is described as follows: The hand was first scrubbed with soap and water and was dried on a clean but not sterile towel. The hand was again dipped in hot water and was scrubbed in 90 per cent. alcohol for three minutes with a brush and for two minutes longer with flannel. The hand was immediately placed in a vessel containing warm sterile water and kept there twenty minutes. It was then passed through the neck of a jar containing 500 c.c. of nutrient broth and immersed below the surface. For a period of one hour the hand was kept in motion in the fluid; the jar was closed and placed in the incubator, but even after several months no growth of germs occurred. The author asserts, however, that certain conditions must be fulfilled in order to render such perfect sterilization possible, and he ascribes the discrepancies between the results he has obtained and those reported by other observers largely to the fact that most of his experiments have been conducted on pupil midwives. The female hand is usually, by its smoothness and favorable conformation about the nails, more advantageous for such experiments than the coarser male member. In addition, Ahlfeld was able to insist more strictly on thoroughness in carrying out the procedure with these pupils than would be the case in dealing with the persons ordinarily used for such experiments. He closes his article with a strenuous plea for the rehabilitation of the naked hand as an obstetrical instrument and supports his contention by referring to the favorable results that have been obtained in the Marburg Gynecological Clinic under his direction. Rubber gloves he condemns for habitual use, on the ground that he has found in actual practice that in 50 per cent of the cases they are punctured or torn in actual operative work. Their widespread use would, especially among midwives, and to a lesser degree among doctors also, undoubtedly lead to a serious degree of neglect of the necessary thoroughness in hand disinfection.

*The American Journal of Medical Sciences, November, 1905.*

**The Influenza Bacillus in Bronchiectasis.**—Thomas R. Boggs, from the researches which he has made in this subject, believes that the influenza bacillus is probably capable of producing extensive pathological changes in the lungs, leading at times to bronchiectasis. The organism may be a secondary invader or associated with other bacteria; the latter may be the preponderant factor. In the writer's small series there was no clinical difference determinable between the pure influenza infections and the mixed or non-influenza cases. The very close clinical resemblance of these cases of bronchiectasis to some cases of chronic tuberculosis with cavity formation is important, and may, in the absence of cultural investigation, lead to wrong diagnosis. Physical signs alone, therefore, cannot be relied upon for a positive diagnosis of tuberculosis. Care should be taken to prevent the possible infection of others from these chronic cases having influenza bacilli in the sputum, as the organisms may not have lost their pathogenicity by a continued growth in these old infections.

**Angioneurotic Edema Involving the Upper Respiratory Tract.**—Thomas H. Halsted calls attention to the fact that while all text-books on the skin describe this disease under one heading or another, nevertheless, text-books on the nose and throat, with few exceptions, have neglected any reference to or description of the diseases in any way. He then gives a description of several interesting cases in which this disease affected the nost and throat. The acute circumscribed swelling of angioneurotic edema as it appears in the mucous membranes of the respiratory and gastrointestinal tract appears, according to the writer, to resemble that on the skin. Its onset is very sudden. Sometimes the patient is asleep, sometimes awake, and the symptoms seem to be largely due to mechanical obstruction. The etiology of this disease is not well understood. In some cases heredity is clearly shown. The individual attacks are probably caused by some toxin which is either produced within the body or introduced from without. It is probable that this disease is often mistaken for manifestations of gout and rheumatism. Worry, mental excitement and fright, anxiety, exposure to cold, and traumatism are without doubt immediate causes for outbreaks. In cases in which this disease affects the upper respiratory tract, the treatment may be divided into the management of the various acute attacks as they occur, the correction of any local disease which may have to do with the localization of the lesions or edemas in the air passages, and the treatment of the constitutional disease which is at the root of the attacks. The writer has had successful results with the use of adrenalin and cocaine locally in edemas in the fauces, pharynx, and larynx, and in more severe cases he has employed scarification. Tracheotomy may be indicated. Ice locally may add to the edema. Quiet in bed and removal of anxiety are most important. Saline laxatives and alkalies reduce the usual hyperacidity of the urine and increase its quantity.

**Report of a Case of Pneumococcus Sepsis.**—John S. Thacher reports this case. He states that before the onset of this illness the patient was said to have been in good health though inclined to indulge too freely in alcohol. The pneumonia occurred unexpectedly and ran a course which did not vary greatly from the ordinary except as it was modified by the alcoholic history. It resolved, though slowly and incompletely. Toward the end of this process an empyema developed, followed immediately by a general pneumococcic infection which attacked the lining of the heart and the membranes of the brain and spinal cord so severely that within a few days ulcerative endocarditis and meningitis developed. The effects of the virulent infection by the pneumococci were very rapid and intense. Autopsy was made 27 hours after death. Ten blood serum tubes were inoculated from the blood of the right and left ventricles and from the pericardium. On one inoculated from the left ventricle, appeared a growth of pneumococci giving the characteristic reaction with Hiss' inulin medium.

**Gonorrheal Septicemia and Endocarditis.**—W. S. Thayer declares that the comparative frequency of gonorrheal septicemia and endocarditis may be regarded as generally recognized. The development of symptoms suggestive of septicemia with fatal results, consecutive to gonorrhea, without evidence *intra vitam* of any focal complication is also not a rarity. The writer has seen a number of cases in which an ulcerative endocarditis has followed gonorrhea. In the only one of these in which cultures were taken *intra vitam* streptococci were obtained. However, in every one of these cases the connection of the urethritis with the development of the symptoms was such as to make it probable that the acute infection had served as the portal of entry. The writer reports two cases at the end of this article which presented the usual features of ulcerative endocarditis, developing on the one hand in a case of acute gonorrhea with arthritis about five weeks after the onset of the disease, and in the other during a urethritis. In both cases with a pure aortic lesion, there was a well marked, presystolic, rumbling murmur (Flint), suggestive of mitral involvement. In one case cultures from the blood during life were positive. In both cases at necropsy pure cultures of the gonococcus were obtained from the affected valves. The writer calls attention to the following points of interest: The demonstration of the fact that the mild, continued fever sometimes seen in connection with gonorrhea without apparent complications is, in some instances, at least, evidence of a true gonorrheal septicemia. A true gonorrheal septicemia in cases in which there is no evidence of local complications may run a course not dissimilar to that of typhoid fever. In doubtful cases of continued fever associated with gonorrhea the possibility of a gonorrheal septicemia should always be borne in mind.

# Society Reports.

## THE NATIONAL ASSOCIATION FOR THE STUDY OF EPILEPSY AND THE CARE AND TREATMENT OF EPILEPTICS.

*Fifth Annual Meeting, Held in New York City, November 29, 1905.*

THE PRESIDENT, DR. WILLIAM P. SPRATLING, OF SONYEA, N. Y., IN THE CHAIR.

**Epilepsy, the Strangest Disease in Human History.**—Dr. WILLIAM P. SPRATLING delivered the presidential address, taking this as his title. (See page 1051.)

**Reports on Progress In the Public Care of Epileptics.**—Dr. H. M. WEEKS, the superintendent of the New Jersey State Village for Epileptics, located at Skillman, N. J., said that this village was established by an act of the Legislature in 1898, and was formally opened for the reception of patients on November 1, of that year. The village contained about 800 acres of land, nearly all of which was under cultivation. There were at the present time accommodations in the village for 300 patients.

Dr. M. L. PERRY, Superintendent of the Hospital for Epileptics at Parsons, Kansas, which was opened for the reception of patients in October, 1903, said that the institution now had a population of 340, and a total capacity of 400 The number of patients was steadily increasing, and it would soon become necessary to refuse applications for admission. There was little doubt, however, that the next Legislature would provide for the construction of several additional buildings, and such other improvements as circumstances might demand. The first aim of the institution was to relieve the State Hospitals for the Insane of their epileptics, and the first patients that were received were transferred from those hospitals. Subsequent transfers had been made, until at the present time the separation of those two classes was complete, and there was not an epileptic remaining in those hospitals. Experience had demonstrated the wisdom of that course, and it had proven beneficial alike to the insane and the epileptic. It had been the policy of the institution from the beginning to allow the patients as much individual freedom as possible, consistent with necessary discipline. All of the patients who were not confined to bed or who were not physical wrecks were required to do some work, and they had found this to be one of the most important and efficient adjuvants to treatment. The results obtained by treatment had varied greatly, but on the whole had been satisfactory. In some of the patients there had been no improvement whatever, but in a great many others there had been a marked diminution in the number of seizures, with decided improvement in their mental state and general physical health. There were several now under treatment who were considered to be on the road to recovery, and three had been discharged as cured. Of those three, all of whom presented well marked cases of epilepsy, two had returned to their homes and work, and had resumed their places in society; the third had been lost sight of. These results might appear to some as trivial and unsatisfactory, but it should be borne in mind that thus far they had been dealing almost exclusively with cases of chronic epilepsy of long standing.

THE PRESIDENT said that at the Craig Colony for Epileptics, at Sonyea, N. Y., there were now under observation and treatment 1,050 patients, and 900 applications were on file from epileptics who could not be received for lack of room. The plant represented an investment of about $900,000, and included seventy-one buildings scattered over 2,000 acres. Additional buildings for the accommodation of 200 more patients had recently been contracted for.

Dr. J. CLIFFORD SCOTT, Superintendent of the Pennsylvania Epileptic Hospital and Colony Farm at Oakbourne, Penn., said that this colony was supported largely by private contributions, and that over 75 per cent. of the patients were on the free list. The colony was located on a farm of 110 acres, and had admitted, up to the present time, 161 patients, of whom nine had died, two had been discharged cured, 67 improved, and 32 unimproved. Fifty-one patients still remained in the institution. An effort was made to furnish employment that was adapted to the ability and natural tendency of the individual. Outdoor work was, of course, most beneficial, and the men were kept employed, excepting in inclement weather, on the farm, lawn, truck garden, and about the buildings. Sufficient vegetables were raised in the garden to keep the table supplied most of the year. The women did most of the household and laundry work, besides having sewing and embroidery classes. Frequent entertainments were given, consisting of musical recitals, dramatic sketches, etc. The results of the colony treatment were most encouraging. The patients became more cheerful and more healthy physically, and without exception the number of their seizures were lessened.

Reports on progress in the public care of epileptics were also presented by Dr. WILLIAM F. DREWRY, the Superintendent of the Central State Hospital at Petersburg, Va., and by Dr. THOMAS C. F. FITZSIMMONS of Wilkes-Barre, Pa.

**The Public Care of Epileptics in Australia.**—Miss ALICE HENRY of London, England, sent a communication on this subject, in which she stated that material progress had been made in regard to the increasing sense of social responsibility toward the epileptic in Australia. Communications were also presented by the Secretary from various sections of the civilized world, as an evidence of the great general interest that this subject had aroused.

**History of a Case of Epilepsy of 52 Years' Duration, With 28,000 Convulsions.**—Dr. MATTHEW WOODS of Philadelphia said that when this patient, a man about 57 years old, first came under his observation, the history obtained from him and from his mother, who had been his constant nurse, was that he had suffered from severe and frequent epileptic attacks for 52 years. The patient himself had kept a carefully tabulated record for many years of his *grand mal* seizures, and he had estimated that during his life he had had over 28,000 severe attacks. During the first fifteen years of his infirmity he had consulted many physicians, and had tried numerous remedies without apparent benefit, so that all treatment had long ago been abandoned. Dr. Woods said it was the first chronic case he had ever seen where the patient did not come to him saturated with the bromides. The patient frequently had three or more attacks daily, and scarcely a day passed that he did not have at least one. The treatment advised by Dr. Woods was as follows: An almost exclusively vegetable diet was ordered, only a little meat being allowed, and that in the middle of the day. The patient's supper was to consist of tea or coffee, with bread and butter, and he was told to avoid eating pork, veal, cabbage, cooked tomatoes, pastry, and other foods difficult of digestion or apt to excite fermentation. A pill containing one-tenth of a grain of capsicum, one-thirtieth of a grain of strichnine, and one-half of a grain of the hydrocyanate of iron was ordered before each meal and at bed-time. Also a dram and a half of the bromide of potassium, divided into four doses, each dose given with the utmost regularity at 8 A. M., at 12 o'clock, and at 4 and 8 P. M. The bromide was ordered to be given in a very weak solution, the quantity of water with each dose being increased by one ounce every week, until each dose was taken in twelve ounces of water. When the attacks were nocturnal, the last two daily doses should be united and taken at 9 P. M. in a pint of water. After two weeks of the above treatment, during which period the patient had two convulsions, he consented to an operation, under ether, for the relief of a phimosis of long standing. The prepuce was removed, together with three calculi and nearly an ounce of thickened, gelatinous, subpreputial secretions. This added very much to his comfort and satisfaction, and made a profound impression

upon him. Subsequent to the beginning of his treatment, the patient had six convulsions in all; four of these occurred while he had temporarily stopped his medicine, and the other two while he was taking medicine, but prior to the operation. His death occurred three years and nine days after his last convulsion, at the age of 60, and was due to valvular insufficiency.

Dr. M. Allen Starr of New York said he heartily commended and thoroughly believed in the colony treatment of epilepsy among the poorer classes, and he would like to see it extended to cases that existed among the well-to-do, but he did not consider that feasible. He agreed with Dr. Woods that it was not uncommon to see a chronic epileptic practically make his family sacrifice their happiness and usefulness to the community to his care.

**Can a Colony for the Care and Treatment of Epilepties Be Made Self-Sustaining? If So, How?**—Dr. Thomas C. Fitzsimmons of Wilkes-Barre, Pa., read a paper with this title. He stated that among the obstacles in the way of accomplishing substantial material aid for the epileptic, the most serious was the securing of sufficient money properly to house and care for all classes who suffered from this distressing malady. The question naturally arose, could a colony of epileptics be made self-sustaining? In the speaker's opinion, it would require from seven to eight years to develop a colony institution sufficiently to place it on a self-sustaining basis. However, with a sufficient acreage, say an average of two acres of arable land to each colonist, and the wise and judicious selection of a soil which should be adapted to the raising of crops most productive and profitable in that locality, he thought such a colony would become self-sustaining.

**Statisties of Epilepties in Hampden Conuty, Mass.**—Dr. Everett Flood of Palmer, Mass., presented this paper. He stated that in general it seemed to be true that the more familiar we became with a community, the more epileptic cases we found. The population of Hampden County was 175,603. The number of epileptic persons reported in the whole county was 224, a ratio of 1 to 783; adding 56 as the number of cases that were probably overlooked, it would give a total of 280, or a ratio of 1 to 550. These statistics were collected in 1900, and revised one year later.

Dr. Spratling said he could corroborate the statement made by Dr. Flood that statistics of the number of cases of epilepsy were misleading, and that many cases remained concealed. The more that was done for the epileptic, the more that he felt was being done for him, the greater the number of cases that would come to light.

Dr. Edwin A. Down of Hartford, Conn., said that the ratio of epileptics to the general population given by Dr. Flood corresponded very closely to the figures he had obtained in Connecticut. The difficulty of securing accurate statistics on this point was increased by the fact that many so-called cases of masked epilepsy went unrecognized.

**The Use of a Bromide-Ferrated-Aperient Water in the Treatment of Epilepsy.**— Dr. G. Kirby Collier of Sonyea, N. Y., presented this paper. He said that while the use of the bromides in the treatment of epilepsy had long been recognized as a valuable adjunct to our materia medica, the many abuses of the drug were well known, as well as its harmful effects. Among these he mentioned chronic bromism, characterized by a loss of appetite, a nauseous, fetid breath, chronic gastritis, constipation, muscular weakness, frontal headache, a sense of mental weakness, failure of memory, congestion of the uvula and fauces, inactivity of the excretory organs, and hallucinations; also various skin eruptions. In order to remove, or at least minimize the injurious effects of the drug, Dr. Collier devised the method of administering the bromides with a saline purgative, in order to promote the elimination of the bromide, and disguising the taste of the two, so that the dosage could be more easily regulated. The method devised was as follows: A concentrated solution of the bromides, the sodium, potassium, calcium, and ammonium salts, was made with the addition of magnesium sulphate. Epsom salt was selected on account of its prompt action without giving rise to any nausea or griping, and its diuretic property. The bromides were used in the strength of sodium bromide, 6 parts; potassium bromide, 3 parts; calcium bromide, 2 parts; ammonium bromide, 1 part, and magnesium sulphate, 8 parts. The bromides and magnesium sulphate in the above proportions were added to a quantity of water sufficient to yield 128 volumes, which gave a concentrated solution. The object in view was to have this so-called bromide water take the place of the ordinary drinking water at meals, two ounces of the concentrated solution being added to one quart of water, preferably iced, the patient drinking one glass, equal, approximately, to one-half pint at each meal, or oftener, if necessary. It was thought desirable to make this a ferrated water, and to that end one fluid ounce of the tincture of chloride of iron was added to the 128 parts of the concentrated solution. The use of the bromides in this form was begun in June, 1905, being given to patients who had previously been taking large amounts of the drug, and the method had resulted in a distinct lessening of the number of seizures, and a marked improvement in the general condition of the patients.

Dr. James W. Wherry of Dansville, N. Y., said that while all recognized the value of the bromides in epilepsy, the harm that frequently followed their use could not be lost sight of. If the combination proposed by Dr. Collier would retain the good qualities of the bromides, and eliminate their injurious ones, it would prove a boon not only to the physician, but to the patient.

Dr. Spratling said that during his fifteen years' experience with 2,500 cases of epilepsy, he had never yet given the bromides with the expectation that they would ever cure the disease. He took the stand that they had a place in the treatment of epilepsy, but it was wholly secondary to any good they could do in the way of a cure. He had yet to see a genuine case of epilepsy cured by the bromides alone; on the other hand, he had seen an enormous amount of harm come from their use.

Dr. M. L. Perry of Parsons, Kansas, said that perhaps a partial explanation of the good results obtained by Dr. Collier with his bromide-ferrated-aperient water could be traced to the eliminative properties possessed by the combination, and the consequent improvement in the patient's general health. The great difficulty was to get the sedative effect of the bromide without its injurious effects upon the patient's general health and mentality.

Dr. Max Mailhouse of New Haven, Conn., raised the query as to how much of the benefit that followed the use of the combination bromide mixture was due to the treatment itself, and how much to the other factors that formed a part of the colony treatment. He was inclined to agree with Dr. Perry that the favorable results were to a certain extent, at least, attributable to the eliminative effects of taking such large quantities of fluid; perhaps by helping to eliminate toxins that were absorbed from the digestive tract.

Dr. Everett Flood of Palmer, Mass., said that when the sedative effect of the bromides was first discovered, and there was great need for a drug of that character, it was very likely that excessive doses were administered. The time had now come when we should be very careful about the dose and the method of administration, and we knew that a small dose would often answer all the purposes of a large one. He was firmly of the opinion that the drug should be given in smaller doses and at longer intervals. He believed that the bromides still had a place in the treatment of epilepsy, and that we should oppose their misuse rather than their use.

Dr. Collier, in closing, said that the dose of the bromide salts in the mixture was about eleven grains to the half pint of water; the patient received eleven gains of the bromides daily, whereas the other patients were receiving from thirty to a hundred grains daily in the ordinary form.

The demand for salines and cathartics was also very much lessened while they were taking this mixture.

**Traumatic Psychic Epilepsy.**—Dr. Pearce Bailey of New York city read this paper. He stated that focal, or Jacksonian epilepsy, resulting from injuries to the motor cortex, was a clinical condition, thoroughly established, of unmistakable identity, and in which the relationship of cause and effect was incontestable. Traumatic general epilepsy, though its individuality was less well assured, was nevertheless recognized by most competent authorities as a legitimate and direct outcome of trauma to the head. Traumatic Jacksonian epilepsy was rarely accompanied by any purely psychic manifestations. General epilepsy from trauma, on the other hand, was not infrequently associated with psychic phenomena. When associated with recurring convulsive seizures there was no difficulty in recognizing the purely mental manifestations as part and parcel with the epilepsy. When, however, all convulsive phenomena were absent, the diagnosis of epilepsy became a much more uncertain matter; and, indeed, it was questionable whether the diagnosis of epilepsy from psychic symptoms alone was justifiable. Neither the periodicity, the amnesias, the automatisms, the periods of depression, nor the myoclonia were in themselves characteristic of epilepsy and of nothing else. This became particularly apparent when observing the occasional mental effects of head injuries. After the initial unconsciousness had passed off some patients continued to present mental symptoms. They were of a delirious, confusional and, especially, impulsive character. They might be continuous, or, more frequently, periodic, with normal intervals. The impulsiveness of these patients closely resembled that in the epileptic psychoses. The patient at one moment might talk rationally and coherently; at the next be irrational, irresponsible, and violent. Dr. Bailey then reported in detail a case of traumatic psychic epilepsy, and said the only point he wished to raise was to call attention to the resemblance between psychoses resulting from brain injuries and epileptic states, and to express his own opinion that a differential diagnosis between the two conditions, if they were individual, was often impossible.

Dr. L. Pierce Clark of New York city said he recently saw a case quite similar to the one reported by Dr. Bailey. The patient was a girl of twelve years who, after an injury to the head, developed attacks corresponding very closely to the description given by Dr. Bailey, excepting that she also had typical *grand mal* attacks, in addition to her psychic manifestations. The speaker said he would be very loath to make a diagnosis of true epilepsy without the presence of some convulsive features, although such a case might be classed as epileptoid.

Dr. Adolf Meyer of New York city said he had seen a number of cases that could be classed in the category of traumatic psychical epilepsy, and he reported such a case coming under his observation. He thought the early recognition of the condition was of great importance, and emphasized the desirability of an operation in certain cases.

Dr. Spratling said that these cases were of great interest from a medico-legal point of view.

**Biographs of Various Types of Epileptic Seizures.**—By Drs. William P. Spratling of Sonyea, N. Y., and Walter G. Chase of Boston, Mass. This paper was illustrated with biographic pictures taken by Dr. Chase at the Craig Colony for Epileptics at Sonyea. Dr. Chase said that some months ago it had occurred to him that the biograph might be employed to depict pathological motion, and that a series of films covering the various phases would not only be useful to the student from a diagnostic standpoint, but of value in studying and analyzing the muscular action. The most difficult pathological movement to reproduce was that of an epileptic seizure, for the reason that it took several minutes to set up and focus a biographic camera, and the patient was not always sufficiently obliging to have his seizure out of doors in an available place, and also at a time when the sun was at its best, for an out-door light or a room with powerful electric lights especially arranged was absolutely necessary to good results. An abundance of material was also necessary. Dr. Spratling, of the Craig Colony, had kindly placed the resources of the colony at his disposal, and with the assistance of the staff he had been able to biograph successfully twenty-one separate seizures, including one of status epilepticus.

**Election of Officers.**—The following officers were elected for the ensuing year: *President,* Dr. Max Mailhouse of New Haven, Conn.; *First Vice-President,* Dr. Everett Flood of Palmer, Mass.; *Second Vice-President,* Dr. William F. Drewry of Petersburg, Va.; *Secretary and Treasurer,* Dr. James W. Wherry of Dansville, N. Y.

## NEW YORK ACADEMY OF MEDICINE.

### SECTION ON SURGERY.

*Stated Meeting, held December* 1, 1905.

Dr. George E. Brewer, Chairman pro tem.

**Result of Interscapulothoracic Amputation for Sarcoma of the Scapula.**—Dr. John Douglas presented this patient, who was a man, 37 years old, a laborer, who was admitted to the hospital on September 19. Nine months previous to admission his left shoulder became stiff, especially in the mornings, and this stiffness would disappear after using the arm for some time. He had had constant pain in the shoulder and along the nerves of the arm. Pain became so bad that he could not use the arm, and for the three months before coming to the hospital could not raise the arm above his head. He was unable to sleep at nights and he lost 35 pounds of weight. The shoulder girth was larger than on the normal side. On September 25 a section of the tumor was removed and submitted to the pathologist, who reported it to be a giant celled sarcoma. On October 6, interscapulothoracic amputation was performed, according to Berger's method, with but a slight modification of flaps. Cocaine was injected into the brachial plexus. Primary union occurred and the patient was up on the sixth day. Jeanbrau and Riche, in the *Revue de Chirurgie,* No. 8, 1905, reported 188 cases, 125 of them verified histologically. Before 1887 the mortality from this operation was 30 per cent., but since that date had been reduced to 8 per cent. Berger reported 129 cases; 69 amputations for tumor of the humerus gave a mortality of 4.5 per cent., 25 amputations for tumor of the scapula gave a mortality of 25 per cent, and 35 amputations for tumor in the axilla gave a mortality of 11 per cent. With regard to the average length of life Jeanbrau and Riche in 105 cases report three years, 24 cases alive after five years, and one after 26 years. The special point of interest was in its rarity; in 129 cases reported by Berger only 25 were for tumor of scapula.

**Modified Method of Resecting the Elbow and Ankle Joints.**—Dr. Albert A. Berg presented two patients. In one the patient, a boy, had an attack of anterior poliomyelitis, which was followed by paralysis of the extensor muscles of the left lower extremity and some of the muscles on the posterior aspect of the leg of the same side. There was also a complete paralysis of the anterior and posterior tibial groups of muscles of the right leg. The boy was totally unable to walk and the mother requested that something be done to prevent the deformities becoming worse. He, therefore, determined to ankylose the ankle on one side, doing an arthrodesis on the left side. In so doing he followed the suggestions of Mayo and with excellent results, the little fellow being able now to move about well.

**Acute Infectious Osteomyelitis.**—Dr. A. V. Moschcowitz presented a patient, 13 years of age, who was admitted to Mount Sinai Hospital December 16, 1904, and was discharged June 1, 1905. During his stay at the hospital it became necessary in successive operations to remove the entire right ulna and the upper four cm. of the right radius, to chisel open the left humerus throughout its entire extent, and to resect its lower two inches. All of these op-

erations were performed for progressive acute infectious (*Staphylococcus aureus*) osteomyelitis, with perforation into the elbow joints. In spite of the bilateral extensive resections the functional result was perfect, the patient having complete flexion and extension.

**A New Method of Excision of the Knee Joint Without Opening the Joint.**—Dr. Carleton P. Flint described this new method, illustrating the steps of the procedure by the lantern. A rectangular skin incision was made, the flap with the subcutaneous tissue being reflected upwards. The next incision was a curved one, with its concavity upwards, and started in the vastus internus a little above the upper limit of the subcrural bursa and was carried down and outwards to the tendon of the quadriceps extensor, one-half an inch above the patella; from here outwards and upwards to a point corresponding to the beginning on the inner side. The muscle with the tendon was completely divided and turned upwards, thus exposing the subcrural bursa. Two small incisions on either side of the femur were next made, starting on each side of the patella in the incision just described and carried downward and backward to the joint line. The one on the inner side divided the tendinous expansion of the quadriceps, the one of the outer side the tendinous expansion and part of the iliotibial band. The subcrural bursa was now separated from the femur and turned down, tilting the patella when not adherent. The last incision was carried transversely across the front of the tibia down to the bone just below the joint line. A flat retractor was next introduced on the inner side behind the head of the tibia close to the joint line in such a way that all the soft parts were held back. The tibia was sawn through as close to the joint as warranted, the leg being held flat on the table. After exposure of the posterior region of the condyles the femur was sawn through from behind forward and slightly downward at a sufficient level to clear the cartilage behind. This saw-cut was carried forward until it reached the margin of the cartilage on the anterior surface of the femur, and the saw was then withdrawn. The leg was then placed in a horizontal position and the saw introduced behind the subcrural bursa at the upper margin of the articular cartilage on the front of the femur and a cut made which would meet the anterior limit of the horizontal saw-cut made from behind. This last cut was almost vertical in the coronal plane, and allowed the articular portion of the femur which extended upwards in front to be removed with the joint. Now it was possible to lift out the joint with the patella and subcrural bursa, the articular surfaces of femur and tibia, all complete without having opened the joint. The subsequent steps of the operation differed in no way from those hitherto used. This method of resection offered the following advantages: It was quick; there was little danger of contamination of the wound by tuberculous or other infections from the joint; hemorrhage could be reduced to a minimum; the operation was thorough, there being but slight chance of leaving diseased tissue behind, thereby diminishing the probability of recurrence.

Dr. Arpad G. Gerster said that the method of operation presented by Dr. Flint was an admirable one, but the advantages recommended were not real; they were, in fact, theoretical and academic, especially the point raised regarding the danger of reinfection of the wound. In his own experience he had never seen a single case of tuberculosis secondary to opening a joint. With regard to hemorrhage due to the application of prolonged constriction with the dissecting away of the capsule little by little, he believed here too the dangers were exaggerated. If the surgeon picked up the larger blood-vessel, made apparent by milking the limb, and if the limb was compressed properly, hemorrhage would be absolutely controlled. He acknowledged the beauty of the procedure demonstrated which removed all that was diseased, but only in cases that were suitable for such an operation. But there were a limited number of cases of tuberculous joints that were suited for this operation in his opinion. Many of them, for instance, requiring resection were already opened and many had a mixed infection. In such cases the method would not be at all applicable.

Dr. Howard Lilienthal agreed with all that Dr. Gerster had said, and that in properly selected cases the operation described by Dr. Flint was the most surgical method for performing resection. With regard to the dangers from contamination he said he had had but three cases, two of resection of the knee, and one of resection of the humerus, in which there was undoubted invasion of distant parts through faulty operative procedure. One man had tuberculosis of the knee and after operation got up an undoubted tuberculous meningitis, from which he recovered. Another had a tuberculous osteomyelitis of the humerus and, after operation, also developed a tuberculous meningitis, from which he died. Therefore, in properly selected cases, the opening the joint in these operations was to be avoided and the method advocated seemed to be a good one.

Dr. Royal Whitman had never had any trouble with hemorrhage following these resections.

Dr. Reginald H. Sayre believed that there were cases in which the method proposed would be a valuable one.

Dr. Eugene H. Pool said that the claims of Dr. Flint for the method described were, in his opinion, justified by the results he had obtained after using that method. This patient had an advanced tuberculous arthritis of the right knee. The pains were so severe that an operation was demanded and he decided to try the method advocated by Dr. Flint, telling the patient, however, that the method might fail and an amputation might have to be done. There was no shock or post-operative bad effects. It was surprising how little hemorrhage there was and how little time was consumed.

**Hand Protection in Roentgen Praxis.**—Dr. Henry G. Piffard read this paper. He said that rays that passed entirely through a tissue without let or hindrance did not affect it, and *per contra* those that were arrested or absorbed by the tissues were the ones that affected and interfered with its physiological functions. The employment, therefore, of non-penetrable (absorbable) rays and their prolonged impact resulted in the most serious disorganizations of the integument. The dermal lesions early received the name of *x*-ray "burns," and the non-penetrating and easily absorbable rays that produced them Dr. Piffard designated as the *caustic* rays to distinguish them from the more penetrating ones that expended their energies on the deeper tissues without appreciable damage to the skin. As a warning to those who might be inclined to carelessness in personal protection he showed the photograph of a hand of a well-known radiologist, which really conveyed but an imperfect idea of the ravages that had followed the incautious use of this form of energy. Not only had fingers been lost, but also hands and arms, and even death had followed in the track of the earlier lesions. Undoubtedly the most frequent cause of hand burn was the pernicious habit of using the hand for the purpose of testing the quality of the rays with the fluoroscope. It was manifest, however, that the use of the human hand as a test object must be abandoned and a suitable substitute be employed. Unquestionably Benoist's radiochromometer afforded the most accurate and definite information as to the penetrating power of the rays issuing from a given tube and in radiographic work gave the information with great precision. The professional radiographer should know the conditions of the tube if he hoped to obtain satisfactory negatives, and he rarely made an exposure without first testing the quality of the rays. This unfortunately was not true always of the radiotherapeutist; some rarely took any cognizance of the state of their tubes or of the quality of the rays issuing from them. This accounted for the somewhat discordant clinical results obtained by different operators. Whichever radiometer was employed, or whenever a tube was in action, some form of protection for the hands should be employed. Many shields that he had used he said he had found somewhat incon-

venient in practice and he had substituted a home-made arrangement that had proved entirely satisfactory. It consisted in simply covering the anterior hemisphere (except a two-inch window opposite the target) with a sufficient number of coats of lead paint to absorb the less penetrating rays. In the one he presented twenty coats of paint were used. A radiograph was here shown taken on an *x*-ray plate, actuated by a 12-inch coil with a current of 8 amperes through the primary and an exposure of .45 seconds. The radiometer showed that penetration of the rays was equivalent to a No. 8 on the Benoist scale. Tested with the electroscope the ionizing radiations were in the ratio of 20 through the window to 1 through the protected portion next adjoining the window. Therefore, it was fair to assume that the protection was amply sufficient so far as the caustic rays were concerned. This statement referred only to the *x*-rays that traversed the anterior hemisphere. Perhaps in most instances parts or the whole of the posterior hemisphere became fluorescent, indicating the direct impact of the cathode rays and subsequent emission of *x*-rays. Such a tube, therefore, became nearly as dangerous from the rear as the front, and unless this tube could be coerced into better behavior, should be entirely enclosed in a non-radiable box, or completely covered with a sufficient coating of lead paint. From his statements it was shown that a tube actuated by a coil was unsafe, behind as well as in front of the target. The usual means whereby the trouble from an inverse current could be obviated was by the use of a Villard valve, largely used abroad but not well known in this country. With this valve, properly connected in series with the tube, the break current had free passage, while the make current was choked off. The hands should be further protected and Dr. Piffard used an old pair of driving gauntlets that were well worn and flexible, and applied six coats of white lead paint to their backs, leaving the fingers unpainted. The gloves were radiographed and showed that the protection was sufficient. The fingers were then painted. In conclusion he said that body protection, *i. e.* protection against the deeply penetrating or sterilizing rays, was of but little moment to those who made but occasional use of the rays, but the professional radiologist had already learned that still more strenuous measures were needed. Briefly, if using a coil, means should be taken to protect from the wild rays generated by the inverse current. In addition to this it was wise to enclose the entire tube in a non-radiable box or to interpose a movable protecting screen between the tube and operator. The lower part of this screen should be covered with sheet lead, while the upper part was furnished with a window of dense lead glass. Some radiologists arranged the tube and patient in one apartment, while they themselves occupied an adjoining one, protected by lead and with a lead glass window, the rheostat and switches being controlled from the protected room. Personally, and as a matter of convenience, he kept a brick wall between himself and the patient during the exposure and observed the behavior of the tube with a mirror.

Dr. L. G. Cole, referring to what Dr. Piffard said of the rays which were absorbed by the tissues causing the burning, or disturbances in the skin, said that this might be so with the so-called caustic ray, but he was inclined to believe that it was the ray which set up secondary rays in the soft parts which caused the trouble; that was to say, the ray coming from the tube generated the ray in the living tissues, of the same character as the one found in that part of the tube. When light was thrown through the tissues one was going to generate in the tissues rays which were a variety of *x*-ray; and this he said was the ray that would give the most trouble, causing sterility and some of the more dangerous manifestations. The ray that generated the ray in the tissues came from the walls of the tube and not directly from the anode. There were two distinct classes of rays from a tube, one capable of setting up indirect rays, the other absorbed by the tissues. Referring to hand protection, he said the covering of the hands was like covering the gauge of a boiler. His own hands had suffered greatly from cracks; but so soon as he stopped working with the rays practically they cleared up.

Dr. Hermann Besser and Dr. Stern discussed the paper.

## American Society of Tropical Medicine.

At a meeting held December 8 in the ampitheater of the Medico-Chirurgical College at Philadelphia, Colonel Wm. C. Gorgas, Assistant Surgeon-General, United States Army, and Sanitary Inspector at the Isthmus of Panama, delivered an address entitled "The Relation of Mosquitos to Yellow Fever on the Isthmus of Panama," in the course of which he declared that yellow fever and malaria are no longer to be feared by those engaged in building the Isthmian Canal by reason of preventive measures that have been instituted. A hospital has been equipped with modern safeguards for preventing the spread of the diseases named. Two wards were carefully screened and although for two years they contained constantly one or more cases of yellow fever no case of the disease developed in the hospital. Each patient suffering from yellow fever is kept in a wire cage bed until all danger of infection is past. In addition the wards are disinfected with sulphur every two weeks. All cisterns and water-barrels in the area of possible infection are screened and to ensure the reporting of all cases the Government offers a reward of $100 for each case reported. In the discussion Dr. Abram Jacobi, of New York, took the ground that American physicians will build the canal. He held that the American physician has accomplished what physicians of no other nation in the world have been able to achieve. If the United States is to become the first Power in the world it will be through the intelligent application at Panama of sanitary principles.

## College of Physicians of Philadelphia.

At a stated meeting held December 6, Dr. Burton K. Chance read a paper entitled "Report of a case of Cerebellar Tumor." The patient was a man who presented severe occipital headache, with vomiting unrelated to food, abducens palsy on the left side and facial palsy on the right side, and restriction of the fields of visions, with the appearance of optic papillitis. Nystagmic movements of the eyeballs developed, but there was no disorder of gait or station. Operation was decided on, but convulsions occurred, and terminated fatally before this was carried out. On post-mortem examination a fibrosarcoma, rather larger than an English walnut was found attached to the left lateral margin of the cerebellum, in which organ it was embedded without infiltration. The growth was of a character and so situated that it might have been enucleated with perfect success. Dr. John H. Gibbon read a paper entitled "Report of a Case of Successful Suture of Penetrating Wound of the Heart." The patient was a colored man who received a knife-wound in the precordium which after rib-resection was found to involve the wall of the right ventricle. The opening in the heart was sutured and drainage provided for and uncomplicated recovery ensued. The patient was exhibited.

## College of Physicians of Philadelphia: Section on General Medicine.

At a stated meeting held November 13 Dr. Frank Billings of Chicago by invitation read a paper entitled "The Medical *versus* the Surgical Treatment of Diseases of the Stomach." He dwelt on the importance of a knowledge of the mechanical conditions of the stomach; namely, the size, position, and motor activity of the viscus, from the diagnostic standpoint. Closely related to these is the gastric chemistry. Special attention was devoted to the consideration of ulcer and carcinoma and the indications for medicinal and surgical treatment respectively. Dr. George E. Brewer of New York read by invitation a paper entitled "The Indications for Surgical Intervention in Diseases of the Stomach in the Absence of Symptoms of

Perforation or Hemorrhage." Dr. JOHN H. MUSSER presented a communication entitled "The Relation of Carcinoma to Ulcer of the Stomach Especially as Influencing the Treatment of Ulcer." Dr. JOHN B. DEAVER read a paper entitled "The Final Results of Operations, Such as Gastroenterostomy, Pyloroplasty, etc., in the Treatment of Diseases of the Stomach." Dr. J. DUTTON STEELE read a paper entitled "Certain Therapeutic Indications Based Upon the Presence of Occult Blood in the Gastric Contents and the Feces."

---

At a stated meeting held November 22 Dr. H. EMERSON WETHERILL exhibited a device of bent heavy wire intended as a holder for various laboratory appliances and numerous other uses of allied character. Dr. JOSEPH SAILER presented a communication entitled "The Quantitative Estimation of the Stomach Contents." He traced the evolution of the study of the gastric chemistry and described in detail modifications of modern methods of testing with the results of his own observations. Dr. J. DUTTON STEELE read a paper entitled "The Treatment of Some Phases of Gastric Indigestion." He pointed out that a condition frequently encountered is hyperesthesia of the gastric mucosa sometimes simulating hyperacidity. The underlying state is often neurasthenic and the most appropriate treatment consists in the administration of nervines and sedatives. Dr. JOHN B. DEAVER read a paper entitled "The Surgical Side of Gastric Indigestion." He insisted upon the necessity of a surgical opinion, at least when relief fails to attend medical treatment carried out for a reasonable time. Among the conditions amenable to surgical intervention are dilatation of the stomach, with or without pyloric obstruction, gastric ulceration under certain circumstances, and gastric carcinoma if discovered at a sufficiently early stage. Dr. ALFRED HAND, Jr., read a paper entitled "Some of the Manifestations of Congenital Syphilis."

---

## Medical Items.

**Contagious Diseases—Weekly Statement.**—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending December 23, 1905.

| | Cases | Deaths |
|---|---|---|
| Measles | 764 | 12 |
| Diphtheria and Croup | 300 | 39 |
| Scarlet Fever | 170 | 6 |
| Smallpox | ..... | ..... |
| Chickenpox | 206 | ..... |
| Tuberculosis | 312 | 174 |
| Typhoid Fever | 72 | 9 |
| Cerebrospinal Meningitis | 15 | 15 |
| Typhus Fever | ..... | ..... |
| Yellow Fever | ..... | ..... |
| Cholera | ..... | ..... |
| Totals | 1,839 | 255 |

**Presence of Saccharomyces in the Milk of the Cow, and Their Bacteriological Activity.**—F. Valgussa and G. Mafera have examined commercial samples of milk as to whether they contain saccharomyces, and the changes that take place in the milk as a result of their activity, with a view to producing a new form of artificial milk suitable to the infant. In all the samples of milk examined saccharomyces were found in greater or less number; they were found in milk with a neutral or acid reaction, especially when pronouncedly acid. It is not possible to classify these germs as found in milk; they vary with the condition and state of preservation of the fluid. Certain germs belonging to the alcoholic ferments are constantly found. When lactic acid fermentation ceases, the germs continue to live on the albumins, fats, and secondary products. In certain conditions, the saccharomyces prevent the action of parasitic germs on the albumins; some coagulate the casein directly, independent of acid reaction, by the action of a ferment analogous to the lab-ferment, and produce a fine precipitate of casein; others segregate the ferments, and give unusually active enzymes of amylolytic power, lactases, glucases, lipases, proteolytic ferments, and probably caseases. Oxidizing ferments and salol ferment are unchanged; some of the alcoholic ferments produce a strong odor in the milk. By the action of saccharomyces it is possible to modify milk in its chemical and physical characteristics and its action toward ferments even when the milk has been sterilized.—*Rivista di Clinica Pediatrica.*

**Indications for the Extirpation of the Adnexa in Connection with Hysterectomy.**—G. Miranda gives certain indications for the removal of the adnexa when hysterectomy is done for causes not connected with diseases of the tubes and ovaries. It is as yet impossible to demonstrate the existence of an internal ovarian secretion, and to foretell the influence on the body processes of the removal of the gland. Clinical observation shows that the preservation of the ovaries has only the influence of causing a slighter grade of atrophy of the genital organs left after hysterectomy, lessening the number of women who have the menopause induced by operation on the uterus. Experimental and anatomopathological researches confirm clinical results, showing that the preservation of the ovaries renders the climacteric less sudden and modifies its disagreeable symptoms; the ovaries atrophy slowly and give the organism time to accommodate itself to the loss of function. There are certain dangers and inconveniences due to the leaving of the ovaries behind which counterbalance the advantages of so doing. It is not possible to leave them when the operation is done for disease of the adnexa or malignant disease of the uterus, or in 60 per cent. of myomata. It is especially in hysterectomy done for accidents of labor, exclusive of osteomalacia and disease of the sexual sphere, that the ovaries should be left, in conjunction with a restriction of the body of the uterus.—*Archivio di Ostetricia e Ginecologia.*

**Health Reports.**—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended December 23, 1905.

SMALLPOX—UNITED STATES.

# INDEX.

A.

Abdomen, penetrating wounds of the, 201, 631; penetrating gunshot wounds of the, 817; significance of certain symptoms in the upper, 109.
Abdominal diagnosis, difficulties in, 469; operations, the binder after, 19; operations, transverse incision in, 779; organs, displacement of the, 927; rigidity, a piezometer for determination of, 911; section, the technique of, 529; symptoms, acute, 32.
Abortion, induction of, in hyperemesis and tuberculosis, 432; treatment of, 1038.
Abortionists in Indiana, 346.
Abrams, Albert, the aortic reflexes, 459.
Abscesses, opening peritonsillar, 669.
Academy of Medicine and the public, 982.
Acetonuria in nondiabetic surgical cases, 68.
Acne, hypertrophic, of the nose, 234; the treatment of, 135.
Acromegaly, the histological basis of, 185.
Actinomycosis of the lung, 7.
Addison's disease, open air treatment of, 792.
Adenitis from venereal ulcers, treatment of, 914; tuberculous, treated by the *x*-rays, 153.
Adenoids, 310; effects of the removal of, 871.
Adnexa, indications for extirpation of the, 1080.
Adolescents, claims of, 758.
Advanced scholarship and morbid mental conditions, 17.
Advertising, objectionable, 512.
Agglutination of bacteria, 1035.
Ainhum, 108.
Air passages, direct methods of examining the, 593; local treatment of neuroses of the upper, 262.
Albu, A., a treatment of spastic constipation, 14.
Albuminuria, and eclampsia, 358 in nephritis, 106; in tuberculosis of children, 833; of adolescence, 669; physiological, 751; senile, 149.
Albuminuric retinitis, duration of life after the appearance of, 192.
Alcohol, effect of on the circulation, 71; pathological effects of, on rabbits, 470.
Alcoholism and drunkenness, 1021.
Aleppo boil, 194.
Alexander, Samuel, observations upon the cause and treatment of perineal abscess and of periurethral suppurations above the triangular ligament, 685.
*Alkaloidal Clinic*, change of name of, 986.
Allen, Charles Warrenne, the high frequency spark in a xanthoma-like degeneration of the lips, 500.
Altruism in the medical profession, 877.
Alvarenga prize of the College of Physicians of Philadelphia, 701.
Amaurotic family idiocy, 156.
Amblyopia due to copper poisoning, 1035; ex anopsia, 309; ex anopsia in strabismus, 73.
Ambulance accidents, 147, 186, 346, 865, 906.
Amebiasis in the tropics, 197, 512.
American Association for the Advancement of Science, 1024; Association of Railway Surgeons, 625; Electrotherapeutic Association, 947; Institute of Homeopathy, 104; invasion turned back, 864; Medical Association, constitution of the, 187; Medical Association: its origin, progress, and purpose, 85; Medical Association, officers of the, 155; Medical Association, principles of ethics of the, 937; Medical Association; was it reorganized on correct principles, and will it, under methods pursued, accomplish what it otherwise might? 25; Medical Editors' Association, 187; Public Health Association, 625.
Anatomical structure, a new, 1030.
Anatomy, normal, in gynecology, 160.
Anemia, diagnosis and treatment of, 750; four cases of essential, 737; grave puerperal, 84; prepernicious, 912.
Anesthesia, discontinued, in laparotomies, 833; in throat surgery, 30; the vapor method of, 609, 637.
Anesthetics, acid intoxication in connection with, 119; late poisonous effects of, 431.
Aneurysm and arteriosclerosis, observations on, 112; diagnosis of, 837; experimental production of, 873; Matas operation for, 271, 349; of the abdominal aorta treated by silver wire and electricity, 351; simulating dyspepsia, 70; treatment of gunshot, 302; treatment of popliteal, 150.
Angina pectoris, the cause of, 669.
Angioma of the quadriceps extensor, 33.
Animal food, increase in the consumption of, 152; remedial preparations, 174.
Ankle, sprained, 755.
Ankylostoma in miners, 354; larvæ, passage of, through the skin, 353.
Anorectal diseases, regional anesthesia in, 231.
Anthrax, a case of, without visible lesion, 819; treated with antianthrax serum, 193.
Antidiphtheritic serum, clinical experience with bivalent, 234.
Antitoxin, free, 383; horses, 103; of unusual dosage in a case of scarlet fever complicated by diphtheria, 819.
Antityphoid vaccine, illness following the use of, 551.
Antivaccination in Kansas City, 906.
Antivivisection law, a proposed, in Massachusetts, 783.
Antral disease, treatment of, through the nose, 512.
Aortic reflexes, the, 459; valves, mechanism of, 142.
Apex beat, double, 953.
Aphasia, motor, without agrafia, 668.
Apocynum, heart disease and ascites treated with, 667.
Apomorphine, experience with, 675.
Appel, D. M., report on the control of tuberculosis in the Philippines, 458.
Appendectomy, some points in relation to, 33.
Appendicitis, 755; and typhoid fever, differential diagnosis of, 111; chronic, 72; diagnosis and treatment of chronic, 153; etiology and treatment of, 710; in children, 549, 911; in nurses, 70; in the diagnosis of pelvic conditions, 642; Long Island, 336; 129 operations for, 513; operation, the most favorable time for, 32 relation of, to pregnancy, 38; simulation of, by cholelithiasis, 229; theory, another, 307; the zigzag incision in, 633; traumatism as a cause of, 992; treatment of, 30, 310; tuberculous colitis simulating, 551; when not to operate for, 31.
Appendicostomy, 442.
Appendix, condition after removal of the, 1033; cyst formation in remnants of the, 710; foreign bodies in the, 433; inflammatory conditions of the, accidentally brought to light in pelvic operations, 38; malpositions of the, as a cause of intestinal disturbances, 671; transmesenteric hernia of the, 473.
Armstrong, Dr., appointment of, as superintendent of Bellevue Hospital, 146.
Army, and Navy, unification of the duties of medical officers of the, 596; canteen, the, 639; health report, 624; medical bill the, 1061; Medical Corps, efficiency of the, 1024; Medical Department, reorganization of the, 674; Medical School, militia officers admitted to, 463; prevention of disease in the, and the best method of accomplishing that result, 595.
Arsenic treatment of yellow fever, failure of the, 384.
Arteriosclerosis affecting the nervous system, 430; hypertensive crisis in, 472; treatment of, 553.
Arteritis, peripheral obliterating, as a cause of triplegia, 233.
Arthritis and endocarditis, an obscure case of gonorrheal, 320.
Ascaris lumbricoides, an error in the diagnosis of, 514.
Ascending currents in mucous canals and gland ducts, and their influence on infection, 246.
Asepsis, a refinement of, 771.
Aseptic technique, a simple, 282.
Ashcroft, F. E., a report of the Whitman method of treatment of fracture of the neck of the femur, 675.
Asphyxia, a case of traumatic, 861; traumatic, 914.
Aspiration in diseases of the ear and nose, 351.
Asthma, 325.
Astigmatism, a cause of vomiting in children, 387; dynamic, 389.
Astragalus, dislocation of the, 1035.
Ataxia of central origin in childhood, 240.
Atlas, and axis, resistance to dislocation of the, 273; dislocation of the, with fracture of the axis, 473.

Atmospheric pressure, influence of, on man, 109.
Atropine, contraindications of, 523.
Autointoxication, 757, 1063; in childhood, 564.
Axillary temperatures, significance of low, 364.
Ayer, James C., serum therapy in erysipelas, results in 33 additional cases, 341.

B.

Bacillus funduliformis, significance of, 391.
Bacteria and toxins, effect of, on the heart muscle, 903; of anaerobic, 502; inhibition of growth in, due to autointoxication, 632; of the bile tracts, 502.
Bactericidal serums, value of, 511.
Bakeries, investigating the, 620.
Balantidium coli, the significance of, 742.
Baldness, causes and treatment of, 273.
Barlow's disease, symptomatology of, 873.
Barnardo, Thomas John, death of, 545.
Baruch, Simon, the treatment of pneumonia, 546.
Bath, a new free, 945.
Beck Carl, a new method of orchidopexy, 245.
Bedford Sanitarium for consumptives, history and work of the, 48
Behring's strange performance, 622.
Bell, William Duffield, some notes on typhoid fever in the Philippines, 535.
Bellevue Hospital, a new superintendent for, 64; beds, troubles over, 345; food, 23.
Benedict, A. L., American hospital economics, 987; the principles of ethics of the American Medical Association, 937.
Beriberi, 479; the nature of, 803, 1031.
Berlin, letters from, 66, 229, 468, 789, 828.
Bermuda, new hospital for, 186.
Bichloride injections, action of, in the urethral mucous membrane, 110.
Bier's congestion treatment in acute inflammation, 1034; osteoplastic amputation, 913.
Bile, bacteriolytic action of, 112.
Bilharzia hematobium, 666.
Billings, John S., routine procedure of, the clinic for the treatment of communicable pulmonary diseases of the Department of Health, 973.
Biograph, use of the, in medicine, 910.
Birkett, H. S., further report of a case of primary lupus vulgaris of the oropharynx and nasopharynx treated by *x*-rays, 739.
Births, registration of, 1024.
Bishop, Louis F., circulatory failure, its nature and treatment, 976.
Blackwater fever, 312, 952; treated with quinine, 431; treated without quinine, 502.
Bladder, extraperitoneal rupture of the, 756, 995; extraperitoneal rupture of the, in fracture of the pelvis, 666; exstrophy of the, successfully treated, 202; inguinal hernia of the, 102; irritation of the, 720; position of the, in fibroid of the uterus, 250; punctured wounds of the, 473; suture of the, 164; the gynecological, 666.
Blastomycosis, systemic, 631.
Blind, information wanted as to the lives of the, 824
Blood, action of sodium formate on the, 874; action of the *x*-rays upon the, 951 alkalinity of the, in febrile toxemia, 1059; cultures, value of, 680; guaiac test for, 629; photoactivity of the, 503; poisoning emanating from the nose and pharynx, 754; pressure, action of caffeine on, 874; pressure observations for practitioners, 150; pressure, three vices of, 790; the study of the, in relation to therapeutics, 287.
Blumer, George, the influence which the acquisition of tropical territory by the United States has had and is likely to have on American medicine, 125.
Board of Health, laboratory of the, 384, 544; new building of the, 1064.
Bobbin, a new intestinal, 762.
Boldine, John A., a plea for local anesthesia in the radical cure of inguinal hernia, based on a study of 300 cases, 645.
Body fluids, surface tension of the, 232.
Boils and carbuncles, 44.
Bond, C. J., ascending currents in mucous canals and gland ducts and their influence on infection: a study in surgical pathology, 246.
Bone lesions, surgical treatment of tuberculous, 435.

Book Notices.

Abdominal operations, by B. G. A. Moynihan, 875.
Acute poisoning, a manual of, by John W. Wainwright, 634.
Addresses and other papers, by W. W. Keen, 315.
Algiers as a winter resort, by A. S. Gubb, 996.
Allegemeine Fierberlehre, von Dr. Edward Aronsohn, 956.
Amerikanische Streiflichter, von Dr. Carl Beck, 1036.
Anatomy, atlas and text-book of topographic and applied, by Oskar Schultz and George D. Stewart, 235.
Anatomy, hand-book of, by James K. Young, 475.
Anesthetics, a guide to, by Thomas D. Luke, 794.
Anus and rectum, diseases of the, by D. H. Goodsall and W. Ernest Miles, 753.
Arbeiten aus dem Pathologischen Institute der Universität of Helsingfors, edited by Prof. Dr. E. A. Homen, 1036.
Atonia gastrica, by Achilles Rose and Robert Coleman Kemp, 274.
Bacteriology, the principles of, by A. C. Abbott, 915.
Blood, diseases of the, by Dr. P. Ehrlich, Dr. A. Lazarus, Dr. K. von Noorden and Dr. Felix Pinkus, 235.
Blues, the, by Albert Abrams, 996.
Book of prescriptions (Beasley) rewritten by E. W. Lucas, 154.
Cancer uterin inoperable, traitement du, par le Dr. J. Recamier, 34.
Cardiopathies artérielles et la cure d'Evian, par le Dr. P. Bergouignan, 634.
Chemical laboratory, a manual for the, by Louis Warner Riggs, 915.
Chemistry, a text-book of, by William R. Jones, 875.
Chemistry, manual of, by W. Simon, 915.
Chest, a text-book of diseases of the, by Egbert Guernsey Rankin, 515.
Cleft palate and harelip, by W. Arbuthnot Lane, 756.
Clinical chemistry, microscopy and bacteriology, a manual of, by Dr. M. Klopstock and Dr. A. Kowarsky, 834.
Clinical diagnosis, by Rudolf V. Jaksch, edited by Archibald G. Garrod, 794.
Clinical diagnosis and uranalysis, by James R. Arneill, 235.
Clinical medicine, a system of, by Thomas D. Savill, 154.
Clinical methods, by Robert Hutchison and Harry Rainy, 996.
Clinical treatises on the pathology and therapy of diseases of metabolism and nutrition, by Prof. Carl von Noorden and Dr. Hugo Solomon, 154.
Color vision and color blindness, by J. Ellis Jennings, 594.
Country house, the sanitation of a, by Dr. Harvey B. Bashore, 434.
Currents of high potential, of high and other frequencies, by William Benham Snow, 956.
Dental surgery for medical practitioners and students of medicine, by A. W. Barrett, 154.
Dermatologische Heilmittel, 274.
Diagnose und Therapie des Eczems, von Dr. S. Jessner, 34.
Diagnostic methods of examination, a treatise on, by Prof. Dr. H. Sahli; edited by Francis P. Kinnicutt and Nath'l B. Potter, 1036.
Diagnostics of internal medicine, by Glentworth Reeve Butler, 794.
Diary of a late physician, arranged by Chas. Wells Moulton, 515.
Die chronische Gonorrhöe der männlichen Harnröhre und ihre Komplicationen, von Prof. Dr. A. Kollmann. Parts ii and iii, 195.
Die palpablen Gebilde des normalen menschlichen Körpers und deren methodische Palpation, von Dr. Toby Cohn, 434.
Diet and nutrition, practical problems of, by Max Einhorn, 274.
Dietetics for nurses, by Julius Friedenwald and John Ruhrah, 515.
Diseases of women, diagnosis of the, by Palmer Findley, 594.
Dispensatory, the national standard, by Hobart Amory Hare, Charles Caspari, Jr., Henry H. Rusby, Joseph F. Geisler, Edward Kremers, and Daniel Base, 875.
Dissecting manual based on Cunningham's anatomy, by W. H. Rockwell, Jr., 996.
Endoscopie de l'urètre et de la vessie, par le Dr. Georges Luys, 195.
Era key to the U. S. P., 712.
Eye manual of disease of the, by Charles H. May, 634.
Eye, mind, energy, and matter, by Chalmers Prentice, 154.
Eye, the, its refraction and diseases, by Edward E. Gibbons, 753.
Feridas e rupturas traumaticas do coraçao, by Francesco S. B. Gentil, 875.
First aid in illness and injury, by James E. Pilcher, 393.
Food analysis, select methods of, by Henry Leffman and William Beam, 355.
Food inspector's hand-book, by Francis Vacher, 712.
Fractures and dislocations, a practical treatise on, by Lewis A Stimson, 434.
Fractures, the treatment of, by Charles L. Scudder, 434.
German-English dictionary of terms used in medicine and the allied sciences, by Hugo Lang, 235.
Grundriss der Semiotik des Harns, von Dr. St. Serkowski, 634.
Gynecology, a text-book on the practice of, by W. E. Ashton, 113.
Hämorrhoiden, die chirurgische Behandlungder, von Dr. Paul Schlacht, 1036.
Hautkrankheiten bei Stoffwechsel-Anomalien, von Prof. Dr. J. Jadassohn, 113.
Health and disease in relation to marriage and the married state, edited by H. Senator and S. Kaminer, 475.
Heart, diseases of the, by E. H. Colbeck, 34.
Human body, development of the, by J. Playfair McMurrich, 235.

Human physiology, by Joseph H. Raymond, 434.
Hygiene, a manual of practical, for students, physicians, and medical officers, by Charles Harrington, 355.
Hysteria and neurasthenia, by J. Mitchell Clarke, 594.
Inn of rest, the, edited by Sheldon E. Ames, 966.
Inorganic chemistry, outlines of, by Frank Austin Gooch and Claude Frederic Walker, 235.
International clinics, edited by A. O. J. Kelly and collaborators, 113, 956.
Kano jiu-jitsu, the complete, by H. Irving Hancock and Katsukuma Higashi, 355.
Knowledge, the new, by Robert Kennedy Duncan, 393.
Krankheiten des Verdauungskanals, von Dr. Paul Cohnheim, 794.
Kystes hydatiques du foie, par le Dr. F. Devere, 434.
L'acide formique et la force musculaire, par le Dr. Clément, 996.
Lehrbuch der inneren Medizin, von Dr. Georg Klemperer, 154.
Les indications des interventions chirurgicales dans les maladies internes, par le Prof. Hermann Schlesinger, 315.
Les médecins aux théatre, par le Dr. Witkowski, 274.

Hemenway, H. B., uncertainties and fallacies in scientific medicine, 939.
Hemmeter, honors for Dr., 865.
Hemochromogen spectrum, the value of the, 632.
Hemoglobin instruments, value of, to the practitioner, 200.
Hemoglobinuria, malarial, 310.
Hemometer, a new, 300.
Hemophilia, animal blood as a hemostatic in, 874.
Hemoptysis, the pneumococcus in, 469; treatment of, in phthisis, 513.
Hemorrhoidal clamp, a new, 523.
Hemorrhoids, annihilant treatment of, 476, 912; gangrenous prolapsed, 60.
Heredity, biological and psychological, 314.
Hernia and volvulus through a mesenteric slip, 473; a new radical operation for femoral, 60; a plea for local anesthesia in the cure of inguinal, 645; congenital umbilical, 491; cure of inguinal, 118; direct inguinal in women, 72; epigastric as a source of gastric symptoms, 230; etiology of, 112; inguinal, in childhood, 920; 110 operations for femoral, 523; radical cure of crural, 671; resection for strangulated, 640; treatment of incarcerated, 194.
Herpes zoster, dry cups in the treatment of, 348; ophthalmicus, 644.
High altitudes, rheumatoid pains following injuries in, 404; frequency electrodes, 1003; frequency spark, the, in a xanthoma-like degeneration of the lips, 550.
Hip, anatomy of congenital dislocation of the, 438; congenital dislocation of the, 442; disease, the value of

traction in, 441; dislocation, desirability of replacing congenital, in infancy, 438; results after bloodless reposition of congenital dislocation of the, 630; treatment of congenital dislocation of the, 203.
Hirst, B. P., case of delayed menstruation; flow established at first spontaneously, subsequently by treatment; conception, 340.
Hoarseness, malignant nature of chronic, 990.
Hodgson, Fred G., ectopic gestation complicated by mental disturbance, 419.
Holmes, the medical discovery of Oliver Wendell, 862.
Hospital boat for Health Department, 103; building in the Philippines, 378; car, a new, 744, 931; corps, efficiency of, in the National Guard, 596; economics, American, 987, 1027; economy, the system of American, 885; new Army, 1065; ships in war, 102; staff, election of, 906; threatened, a, 545; Toyama at Tokyo, the, 1069.
Hospitals, bequests to, 64, 104, 146, 866, 946, 1025; the cost of modern, 616.
Housemaid's knee, treatment of, 709.
Houghton, Harris, A., bacteria in the normal adult intestine, with special reference to the etiology of enterotoxismus, 1053.
Howard, William Lee, advanced scholarship and morbid mental conditions, some clinical cases, 17.
Humbert, prize awarded by King, 701.
Humerus, acute flexion in the treatment of fractures of the, 233; spontaneous fracture of the, 957.
Hunger and anorexia, nature of, 388.
Hunt, Edward Livingston, sixty cases of general paresis—a clinical study, 498; the mental symptoms of neurasthenia, 141.
Hurd, Lee M., a submucous resection operation for deviation of the nasal septum; with a description of several new instruments, 853.
Hutchinson, the triad of, 901.
Hydatids, use of turpentine in renal, 431.
Hydriatic procedures, of short duration, effects of, 102.
Hydrick, E C., amblyopia ex anopsia, 309.
Hydrocephalus, acquired, with complications, 600; a case of acute internal, 500; treated by auto drainage, 82.
Hygiene, address in, 679; teaching of, in public schools, 877.
Hygienic wisdom, 101.
Hyperchlorhydria, 750.
Hyperemia, artificial, in surgery, 719.
Hyperesthesia and hypalgesia and their significance, 163.
Hypernephroma, three cases of, 233.
Hyperpyrexia, 377.
Hypertrophy of the pylorus in infants, opium in, 991.
Hypnotic cumulative action, 270.
Hypochondrium, malignant tumor of the, 831.
Hypodermic syringe, a new, 596.
Hypoleucocytosis, relation of, to the bone marrow, 470.
Hypospadias, 952.
Hysterectomy, drainage after, 563; results of, with and without drainage, 707.

I.

Ideal laparotomies, 1032.
Iden, J. H., a penetrating gunshot wound of the abdomen, 817.
Illinois Commissioners of Public Charities, 946; medical colleges in, 384; National Guard Surgeons, 1025.
*Illinois Medical Journal*, 946.
Illiteracy in the United States, 945.
Immigrants, medical examination of, 520; mortality statistics in, 345.
Immigration figures, 1025; increase in, 266.
Impetigo contagiosa, 30.
Impulse, a fatal, 64.
Incontinence of urine in children, treatment of, 30; neurasthenia; treatment of, by electricity, 990; in women, surgical treatment of, 40.
In corporee vili, 382.
Indian agencies, vacancies for physicians at, 702.
Industrial wastes and their sanitary significance, 635.
Inebriate manias; a medicolegal study, 15.
Inebriates, State prison for, 226.
Infant feeding, a classification of the methods of modifying cow's milk for, 408; feeding, the future viewpoint and practice of, 1040; the premature, 268.
Infants, death rate of, in summer, 469; milk, the fatty constituents of for, 660; rules for the care of, in public institutions, 156.
Infection, a new channel of, 263; in transportation, 310; the natural defenses of the organism against, 781.
Infectious diseases, an act prescribing the duties of physicians and others relative to, 464; radiotherapy in, 944.
Inferior rectus muscle, congenital paresis of the, 432.
Influenza, an epidemic of, 832; bacillus in bronchiectasis, 1074; diagnosis of, 353.
Ingals, E. Fletcher, actinomycosis of the lung, 7.
Ingrowing toenail and hallux valgus, operations for, 589.
Innominate artery, ligation of the, 313, 444.
Insane patients, transferring, 345; the complexion of the, 1070; the digestion in the, 711; treatment of the morally, 506.
Insanity and pelvic disease, 1020; in England, 583; in New York State, 985; relation of emotional states to, 666; therapeutics of acute, 550.
Insect pests, diseases of, 587.
Insomnia, 783.
Insurance, examination for, 560; examiners, relation of, to sanitation, 561; instruction of students in examining for, 560.
Intention tremors in children, 832.
Intercostal muscles, paralysis of the, causing dropsy, 668.
Intestinal anastomosis, a new method of extirpating the, 349.
International Anatomical Congress, 266; College of Hydrology, 346; Tuberculosis Association, 23; Tuberculosis Congress, the 584.
Interscapulothoracic amputation for malignant tumors, 474.
Interurban Clinical Society, 985.
Intestinal anastomosis, a new method for, 1031; antisepsis, its theory and application, 683; fermentation, putrefactive substances formed in, 997; functions, determination of, by a test-regimen, 45; hemorrhage in a child, 82; obstruction, 642; occlusion, experimental, 995.
Intestine, bacteria in the, with reference to enterotoxismus, 1053; high irrigation of the, 504; rupture of the, 950.
Intracranial hemorrhages of the newborn, operations for, 80.
Intramuscular injections in the treatment of syphilis, 377.
Intraspinal tumors, surgical treatment of, 240.
Intubation, prevention of laryngeal stenosis after, 832.
Intussusception, 283; in infancy, 981.
Iodine, absorption of, by cataphoresis, 153; as a germicide, 289; catgut, advantages of, 522; poisoning of the oral mucosa by tincture of, 954.
Iodoform, a simple substitute for, 147.
Iowa State Tuberculosis Association organized, 585.
Irish Medical Graduates' Association, 266.
Iritis, oral sepsis as a cause of, 232; tuberculosa, 667.
Iron precipitates in the blood, 469.
Isaacs, A. E., dermoid ovarian cyst simulating floating kidney, 1058.
Isthmus, a sane policy on the, 503.

J.

Japan, losses of, in the war, 545, 585; observations in, 639; the real triumph of, 630.
Jaundice, the mechanism of, 264.
Jaw, endothelioma of the, 919; ossification of the lower, 431.
Jersey City Hospital, 785.
Jewish Hospital fair, 865; 905; physician, the, in history, 660.
Joint disease, chronic non-tuberculous, in adults, 441; stiffness, treatment of, by gradual rectification and massage, 732.
Joints, hot air treatment of inflamed, 469.
Jones, J. D., a case of anthrax—probably due to inoculation—without a visible lesion, 819.

K.

Kala-azar, a vaccine for, 544; two cases of, 361.
Keloids, *x*-ray treatment of, 838.
Kelsey, Charles B., the office treatment of diseases of the rectum, with a description of some new methods, 605.
Kennedy, T. C., gall-bladder surgery, 455.
Kentucky State Medical Association, 784.
Kerley, Charles Gilmore, the prevention and management of summer diarrhea among tenement children, 133.
Kernig's sign and its pathogenesis, 413; negative value of, 472.
Kerrison, Philip D., the indications for operating in acute mastoiditis, 690.
Kidney, end results in surgery of the, 236; etiology and surgical treatment of floating, 641; fixation of movable in dyspepsia and neurasthenia, 270; movable, 968; movable, due to colon displacement, 510; multiple abscesses of the, due to ascending infection, 791; papilloma of the, 150; pathology of the, 196; surgical notes on tuberculosis of the, 31; traumatism of the, 151; tuberculosis of the, 202.
Kidneys, congenital absence of the, 191.
Kilbane, Edward F., the hypodermic use of the salicylate of mercury in the treatment of syphilis, 179.
Killian's inspection of the trachea and esophagus, 516.
Kilmer, Theron Wendell, a few practical points in pediatrics for the general practitioner, 289.
Knee and tarsal joints, inflammatory fatty tumors in the, 313.
Knee joint, internal lesions of the, 671.
Knives, sterilization of, 44.
Knock ankle, 630.
Knopf, S. A., the treatment and care of advanced cases of pulmonary tuberculosis, 805.

Koch's journey to Africa, results of, 993.
Kohn, Samuel, asthma, 325.
Koller, Carl, poisoning by wood alcohol; a case of complete blindness (transitory) with recovery of vision, 10.
Kölliker, death of Prof. von, 906.
Kommel, L. M., report of a case of fractured tibia and fibula; delayed union and its treatment, 980.
Korsakoff's psychosis, two cases of, 69.
Kraske's operation, hernia following, 310.
Kyphoscoliosis, epileptogenic, 706.

L.

Labor cases, present-day conduct of, 162; methods for induction of, 70.
Landry's paralysis, 991.
Laparotomy, after-treatment of, 556; drainage in, 869; insufflation of oxygen into the abdomen in sepsis after, 555; prophylactic nourishment in, and puncture of the intestines, 553; technique of, 718.
Laparotomies, statistics of, 731, 793.
Laryngeal diphtheria complicating cerebrospinal meningitis, 454; stridor, congenital, 354.
Larynx, cancer of the, 516, 760; epithelioma of the, 397; primary erysipelas of the, 554; removal of foreign bodies from the, 924; Roger's treatment of stenosis of the, 398.
Lateral sinus, dressing for septic thrombosis of the, 820; its relation to ear surgery, 469.
Lavage, a comparison of methods of, 230.
League of Pitiful Deliverance, 603.
Leg and ankle, causes of disability after fracture of the, 468.
Legs, skiagraphic revelations in rachitic deformities of the, 437.
Lens, the crystalline, in health and in cataract, 1033.
Leprosy, alleged cure for, 307; a probable mode of communication of, 343 Rontgen ray treatment of, 948; the cure of, 230.
Lerch, Otto, displacement of the abdominal organs, 927.
Leszynsky, William M., sciatica and its treatment, 405.
Leucocyte counting, a convenient method of, 510.
Leucocytemia, treated by *x*-rays, 100.
Leucocytes, behavior of, in malignant growths, 312; examination of the, as an aid in diagnosis, 790; in whooping-cough, the, 604.
Leukemia, a case of mixed celled, 390; acute lymphatic, 950; lymphatic, in a child, 348; the leucocytes in the *x*-ray treatment of, 391; *x*-ray treatment of, 839.
Lewis, Denslow, the technique of abdominal section, 529.
Library and museum at Los Angeles, 662.
License, litigation to secure a, 824.
Life Insurance, Medical Directors of America, Association of, 743.
Life, the principles of, 870.
Ligature-carrying needle, a, 284.
Ligatures, a finger ring for, 608.
Light, neurasthenic states caused by excessive, 1005.
List practice, 549.
Lithemia in the spine and lower extremities, simulating orthopedic conditions, 591.
Liver, abscess of the, 830; cirrhosis of the, 968; hemorrhagic cirrhosis of the, 514; incising and suturing the, 311; sodium glycocholate in diseases of the, 590; surgical treatment of cirrhosis of the, 309, 958; surgery of the, 201, 557; syphilis of the, 108; Talma-Morrison operation for cirrhosis of the, 444; thrombosis of the receptaculum chyle, complicating cirrhosis of the, 830.
Lodge practice in California, 63.
London, letters from, 28, 65, 106, 148, 188, 227, 267, 308, 385, 426, 466, 508, 547, 588, 627, 664, 704, 786, 826, 867, 907, 948, 988, 1028, 1067.
Long Island Sanatorium Association, 745.
Loomis, Henry P., clinical suggestions from the study of 500 cases of pulmonary tuberculosis, 165.
Louisiana State Board of Health, 945.
Lower extremities, deformities in, 469.
Lumbago and sciatica, pseudorheumatism, 674.
Lumbar puncture, diagnostic value and therapeutic effects of, 62; value of, in otology, 110; value of, in the newborn, 474.
Lung negatives, interpretation of, 837; suture of the, 953.
Lupus, nasal origin of, 914; of the pharynx and nasopharynx, 394; vulgaris of the pharynx treated by the *x*-rays, 739.
Lymph nodes, an obscure disease of the, 432; treatment of tuberculous, 314.
Lymphatic glands, germ centers and secondary carcinoma deposits in, 551.
Lymphocytes, granulations of the, 152; migration of, 670.
Lymphoma, a case of malignant, 680; tuberculous, of the neck, 314.
Lyons, Frederick A., the quick curative treatment of gonorrhea, 731.

M.

McCaskey, Donald G., hospital building in the Philippine provinces, 378; the Toyama Hospital at Tokyo, Japan, 1069.
McDavid, J. T., capital punishment, 629.
McGraw elastic ligature, use of the, 119, 708.
McIntosh, Edward F., diagnosis in carcinoma of the stomach, 655.
Macmillan, J. A., the treatment of chronic constipation, 979.
McMurtry, Lewis S., the American Medical Association: its origin, progress and purpose, 85.
McNutt, Sarah J., notes in non-operative gynecology, 765.
McWilliams, Clarence A., remarks on the treatment of certain affections interesting both the physician and the surgeon, 968.
Magnesium salts, inhibitory and anesthetic properties of, 665, 998.
Maine Medical School, changes in the faculty of the, 784; suicide in, 586.
Malaria, acute anasarca in, 861; a new parasite in pernicious, 631; in the vicinity of New Haven, 981; is the mosquito the only etiological factor in? 77; prophylaxis against, near Rome, 72; typhoid fever with, 957; with symptoms of peritonitis, 874.
Malarial disease, tropical, 69.
Malay, the normal and the insane, 260.
Malignant tumors of mice, 230.
Malpractice defence, value of organized, 676.
Malta fever in South Africa, 900.
Manila, letters from, 149, 190, 467, 548, 628, 705, 748, 788, 948, 1068.
Marine Hospital Service, 985; alleged extravagance in the, 624; laboratory for, at San Diego, 905.
Marriages, medical control of, 586.
Massachusetts Medical Society, 24.
Massey, G. Betton, some aspects of the cancer problem, 12.
Mastoid operation, the, 644.
operation, peculiar symptoms following, 831.
Mastoiditis, 644; indications for operating in acute, 690; indications for operating in, 519.
Maternal impression superstition, 162.
Maxilla, fractures of the upper, 150.
Maxillary sinus, the, 395.
Measles, 390; bacteriology of, 153; in Evanston, 347.
Meckel's diverticulum, abdominal crises due to, 550; as a cause of abdominal crises, 201.
Medical City Officer, a new, 1025.
Mediastinum, tumors of the, 715.
Medical charity, abuse of, 223; control of State institutions, 384; education, 898; ethics, instruction in, 507; Examiners of New York State, 904; Examining Board, bill favoring one, 672; licensure, a setback to reciprocity in, 344; reciprocity, 784; Society of the County of New York, 701; Society of the Missouri Valley, 424; Society of the State of New York, 945; study in Germany, 906; union assured, 661; union in New York State, 621.
*Medical News* and *New York Medical Journal*, consolidation of, 825.
Medically trained legislators, 72.
Medicinal agents, the influence of chemical constitution on the character and application of, 303.
Medicine, uncertainties and fallacies in scientific, 939.
Medicolegal Section of the Fifteenth International Congress, 783.
Meltzer, S. J., inhibitory and anesthetic properties of magnesium salts, 965.
